PRODUCT DESCRIPTION

This report is an updated edition of the longtime industry standard EPRI *Transmission Line Reference Book*, or the "Red Book," which was last issued in 1987. Publication of this new edition is the culmination of three years of research by a global team of experts. The report includes the latest information on research, technology, and materials and represents a significant contribution to the global industry of electric power transmission.

Results & Findings

This new edition of the Red Book preserves the style and depth of previous editions while including the latest information on topics associated with the design of high-voltage transmission lines. Accordingly, eleven chapters in the previous edition of the book have been extensively updated. The new edition also adds four new chapters—Chapters 12 through 15—on shared use of rights-of-way, inspection and maintenance concerns, voltage upgrading, and experience with lines above 700 kV. These new chapters reflect both changing concerns over the past 15 years as well as the availability of experience in line design, operation, and maintenance.

In addition to the revised text, the new edition of the Red Book also includes 50 applets, which are small software programs, or stand-alone calculation modules. These applets enable users to make specific calculations for transmission-line design parameters and include associated example and design features.

Challenges & Objectives

Since publication of the last edition of the Red Book in 1987, theories and technologies related to transmission line design have advanced, and the Red Book had fallen behind. As a result, it was necessary to upgrade the book.

Updating the Red Book was undertaken with several objectives:

- Preserve the style of previous editions.
- Present the science and technology in the same depth as earlier editions.
- Maintain focus on the electrical design and performance of transmission lines.
- Expand the international quality of the presentation to include international practices, technology, sources of information, and use of units.
- Direct the presentation to line designers and engineers and assume at least two years of university training in mathematics and physics.
- Take advantage of advances in electronic media, including integration of software routines and incorporation of video and tutorial material.

- Add a glossary and index.

Applications, Values & Use

The Red Book has been recognized for some 25 years as the worldwide industry standard for transmission line design. The latest update represents a significant advance on the previous edition and will provide an essential resource for all utilities involved in line design.

EPRI Perspective

The EPRI report, *Transmission Line Reference Book, 345 kV and Above* (EL-2500-R1), was originally printed with a red cover and quickly became known in the industry simply as the "Red Book." The book had its origins in the 1960s when General Electric established the Lenox Laboratory in Lenox, Massachusetts, to experiment with transmission lines on the order of 1 MV. Known as Project UHV, the Lenox Laboratory site designed and tested transmission lines at ultra high voltages. The Red Book was written essentially as the final report for Project UHV. The first edition was published in 1975, the second in 1982, and the second revised edition was issued in 1987.

Approach

While the original edition was essentially a final report to a research project, the approach used to write it and present the information has proved to be very successful. Each chapter in the book is a refereed paper on a specific topic. The chapters are not intended to be a complete thesis on a subject; a comprehensive list of references is provided at the end of each chapter if readers need more detailed information.

Chapter 1: Transmission Systems

Authors: Jan P. Reynders, Raymond Lings, Robert G. Stephen, Lori A. Nielsen, Andrew C. Ludwig
Reviewer: Luciano E. Zaffanella

Chapter 2: Electrical Characteristics of Conductor Configurations and Circuits

Authors: Dale A. Douglass, James R. Stewart, Bernie Clairmont
Reviewers: Sven Hoffmann, Vic Morgan, and Robert G. Stephen

Chapter 3: Insulation Design

Authors: Nicholas C. Abi-Samra, Ian Grant
Reviewers: Jan P. Reynders, Luciano E. Zaffanella, William A. Chisholm, Andrew Phillips, and Christiaan S. Engelbrecht

Chapter 4: Insulation for Power Frequency Voltage

Authors: Andrew Phillips, Christiaan S. Engelbrecht
Contributor: William A.Chisholm
Reviewers: Ray Houlgate and John Kuffel

Chapter 5: Switching Surge Performance

Authors: Luciano E. Zaffanella
Reviewer: John M. Van Coller

Note: Brief profiles of the authors appear at the start of each chapter.

Chapter 6: Lightning and Grounding

Authors: William A. Chisholm, John G. Anderson
Reviewer: Mat Darveniza

Chapter 7: Electric and Magnetic Fields

Author: Luciano E. Zaffanella
Reviewers: Jan P. Reynders and James R. Stewart

Chapter 8: Corona and Gap Discharge Phenomena

Author: P. Sarma Maruvada
Reviewers: Jan P. Reynders and Giao N. Trinh

Chapter 9: Electromagnetic Interference

Authors: Robert G. Olsen, Vernon L. Chartier
Reviewers: P. Sarma Maruvada and Tony Britten

Chapter 10: Audible Noise

Authors: Tony Britten, Vernon L. Chartier, Luciano E. Zaffanella

Chapter 11: Corona Loss and Ozone

Author: P. Sarma Maruvada
Reviewer: Vernon L. Chartier

Chapter 12: Shared Use of the Right-of-Way

Authors: Robert G. Olsen, T. Dan Bracken
Reviewers: James R. Stewart and Monty W. Tuominen
Contributors: Paul Wong and Richard Harness

Chapter 13: Considerations for Inspection and Maintainability

Authors: Andrew Stewart, George Gela
Contributors: Andrew Phillips, Gail Carney, Fabio Bologna, George Watt, John K. Chan, Lance Powell, Kurt Bell, Robert Kluge, John Peckinpaugh, Cal Stripling, Terry S. Eagar, Alan Holloman, Bill Hewitt, and J. A. Tony Gillespie

Chapter 14: Voltage Upgrading of Existing Transmission Lines

Authors: Dale A. Douglass, James R. Stewart
Reviewers: Anand Goel and Jerry Reding

Chapter 15: Transmission Lines Above 700 kV

Authors: Vernon L. Chartier, P. Sarma Maruvada
Reviewers: J. P. Gingras, A. Dutil, H. Létourneau, L. Allard, J. M. Gagnon, J. C. Carrière, D. Bouchard, M. Hamel, L. Vo Van, M. Lavoie, D. Goulet, Y. Deshaies, Eric Engdahl, Ed Schnell, Viktor Rashkes, Jose Antonio Delgado Garcia, Javier Tarazona Gomez, Jose Antonio Pardinas, Carlos Garcia Cuestas, Joaquin Oliveira Da Silva, Paulo Cesar Vaz Esmeraldo, Ben Shperling, Peter S. Foreword

In 2001, the Electric Power Research Institute (EPRI), with technical and financial support from the global transmission industry, decided to redraft and reissue the internationally renowned handbook entitled "Transmission Line Reference Book: 345 kV and Above." Because of the red cover of previous editions, the book has become affectionately known as the "EPRI Red Book." The cover of this new edition preserves the tradition.

The origin of the Red Book dates back more than three decades. In 1968, the Edison Electric Institute published the EHV Transmission Line Reference Book, a design handbook for U.S. electric utilities. The book was based on the results of many years of research sponsored by General Electric and the industry at what was then Project EHV in Pittsfield, Massachusetts. This research evolved around the design and development of EHV transmission from 345 to 735 kV, the latter being the maximum expected ac transmission voltage in North America for several years to come.

However, before the book was published, AEP (American Electric Power Service Corporation) in April 1966 (The Wall Street Journal, Wednesday, April 27, 1966) announced plans to build 1050 miles of 765-kV transmission in five states. In making this decision, AEP had the benefit of the research conducted at both Project EHV and The Apple Grove 750-kV Project, which was a joint project of AEP and Westinghouse. The impetus for lines operating at even higher voltages resulted in plans in the early 1970s to construct facilities where research above 1000 kV (UHV) could be conducted. The drive to UHV voltages led to a number of large collaborative research efforts under the banner of Project UHV (a successor of Project EHV). These efforts culminated in the EPRI handbook, published in 1975. A second edition of this handbook was published in 1982, and the second edition revised was issued in 1987.

Early on in the latest revision of the Red Book, we made a number of decisions. Today the majority of new and existing transmission is in the range of 200 to 400 kV. As a result, we decided to select a "region-neutral" voltage, rather than list a voltage limit for the book that matched either a "standard" within North America (i.e., 230 or 345 kV) or a "standard" European voltage (220, 275, or 400 kV). The level of 200 kV was considered appropriate because it addresses the issue above and incorporates the 220- and 230-kV series of lines. We also decided to include the term "ac" in the title. There is a growing trend again towards HVDC (High-Voltage Direct Current), and the intention is to differentiate this book from books covering "dc".

In drafting this new edition, we paid particular attention to the needs of utilities and students. The following is considered the audience profile:

- Experienced line designers who need to confirm design parameters, select technology, optimize designs, defend decisions, and understand non-routine design topics.
- Students of line engineering with college or third-year engineering calculus and physics.
- Utilities that have the need to preserve institutional knowledge.
- Other users, including public utility commissions, lawyers, and the public-at-large. (While the book is not written for this audience, it is recognized that this latter audience will turn to this resource for guidance.)

The new edition has the following attributes:

- Technical Depth. Every attempt was made to keep the same technical depth as previous editions. It was clear that the format of previous editions resonated well with the intended audience. Chapters do not attempt to replace the many handbooks and texts dedicated to each topic.
- International Developments. The focus of the book was expanded to include developments outside of the United States. There was a conscious effort to find an international author or reviewer for each chapter. Further, there was a very clear effort to make sure the book was truly international in its content. Extensive use was made of IEC, CIGRE, and international experts to complement the existing North American content.
- Self-Contained Chapters. Each chapter is self-contained, having its own appendices, references, and applets. However, it was recognized that making the chapter boundaries very steep would result in duplication within the handbook, so some compromise in terms of cross-referencing was necessary.

- References. Each chapter contains a very comprehensive and updated list of references. Readers of the previous editions have regularly turned to the reference list at the end of each chapter for guidance. The new edition preserves this capability.
- Applets. Where appropriate, the design theory is translated into software code and included with the handbook in the form of "applets." These are software applications with very useful help files, simple input and output screens, and the ability to export results to spreadsheets, graphs, etc. The new book contains some 51 applets covering many of the chapters. The inclusion of applets will make it considerably easier to review and exercise the theory. The inclusion of graphing allows the reader to see precise results as well as trends. The addition of applets to this edition of the book will, in our mind, add considerable value and expand the use of this book.

The new edition of the book rearranges the chapters to better align with the design process. The book is organized into themes with a "foundation" chapter at the start of each theme and specialized chapters behind the foundation. It was also decided to include new chapters focused on understanding how lines designed using previous editions of the Red Book have stood the test of time. In addition, chapters are included that attempt to close the feedback loop from actual field experience back to the designer.

As a result, the revised edition includes three general themes:

- **Insulation Coordination.** This theme spans Chapters 3 to 6, and covers general insulation coordination, power frequency insulation, switching, and lightning and grounding
- **Corona and Field Effects.** This theme spans Chapters 7 to 11, and covers corona and its effects (corona loss, audible noise, and high-frequency electromagnetic interference) and the effects of power frequency electric and magnetic fields.
- **Application.** This theme spans Chapters 12 to 15, and includes right-of-way management, designing for inspection and maintenance, voltage upgrading, and the field performance of lines designed to operate above 700 kV. This theme is a new addition to the book.

As regards application, Chapter 15 is a particularly unique chapter. This chapter pulls together the theory in the Red Book and shows how life was breathed into this theory. The authors surveyed some 10 utilities from around the globe that have transmission lines above 700 kV. The chapter starts with a history and EHV and UHV transmission research and then completes a design review of each line—covering the reasons why the technology was chosen, the approach to the design, and the operation and maintenance experience.

At the time of writing this third edition, two countries have lines over 1000 kV (Russia and Japan). However, both networks are presently operated at 500 kV. Eskom (South Africa) will, quite rightly, argue that its operating 765-kV line at high altitude is "equivalent" to a 1000-kV line at sea level. The Foreword to the previous edition of the Red Book noted "no upper limit to ac transmission voltages is apparent." While the dream of "no upper limit to ac transmission" has yet to materialize, developing regions around the globe (China, in particular) are considering UHV (1000 kV and above) transmission—the driver being the transmission of bulk power over long distances from inexpensive hydro-generation to load centers. It is predicted that we will again see lines operating above 1000 kV. In the United States, AEP has just been awarded a license to extend its existing 765-kV network. It took 10 years to secure the license. While the notion of ever-increasing transmission voltage may have been lost in the 1980s and 1990s, it appears set to make a rebound in the 21st century.

The new edition also contains a number of useful additions:

- **Glossary.** A glossary is provided that draws off both the IEEE and the IEC.
- **Base Cases.** To help demonstrate the theory, a large number of bases cases are provided. These base cases are loaded into the applets. The base cases help the reader exercise the theory and also gauge the technical limits of various line design parameters.
- **Index.** Previous editions of the book did not contain an index. While each chapter is self contained, the index helps readers find the right information across the entire handbook.
- **Harmonized Technical Units.** The focus is on SI units. While this is not always possible since many historical results are in English units, every attempt has been made to harmonize technical units used. An applet that allows conversion of units is provided.

It is important that we recognize a number of key individuals who played pivotal roles in bringing this new edition to life: Standing head-and-shoulders above the rest, Luciano Zaffanella was a technical powerhouse. His contribution—both on individual chapters and the overall handbook—was phenomenal. His leadership and experience shines through in every chapter. His ability to translate complex theory into a simple applet is unique. This book stands testimony to Luciano's leadership in high-voltage power

transmission. The editorial team was complemented with Professor Jan Reynders of the University of the Witwatersrand, South Africa and key advisor to Eskom and CIGRE. Jan's role was to present the "European" approach to transmission-line design. Finally, the text was edited and laid out under the expert guidance of Jonas Weisel. Jonas worked wonders with the large number of contributors and established a very high editorial and publishing standard. He was assisted by Lee Lehrman, who laid out the pages and redrew many of the illustrations.

Each author is recognized at the start of each chapter with a picture and short biography. The reviewers and the authors are also recognized on a specific "Authors and Reviewers" page. The team was particularly privileged to be able to draw on John Anderson. Well into his eighties, John is someone to marvel at and a real inspiration to all. Having been associated with Lenox for "countless-years," John brought considerable insight and energy to this edition. Chapter 6 on lightning, for the first time, captures his extensive knowledge and experience in one place.

This book would not have been possible without the technical and financial support of utilities from around the globe. A page of "Acknowledgments" recognizes those who funded the third edition.

Finally, on a personal level, the regular semi-annual meeting of the authors will, I am sure, remain in the memory of all participants for the rest of our lives. The extremes of Lenox, Massachusetts in midwinter and then again in midsummer each year for four years is something to be experienced. The idea of pulling together over 25 experts from around the globe into one room for three days to debate the structure of each chapter conjures up an image of "mind-numbing intellectual debates." These fears were totally unfounded. The debates were very spirited, very constructive—with every author making a point of helping the other. The process of constructing the contents page, debating where information should reside, and the inevitable trading of text between chapters was an absolute pleasure to facilitate. It would be fair to say that every author left the project having learned something from his peers. Solid friendships were either made or rekindled during the four years of this project.

In every engineer's life there are those events that leave a lasting impression. This book marks such an event for many associated with this monumental effort. Finally, it is the wish of all participants that this new edition will spur a renewed interest in high-voltage transmission—ultimately leading to a new generation of transmission-line engineers.

5.7 SWITCHING IMPULSE STRENGTH OF STATION INSULATION 5-21
Introduction 5-21
Horizontal Insulator Strings 5-21
Station Post Insulators 5-21
5.8 PHASE-TO-PHASE SWITCHING SURGE STRENGTH 5-22
Introduction 5-22
Phase-to-Phase Strength for a Horizontal Rod-Rod 5-24
Phase-to-Phase Strength of the Air Gap Between Conductors 5-25
Phase-to-Phase Strength of Other Insulation Geometries 5-26
Phase-to-Phase Insulation Stress 5-26
Design of Phase-to-Phase Gap Length 5-26
5.9 VARIATION OF FLASHOVER PROBABILITY WITH VOLTAGE 5-27
Withstand Voltage Level 5-28
5.10 EFFECT OF WAVESHAPE ON SWITCHING IMPULSE STRENGTH 5-28
5.11 EFFECT OF AIR DENSITY AND HUMIDITY ON SWITCHING IMPULSE STRENGTH: CORRECTION TO STANDARD CONDITIONS 5-29
Introduction 5-29
Standard Air Density and Humidity Conditions 5-29
Effect of Air Density 5-29
Effect of Humidity 5-31
5.12 EFFECT OF RAIN AND OTHER WET WEATHER CONDITIONS ON SWITCHING IMPULSE STRENGTH 5-32
Air Gaps and Clean Insulators 5-32
Switching Impulse Strength of Contaminated Insulators 5-33
5.13 RISK OF FAILURE OF PHASE-TO-GROUND INSULATION 5-34
Introduction 5-34
Distribution of Switching Surges on Transmission Lines 5-34
Parameters Affecting Risk of Failure Caused by Switching Surges 5-34
Simplified Design Procedure 5-35
5.14 CONSIDERATION OF SWITCHING SURGES DURING LIVE-LINE MAINTENANCE 5-37
Introduction 5-37
Minimum Number of Insulators to Withstand Switching Surges 5-38
Performance of Portable Protective Gaps 5-38
Effect of Floating Objects 5-39
Appendix 5.1 COMPUTATION OF THE SWING ANGLE DISTRIBUTION 5-40
Appendix 5.2 MODEL FOR THE CALCULATION OF SWITCHING IMPULSE STRENGTH OF AIR GAPS 5-41
REFERENCES 5-44

Chapter 6 **Lightning and Grounding**
6.1 INTRODUCTION 6-2
Historical Context 6-2
Lightning Protection of Transmission Lines 6-2
Simulation of Lightning on Transmission Lines 6-2
Capital Cost of Lightning Protection for Transmission Systems 6-3
Benchmark: Cost of Avoided Momentary Outages 6-4
Organization and Contents of the Chapter 6-5
6.2 THE LIGHTNING FLASH 6-6
Cloud Electrification 6-6
The Stroke Mechanism—Negative Downward Leaders 6-7
The Stroke Mechanism—Upward Positive Leaders 6-8
The Stroke Mechanism—Positive Flashes 6-9
Charge and Voltage 6-9
Leader Diameter, Visibility, and Branching 6-9

Structure and Progression of the Positive Upward Connecting Leader 6-10
First Return Stroke Waveshapes 6-11
First Negative Return Stroke Parameter Distributions 6-14
Positive Return Stroke Parameter Distributions 6-16
Subsequent Stroke Parameters 6-17
Electromagnetic Fields from Return Strokes 6-19
Upward Flashes from Tall Structures 6-19
Experience on 60–140 m Towers 6-20
Winter Lightning 6-20
Arc Damage from Flash Charge 6-21

6.3 REGIONAL LIGHTNING FLASH STATISTICS AND DATA 6-22
Isokeraunic Maps, OTD Measurements, and Lightning Flash Counters 6-23
General Observations 6-26
The North American Lightning Detection Network 6-29
Inter-comparison of Lightning Detection Methods 6-31

6.4 SURGE IMPEDANCE AND CORONA EFFECTS 6-31
Surge Impedance of Single Wires and Bundles 6-32
Surge Impedance of Towers 6-37
Calculation of Insulator Voltage and Lightning Performance 6-45

6.5 INSULATION STRENGTH FOR LIGHTNING IMPULSES 6-45
Volt-Time Curve Penetration Algorithm, Evaluated at Span Reflection Time 6-46
The Disruptive Effect (DE) Algorithm, Typically for Faster-Front Flashover/Puncture 6-46
The Leader Progression Model, Typically Evaluated for Several Span Reflection Times 6-47
Insulator Puncture Strength 6-48

6.6 SHIELDING FAILURE CALCULATIONS 6-48
The Shielding Failure Process 6-49
Uncovered Areas in the Shielding Failure Models 6-50
Recommended Strike Distance Equations 6-50
Perfect Shielding 6-51
The Method of Maximum Heights 6-51
Cascading Flashovers 6-52
Transmitted Stress to Terminals 6-52
Calculation Procedures 6-52
Simplified Models 6-53

6.7 INITIATION OF BACKFLASHOVERS 6-55
The Backflashover Process 6-55
Dynamic Models for Electrical Insulation Strength 6-56
Calculation Procedures 6-57
Digital Models for Backflashover 6-57
Applet Descriptions 6-59

6.8 INITIATION OF INDUCED FLASHOVERS 6-60
Induction from EM Fields of the Lightning Flash 6-60
Simplified Model for Induced Overvoltages 6-60
Protection against Induced Flashovers 6-61
Importance for Subtransmission and Underbuilt Distribution 6-61

6.9 INITIATION OF MIDSPAN FLASHOVERS 6-62
The Failure Mechanism 6-62
Corona Coupling at Midspan 6-62
Current Injection into Phase Conductors 6-63
Tower Flashovers Caused by Midspan Strokes 6-63
Cascading Flashovers at Adjacent Structures 6-63
Rules for Midspan Spacing 6-63
Importance for Subtransmission and Underbuilt Distribution 6-64

6.10 TRANSMISSION-LINE GROUNDING 6-64
Mechanical Integrity 6-64
Guy Anchors for Additional Strength 6-64
Corrosion and End-of-Life Aspects 6-64
Steady-State Tower Potentials 6-65
Earth Resistivity—Its Importance and Measurement 6-69
Influence on Dielectric Strength of Soils 6-69
Vertical and Horizontal Layering 6-69
Measurement Techniques and Typical Results of Field Tests 6-70
Capacitance, Electrolytic and Dielectric Effects 6-70
Dynamics of Ground Resistance (Applets L-1 and L-3) 6-71
Nonlinear Dynamics of Ground Rods 6-71
The Liew-Darveniza Calculation of Rod Dynamic Resistances 6-71
Use of the Korsuncev Criterial Curve 6-72
Metal Tower and Reinforced Concrete Foundations 6-73
Radial and Continuous Counterpoise 6-74
Recommendations for Line Flashover Calculations 6-74
Step, Touch and Transferred Potentials 6-75
Coordination With Safe Body Withstand Levels 6-77
Calculation of Surface Potentials Using L-6 Applet 6-77

Appendix 6.1 THEORY OF THE DISRUPTIVE EFFECT ALGORITHM 6-79

Appendix 6.2 ELECTROMAGNETIC FIELDS FROM LIGHTNING 6-80

REFERENCES 6-83

Chapter 7 **Electric and Magnetic Fields**

7.1 INTRODUCTION 7-2

7.2 BASIC ELECTRIC AND MAGNETIC FIELD PRINCIPLES 7-3
EMF: Electric and Magnetic Fields 7-3
Phasors and Vectors 7-4
Electric Field 7-4
Magnetic Fields 7-7

7.3 CALCULATION OF ELECTRIC FIELDS 7-11
General Method for Transmission Lines 7-11
Lateral Profile of Electric Field at Ground Level 7-14
Maximum Electric Field at Ground – Generalized Curves 7-15
Effect of Line Parameters 7-16
Electric Field of Double-Circuit Lines 7-17
Electric Field in Substations 7-18

7.4 CALCULATION OF MAGNETIC FIELDS 7-19
General Method for Transmission Lines 7-19
Example Calculation 7-21
Calculation of Magnetic Field from Power Lines Using Simple Equations 7-21
Calculation of Magnetic Field from Sets of Conductors in Three Dimensions 7-22

7.5 MEASUREMENT OF ELECTRIC FIELDS 7-25
Techniques for Measuring the Unperturbed Electric Field 7-25

Measurement of the Electric Field on a Boundary Surface 7-28
Measurement of the Space Potential 7-29

7.6 MEASUREMENT OF MAGNETIC FIELDS 7-30
Magnetic Field Meters 7-30
Measurement of Magnetic Field from Power Lines 7-31
Waveform Capture Instrumentation 7-32

7.7 COMPARISON BETWEEN HV TRANSMISSION-LINE AND COMMON ENVIRONMENT ELECTRIC AND MAGNETIC FIELDS 7-32

7.8 ELECTRIC FIELD INDUCTION IN OBJECTS 7-34
Introduction 7-34
Electrical Parameters of Objects with Different Shapes 7-35
Accuracy Expected in Calculating Short-Circuit Currents 7-40
Electric Field Induction in Long Objects in a Nonuniform Electric Field 7-41
Impedance of Vehicles to Ground 7-42

7.9 MAGNETIC FIELD INDUCTION IN OBJECTS 7-44
Short-Circuit Currents and Open-Circuit Voltages of Sets of Conductors Parallel to Transmission Lines 7-44
Shield Wire Currents 7-46

7.10 RESPONSE OF PEOPLE TO TRANSMISSION-LINE FIELDS 7-47
Induced Currents and Their Distribution 7-47
Field Enhancement on the Surface of the Body 7-48
Currents Induced by Spark Discharges 7-49
Transient Currents Induced by Switching Surges 7-51
People Response to Short-Term Exposure to Electric Field 7-51

7.11 BIOLOGICAL EFFECTS OF ELECTRIC FIELDS 7-57

7.12 CURRENTS INDUCED IN THE HUMAN BODY BY TRANSMISSION LINE MAGNETIC FIELDS AND A COMPARISON WITH THOSE INDUCED BY ELECTRIC FIELDS 7-57

7.13 BIOLOGICAL EFFECTS OF MAGNETIC FIELDS 7-58

7.14 FUEL IGNITION 7-59
Fuel Ignition Caused by Spark Discharges 7-59
Corona-Induced Fuel Ignition 7-61

7.15 EFFECTS OF HIGH-INTENSITY ELECTRIC FIELDS 7-62
Wood Pole Burning 7-62
Dead Tree Burning 7-62
Tree Tip Damage 7-63
Corona on Grounded Objects 7-63

7.16 METHODS FOR REDUCING TRANSMISSION-LINE ELECTRIC FIELDS 7-64
Introduction—Passive and Active Shielding 7-64
Shielding by a Horizontal Grid of Grounded Wires 7-65
Shielding By a Vertical Grid of Grounded Wires 7-66
Shield Wire Mesh 7-67
Shielding by Objects 7-67
Effect of Underbuilt Lines on Electric Field (Active Shielding) 7-69

7.17 METHODS FOR REDUCING TRANSMISSION-LINE MAGNETIC FIELDS 7-70
Line Design for Low Magnetic Field 7-70
Optimization of Line Parameters 7-70
Line Compaction 7-73
Split-Phase Lines 7-76
Passive Shielding of Transmission Line Magnetic Field Using Cancellation Loops 7-78
Example of Cancellation Loops Applied to a 345-kV Corridor 7-88
Fourth-Wire Scheme 7-92

Appendix 7.1 CALCULATION OF FIELD ELLIPSE PARAMETERS 7-93

Appendix 7.2 USE OF TWO-DIMENSIONAL DIPOLES AND QUADRUPOLES FOR CALCULATING TRANSMISSION-LINE MAGNETIC FIELDS 7-95

Appendix 7.3 STANDARDS AND GUIDELINES 7-99

Appendix 7.4 MONITOR JITTER CAUSED BY TRANSMISSION-LINE MAGNETIC FIELDS 7-103

Appendix 7.5 MAGNETIC INDUCTION WITH RESISTIVE GROUND RETURN 7-107

Appendix 7.6 ELECTRIC FIELD CALCULATIONS FOR THREE-DIMENSIONAL GEOMETRY 7-109

REFERENCES 7-113

Chapter 8 **Corona and Gap Discharge Phenomena**

8.1 INTRODUCTION 8-2

8.2 MECHANISM OF CORONA DISCHARGES 8-2
Basic Discharge Physics 8-2
Discharges in Uniform Fields 8-5
Discharges in Nonuniform Fields 8-6
Modes of Corona Discharge 8-7

8.3 GAP DISCHARGES 8-12

8.4 CORONA ONSET ON CONDUCTORS AND HARDWARE 8-14
Conductors 8-14
Hardware 8-16

8.5 CORONA EFFECTS 8-17
Corona Loss 8-17
Electromagnetic Interference 8-18
Audible Noise 8-19
Ozone and NO_X 8-19
Light Emission 8-20
Electrical Wind and Corona-Induced Vibrations 8-20
Other Effects 8-20

8.6 FACTORS INFLUENCING CORONA PERFORMANCE 8-21
Fair Weather Corona Sources 8-21
Conductor Surface Conditions 8-21
Influence of Water on Conductors 8-22
Influence of Weather Conditions 8-22
Influence of Conductor Heating 8-23
Statistical Consideration of Corona Performance 8-23

8.7 GENERATION QUANTITIES OF CORONA EFFECTS 8-24
General Principles of Corona Testing 8-24
Generated Corona Loss 8-25
Radio Noise Excitation Function 8-26
Generated Acoustic Power Density 8-28
8.8 CORONA ATTENUATION OF POWER SYSTEM OVERVOLTAGES 8-28
Lightning Overvoltages 8-29
Switching Overvoltages 8-30
Temporary Overvoltages 8-32
Appendix 8.1 GUIDELINES FOR CORONA TESTING OF HARDWARE 8-33
Appendix 8.2 CURRENTS INDUCED BY MOVING CHARGED PARTICLES 8-37
REFERENCES 8-38

Chapter 9 **Electromagnetic Interference**
9.1 INTRODUCTION 9-2
9.2 CHARACTERISTICS OF TRANSMISSION-LINE EMI 9-4
EMI Due to Conductor Corona 9-4
EMI Due to Hardware Corona 9-8
Gap Discharge EMI 9-9
9.3 DESIGN CONSIDERATIONS AND EMI GUIDELINES AND LIMITS 9-10
EMI Tolerability Criteria 9-10
Design Guidelines and Limits 9-15
9.4 MEASUREMENT OF EMI 9-16
EMI Instrumentation 9-17
Weighting Circuits 9-17
Meter Response – Bandwidth and Pulse Repetition Rate 9-19
Actual Band-Pass Characteristics 9-22
Antenna Systems 9-23
Measurement of Transmission-line EMI 9-24
Pre-construction, Pre-energization and Post-energization Measurements 9-25
9.5 CALCULATION OF EMI FROM CONDUCTOR CORONA BELOW 30 MHZ 9-27
Philosophy of Modeling 9-27
Analytical Methods 9-29
Empirical Methods 9-45
9.6 CALCULATION OF EMI FROM CONDUCTOR CORONA ABOVE 30 MHZ 9-46
Introduction 9-46
Analytical Methods 9-47
Empirical Methods 9-49
Calculation of TVI – Low VHF Band 9-51
9.7 PASSIVE INTERFERENCE 9-51
AM Broadcast Reradiation 9-51
TV Broadcast Reradiation 9-54
Appendix 9.1 CALCULATION OF CORONA-INDUCED CURRENT ON PHASE CONDUCTORS 9-55
Appendix 9.2 STATISTICAL AVERAGES 9-64
Appendix 9.3 EVALUATION OF INVERSE SPATIAL TRANSFORMS 9-64
Appendix 9.4 APPROXIMATIONS FOR Fey, Fhx, AND Fez 9-66
Appendix 9.5 GROUND CONDUCTIVITY 9-69
REFERENCES 9-70

Chapter 10 **Audible Noise**
10.1 INTRODUCTION 10-2
10.2 CHARACTERISTICS OF TRANSMISSION-LINE NOISE 10-2
10.3 AUDIBLE NOISE AS A DESIGN FACTOR 10-4
Effect of Weather Conditions and Load Current 10-5
Effect of Line Geometry and Conductor Surface Conditions 10-8
Audible Noise from Insulators and Fittings 10-9
10.4 CALCULATION OF TRANSMISSION-LINE AUDIBLE NOISE 10-10
Introduction 10-10
Generation and Propagation of Audible Noise 10-11
Calculation of A-Weighted Audible Noise-Levels in Rain 10-15
Audible Noise in Fair Weather 10-17
Influence of Tower, Sag, and Ground Wires 10-19
Effect of Rain Rate 10-20
Effect of Conductor Aging 10-21
Effect of Altitude above Sea Level 10-23
Effect of Bundle Orientation 10-23
Comparison of Audible-Noise Calculation Methods with Measured Data (Rain) 10-24
Generation and Calculation of Hum 10-24
10.5 MEASUREMENT OF AUDIBLE NOISE 10-27
Sound Pressure, Sound-Pressure Level, the Decibel 10-27
Weighted Sound Level 10-28
Statistical Descriptors 10-28
Leq, Ldn and CNEL 10-28
Instrumentation 10-28
Measurements 10-29
10.6 ASSESSING THE IMPACT OF TRANSMISSION-LINE AUDIBLE NOISE—AUDIBLE-NOISE REGULATIONS 10-30
Noise Evaluation Studies 10-30
Noise Ordinances—United States 10-31
Case Study: Example of Limits Based on Any One Hour 10-33
Case Study: Example of Limits Based on Some Variation of the EPA “Levels Document” 10-33
Case Study: Example of Limits Based on South African Noise Code 10-36
10.7 AUDIBLE-NOISE REDUCTION TECHNIQUES 10-37
Introduction 10-37
Bundle Geometry Optimization 10-37
Other Techniques of Audible Noise Reduction 10-40

Appendix 10.1 ADJUSTMENT OF MEASURED AUDIBLE-NOISE LEVELS TO ACCOUNT FOR AMBIENT NOISE INTRUSIONS 10-43

Appendix 10.2 AMBIENT NOISE DURING RAIN 10-44

REFERENCES 10-46

Chapter 11 **Corona Loss and Ozone**

11.1 INTRODUCTION 11-2

11.2 PHYSICAL MECHANISM OF CORONA LOSS 11-3

11.3 MEASUREMENT OF CORONA LOSS 11-4

11.4 CORONA LOSS IN FAIR WEATHER 11-6

11.5 CORONA LOSS IN FOUL WEATHER 11-9
Corona Losses in Rain 11-9
Corona Losses in Snow, Ice, and Hoarfrost 11-13
Influence of Conductor Heating 11-14

11.6 EFFECT OF ALTITUDE ON CORONA LOSS 11-14

11.7 EVALUATION OF CORONA LOSS 11-15

11.8 INFLUENCE OF CORONA LOSSES ON LINE DESIGN 11-16

11.9 OZONE AND NO_X 11-18
Mechanism of Generation 11-18
Rates of Generation 11-18
Ozone Dispersion from Transmission Lines 11-18
Ozone Levels Near Transmission Lines 11-19
Standards for Ambient Ozone Levels 11-20

REFERENCES 11-21

Chapter 12 **Shared Use of the Right-of-Way**

12.1 INTRODUCTION 12-2
Background 12-2
EMC Regulations, Standards and Guidelines 12-2
Elements of EMC 12-2
Electric Power Transmission-Line Sources 12-3
Coupling Paths 12-4
Receptors 12-5
Organization and Contents of the Chapter 12-5

12.2 INTERFERENCE WITH THE OPERATION OF RAILROADS 12-6
Background 12-6
Introduction to Coupling Mechanisms between Power Lines and Railroads 12-7
Electric-Field (Capacitive) Induction 12-7
Magnetic-Field (Inductive) Induction 12-8
Conductive (Resistive) Induction 12-9
Common and Differential Modes 12-9
Coupling between Common and Differential Modes 12-10
Overview of Railroad Signaling 12-10
Abnormal Operation of Railroad Equipment 12-10
Damage to Railroad Equipment 12-10
Personnel Safety Considerations (Steady-State Operation) 12-11
Personnel Safety Considerations (Fault Conditions) 12-11
"Rules of Thumb" of Railroad Signals and AC Interference 12-11

12.3 INTERFERENCE WITH THE OPERATION OF PIPELINES 12-12
Background 12-12
Electric-Field Induction 12-12
Magnetic-Field Induction 12-13
Conductive Coupling 12-17
Damage to Pipelines 12-17
Personnel Safety 12-18

12.4 INTERFERENCE WITH THE OPERATION OF POWER LINE COMMUNICATION SYSTEMS 12-19
Power Line Carrier 12-19
High-Speed Communications 12-19

12.5 INTERFERENCE WITH THE OPERATION OF OPTICAL FIBER COMMUNICATIONS 12-21
Introduction 12-21
Comparison of OPGW, ADSS, and WRAP 12-21
Experience with WRAP 12-22
OPGW EMC Issues 12-22
ADSS EMC Issues 12-24

12.6 CONSEQUENCES OF INSTALLING COMMUNICATION SYSTEM ANTENNAS ON TRANSMISSION-LINE TOWERS 12-26
Introduction 12-26
Influence of the Power Line on the Antenna 12-26
Issues Relating to Grounding and Low-Voltage Feeds 12-27
Exposure to RF Electromagnetic Fields 12-27

12.7 INTERFERENCE WITH THE OPERATION OF SYSTEMS FOR WARNING AIRCRAFT 12-29
Introduction 12-29
Warning Lights 12-29
Airway Marking Balls 12-29

12.8 INTERFERENCE WITH THE OPERATION OF TELEPHONE SYSTEMS 12-29
Telephone Lines 12-29
Cordless Phones 12-30
Cell Phones 12-30

12.9 CONSEQUENCES OF INSTALLING DISTRIBUTION LINES UNDER TRANSMISSION LINES 12-31

12.10 INTERFERENCE WITH THE OPERATION OF RADIO NAVIGATION SYSTEMS 12-32
LORAN-C 12-32
Instrument Landing Systems (ILS) 12-32
Global Positioning System (GPS) 12-33
Differential Global Positioning System (DGPS) 12-34

12.11 INTERFERENCE WITH THE OPERATION OF COMMUNICATION RECEIVERS 12-36

12.12 IMPACTS ON AGRICULTURAL OPERATIONS NEAR TRANSMISSION LINES 12-36
Introduction 12-36
Operation of Irrigation Equipment 12-37
Interference with Cornering Guidance Systems 12-37

12.13 USE OF VEHICLES AND LARGE EQUIPMENT NEAR TRANSMISSION LINES 12-38
Introduction 12-38

Induced Currents from Vehicles 12-39
Spark Discharges (Induced Voltages) from Vehicles 12-40
Fuel Ignition 12-40
Parking Lots 12-40

12.14 IMPACTS ON BUILDINGS NEAR TRANSMISSION LINES 12-41

12.15 IMPACTS ON PUBLIC USE OF RIGHTS-OF-WAY 12-42
Introduction 12-42
Exposure Guidelines for the General Public 12-42
Nuisance Shocks 12-43
Open-Space Uses of the Right-of-Way 12-44

12.16 AVIAN INTERACTIONS WITH TRANSMISSION LINES 12-45
Introduction 12-45
Bird Electrocutions 12-45
Bird Collisions 12-45
Nesting Issues—Structural 12-46
Nesting Issues—Electrical 12-46
Nesting Issues—Legal 12-47
Nesting Issues—Liability 12-47
Bird Pollution 12-47
Bird Streamers 12-48
Other Bird Issues 12-48

REFERENCES 12-49

Chapter 13 **Considerations for Inspection and Maintainability**

13.1 INTRODUCTION 13-3

13.2 DESIGNING FOR INSPECTION AND MAINTAINABILITY 13-3
Introduction 13-3
Background 13-4
Designing for Durability and Longevity 13-14
Design Examples 13-45

13.3 OPTIMIZING THE DESIGN FOR EFFECTIVE LIVE WORKING 13-48
Introduction 13-48
Brief Overview of Live Working (LW) 13-49
Design and Construction Aspects Important to LW 13-54
Low-Cost-Impact Design Modifications That Help Facilitate LW 13-63
High-Cost-Impact Design Modifications That Help Facilitate LW 13-64
Examples and Lessons Learned 13-64
Determining Whether a Line is Maintainable Using LW Methods 13-68

REFERENCES 13-70

Chapter 14 **Voltage Upgrading of Existing Transmission Lines**

14.1 INTRODUCTION 14-2

14.2 SYSTEM LEVEL STUDY OF POWER FLOW NEED AND VOLTAGE STRATEGY 14-4
Reactance Limits, Stability, and Surge Impedance Loading 14-5
Voltage Drop 14-7
Thermal Uprating 14-8

14.3 ASSESSING ELECTRICAL FEASIBILITY 14-9
Data Gathering 14-10
Review of Line Design 14-10
Electrical Clearances and Right-of-Way 14-10
Review of Electrical Design Criteria 14-11
Insulation and Conductor to Structure Clearances 14-12
Corona and Field Effects 14-13
Grounding and Bonding 14-14
Other Issues 14-14

14.4 ASSESSING MECHANICAL FEASIBILITY 14-15
Mechanical Data Gathering 14-16
Review of Original Structure Loads 14-16
Sag-tension Calculations 14-17
Hardware/Connectors 14-19
Insulator Strength 14-19
Structure Phase Geometry 14-19
Shield Wires 14-19
Right-of-Way 14-19
Wind and Ice-Induced Conductor Motions 14-20

14.5 EVALUATION OF PRESENT LINE CONDITION 14-20
Physical Examination 14-21
Historical Damage Report Examination 14-23

14.6 DETAILED ENGINEERING DESIGN FOR VOLTAGE UPGRADING 14-24
Detailed Review of Criteria Applied to Upgrading 14-25
Power Frequency Insulation 14-25
Switching Surge 14-26
Corona and Field Effects 14-27
Lightning 14-28
Structural Analysis and Reinforcement 14-29
Detailed Economic Review 14-29
Maintenance and Minimum Approach Distance Requirements 14-29
Conductor Motion 14-29
Laboratory Tests of Prototype Upgraded Structure 14-30

14.7 EXAMPLES OF VOLTAGE UPGRADES 14-30
Example 1: 115 to 230 kV Voltage Upgrading 14-30
Example 2: 230 to 345 kV Voltage Upgrading 14-31
Example 3: 300 to 420 kV Voltage Upgrading 14-32
Example 4: 230 to 500 kV Voltage Upgrading 14-34

REFERENCES 14-36

Index **I-1**

Symbols

Symbol	Quantity
A	Generated acoustic power (dBA)
A	Surface areas (m^2)
A *(or Alt if A used for another quantity in equation)*	Altitude above sea level (m)
A,B,C	Phasing
B	Magnetic flux density (mG)
c	Velocity of light
C	Capacitance (F)
d	Subconductor diameter (cm)
d_b	Bundle diameter (cm)
d_{eq}	Equivalent diameter of a bundle (cm)
D	Distance conductor-to-measuring point
D	Dissipation factor
$D_{subscript}$	Distances between phases (m)
$D'_{subscript}$	Distance to images
E	Electric field away from conductors (kV/m)
E_{av}	Average surface gradient of a subconductor (kV/m)
E_c	Corona onset gradient (kV/cm)
E_m	Maximum surface gradient of a subconductor (kV/m)
E_{max}	Conductor surface gradient (average of max of subconductor gradients) (kV/m)
f	Frequency (Hz)
GMD	Geometric Mean Diameter
GMR	Geometric Mean Radius
GMR_B	Geometric Mean Radius (bundle)
GMR_C	Geometric Mean Radius (subconductor)
h	Humidity
H	Magnetic field strength (A/m)

Symbol	Quantity
H	Conductor height above ground (m)
I	Current (A)
J	Power Density
J	Current Density
L	Inductance
L_{50}	50% exceedance level
L_5	5% exceedance level
L_{seg}	Length of a segment (m)
log	Base 10
ln	Base e (Natural log)
m	Conductor surface irregularity factor
n	Number of subconductors in a bundle
N	Number of elements
p	Pressure
p	Barometric pressure
P	Power loss (W/m)
P	Potential coefficients (1/F or m/F)
q *(instantaneous value)*	Line Charge (C/m)
Q *(phasor magnitude)*	Line Charge (C/m)
r	Conductor radius
r_b	Bundle radius (cm)
r_{eq}	Radius of equivalent zero potential cylinder
r_{eq}	Equivalent radius of a bundle (cm)
r_s	Average radius of space charge
R	Resistance (Ω)
RR	Rain rate (mm/h)
s	Subconductor spacing (cm)
t	Time (s)
t	Time interval (s)

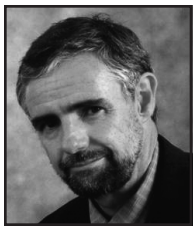
Symbol	Quantity
T	Temperature
v	Speed of wave (m/s)
V	Voltage (kV)
V_{sp}	Space potential (kV)
W	Energy
X	Reactance
X_a	Inductive reactance at 1-foot spacing
X'_a	Capacitive reactance at 1-foot spacing
Y	Admittance
Z	Impedance
Z_o	Surge impedance
x,y,z	Orthogonal coordinates
α	Phase angle

Symbol	Quantity
β	Phase angle
δ	Air density (Kg/m^3)
δ	Loss angle
δ_i	Image depth (m)
δ_r	Relative air density
ε	Permittivity (F/m)
γ	Phase angle
Γ	Radio noise excitation (or generation function)
μ	Permeability (H/m)
μ	Ion mobility (m/s per V/m)
ρ	Resistivity (m)
σ	Surface charge density (C/m^2)
σ	Standard deviation

CHAPTER 1

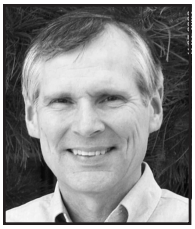
Transmission Systems

Jan P. Reynders—University of the Witwatersrand
Raymond Lings—EPRI
Robert G. Stephen—Eskom
Lori A. Nielsen—EDM International, Inc.
Andrew C. Ludwig—ENSR International



This chapter provides a broad introduction to power transmission. It describes the evolution of transmission from the late 19th century to developments in the early 21st century. The chapter also introduces the topic of line permitting. While not directly applicable to the electrical design of a transmission line, line permitting today is seen as the single largest hurdle to the expansion of the global transmission system.

Jan P. Reynders has been a researcher and academic in the field of electrical engineering since 1964. He has been active as a specialist on working groups in CIGRE since 1978, all largely in the field of insulation and insulation coordination. He has served on the Administrative Council and the Technical Committee of CIGRE, as well as being the National Member on Study Committees 15 and 33. On the academic level, he served as head of the Department of Electrical Engineering and as Dean of the Faculty of Engineering at the University of the Witwatersrand. He had two terms as a member of the University Council. Along with his masters and doctoral students, he has published 170 journal and conference papers on various aspects of electrical power and engineering education. Jan is a Registered Professional Engineer in South Africa, and has been appointed as a consultant to a wide variety of organizations both in South Africa and elsewhere in the world.



Raymond Lings is the Area Manager for Transmission and Substations within the Science and Technology Development Division of EPRI. In his present duties, Lings is responsible for the management and execution of EPRI's research in overhead and underground transmission, substations, increased transmission capacity, EMC (electromagnetic compatibility), energy storage for T & D applications, and applications of superconductivity. Lings joined EPRI in 1998 as a project manager in substations. Prior to joining EPRI, he was the Research Operations Manager at Eskom, South Africa, where he worked for 11 years, starting as an Engineer-in-Training and rising to Manager of Electrical Research and then to Research Operations Manager covering research in distribution, transmission, and generation. As Manager of Electrical Research, he managed Eskom's extensive electrical laboratories. Lings is a senior member of the IEEE and is a registered professional engineer in South Africa. He is the author or co-author of more than 15 publications in the field of transmission and distribution, with the majority of his publications covering electronic domestic metering. As EPRI project manager for this edition of the Reference Book, Lings led the editorial committee, and had overall management responsibility for the new edition. He has also represented South Africa and the United States on an IEC Working Group on the reliability of metering. Lings holds a number of degrees including a Masters Degree in Electrical Engineering (MSc) and a Masters of Business Administration (MBA).

Robert G. Stephen has been actively involved in line design and line optimization since 1985. He has led the design and project engineering team in Eskom, the South African utility, and has introduced optimization processes for line designs that have resulted in large cost reductions. He specializes in thermal rating of lines, and was instrumental in drafting the CIGRE documents on steady-state determination of conductor temperature as well as probabilistic rating. Stephen has authored a number of local and international papers on the subject. For 9 years he was chairman of CIGRE SC B2 -12 dealing with electrical aspects of overhead lines. He received the Technical Committee award for CIGRE in 1996, served as Special Reporter for SC B2 in the same year, and was chairman of CIGRE SC B2 (Overhead lines) from 2000 to 2004. He is an honorary member of CIGRE and a fellow of the South African Institute of Electrical Engineers.

Lori Nielsen with EDM International, Inc. has more than 18 years experience managing and coordinating environmental permitting, biological studies, mitigation plans, and monitoring programs in the United States. Her focus has been on permitting and compliance for projects subject to national, state, local, and tribal regulatory review. Ms. Nielsen has provided technical expertise on, or managed, over 55 Environmental Assessments (EAs) and Environmental Impact Statements (EISs), including routing and siting studies for generation and transmission projects, permit review and authorization for projects on public lands, and regulatory compliance for sensitive biological resources. In addition to these federal reviews, she was involved with five solar energy generating projects over eight years with the state permitting review in the western Mojave Desert of California. She works closely with a range of utilities, including investor owned, municipalities, federal, public, and the Rural Utilities Service Electric Cooperatives. As a senior wildlife biologist, Ms. Nielsen is also involved in permitting review and compliance for a number of environmental regulations pertaining to power line siting, construction, and operation, encompassing over 40 biological reviews and problem resolution for electric utilities under the United States Endangered Species Act and International Migratory Bird Treaty Act.

Drew Ludwig has been with ENSR International in Fort Collins, Colorado for the past 28 years, and has 32 years total experience in environmental analysis and report preparation for capital development projects, including transmission lines and power plants. He has been involved in transmission line, pipeline, and generating station siting analysis since beginning his career with Commonwealth Associates in 1973 and has worked on numerous projects in the eastern and western United States and Canada, including nuclear, coal-fired, and gas turbine power plants and high-voltage electric transmission lines from 69-kV to 765-kV. These projects have required the preparation of EAs and EISs for the Rural Utilities Service (and its predecessor the Rural Electrification Administration), as well as the Department of Energy, Bureau of Land Management, and National Park Service. In total, Mr. Ludwig has participated in the preparation of more than 40 EAs and EISs in both technical and management roles. His transmission-line experience includes testimony on environmental issues before the Wyoming Public Service Commission and New York Public Service Commission.

1.1 INTRODUCTION

1.1.1 Background

This chapter introduces the subject of transmission-line design through a brief, high-level overview of fundamental concepts and industry issues bearing on the role of line design.

Given the requirement of the electricity system for precisely balancing supply and demand while rapidly and reliably delivering electromagnetic energy across thousands of miles, it is not surprising that the system is often described as the most complex machine ever built. It is also arguably the most influential machine of the last century. In fact, the U.S. National Academy of Engineering voted electrification as the number-one engineering achievement of the 20th century due to its impact on the course of industrialization and its contribution to the quality of life in innumerable applications (Constable and Somerville 2003).

Modern society is dependent on the ready availability of energy and communication, both of which are indispensable for economic growth and sustainability. Electricity plays a vital role in providing these two resources. Electrical generation and transmission systems take natural energy sources in their raw, and often difficult-to-use, state and deliver power in a highly controllable, clean, and usable form to wherever it is needed. Electrical power is converted into heat, light, and mechanical energy. It provides the power for mass transport systems; it makes audible and visual communication as well as data transmission possible with amazing speed and efficiency. Industry, business, banking, education, medical facilities, and family life are all dependent on the availability of low-cost, highly reliable electricity.

Despite its ubiquity, electricity is generally taken for granted by most users—at least until there is a widespread outage, when the central critical role of electricity in modern economies is demonstrated. This was evidenced by the blackout of August 14, 2003, in the northeast United States and Canada, the largest blackout in North American history. In just a few days, this outage affected 40 million people across eight U.S states and 10 million people in Canada—a third of that country's population. It involved more than 250 power plants and 62,000 MW of power, closed 12 airports, disrupted water and communications systems, and resulted in $6 billion of economic losses in goods and services (U. S. DOE 2003, 2004; U. S.–Canada Power System Outage Task Force 2003). Where electricity is unavailable or costly, many of the resources needed in society remain primitive, economic growth is hampered, health services and education remain problematic, and transportation grinds to a halt.

Transmission lines are the means whereby the electrical energy is transported from the source of generation to the places of use. Distances involved can be very long, and the lines may traverse a variety of environments. The lines must be capable of operating reliably in all the environmental conditions that they experience and should have as low an impact as possible on these environments.

Power lines have been in existence for almost 120 years, as illustrated in Table 1.1-1. In the U.S. in the early 1880s, Thomas Alva Edison and his team established the first power company in New York City and designed a small but complete electrical system based on direct current (dc). A few years later George Westinghouse established a rival company, and after purchasing patents from Nikola Tesla, began building electrical systems with alternating current (ac).

Initially, the electrical grid in North America primarily consisted of small, isolated, locally operated networks serving urban centers. However, beginning in the 1930s, and intensifying in the 1950s and 1960s, there evolved a large, interconnected system of interstate transmission lines linking many different electrical systems. Large generation plants were built to take advantage of economies of scale, and transmission lines with increasingly higher voltages were constructed to allow the bulk delivery of power over great distances. Figure 1.1-1 shows the rise in maximum operating transmission voltages over the years.

From these humble beginnings, the North American grid today contains more than 200,000 miles (322,000 km) of high-voltage lines operating above 230 kV and serving over 120 million consumers and nearly 300 million people. The U.S. electricity delivery system—which consists of the grid and the downstream distribution system—is a $360 billion asset.

Worldwide, there are now dc lines operating up to ±533 kV and ac lines that have been designed and operated up to 1200 kV (as described in Chapter 15). These lines traverse distances of 1500 km or more.

These achievements have been realized with the constant dynamic of reducing cost, improving reliability, and mini-

Table 1.1-1 First Electrical Power Lines (Glover and Sarma 2002)

	ac/dc	Length (km)	Voltage (kV)	Date	Location
First line	dc	50	2.4	1882	Germany
First single-phase line	ac	21	4	1889	Oregon, USA
First three-phase line	ac	179	12	1891	Germany

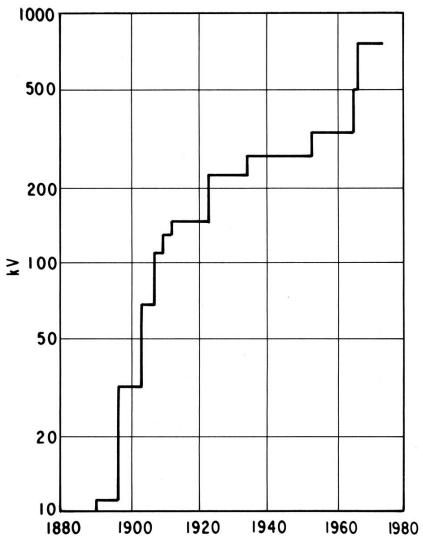


Figure 1.1-1 Highest ac transmission voltages in North America (EPRI 1982).

mizing environmental impact. There is a constant evolution in design to address these requirements. Modern guyed structures have contributed to the compaction of lines, and this has resulted in reductions in cost, improvements in performance, and lower levels of environmental impact. Structures and their foundations, the electric and magnetic fields produced by the voltage and current, and audible and radio interference produced by corona must all conform to demanding requirements. The challenge facing the designer is to design a cost-effective and reliable line within the bounds set by the performance and regulatory requirements.

1.1.2 Transmission System Characteristics

Around the world, the underlying principles governing operation of transmission systems are generally similar. From country to country, the differences lie in design specifications and margins of operation.

In addition, there are differences in frequency and standard voltages. As regards frequency, two basic types of power systems are in use around the world. For convenience, they can be referred to as North American-type systems and European-type systems. Most power systems share basic characteristics with one of these two types (see Figure 1.1-2).

North American systems are characterized by 60 Hz as the fundamental frequency, while European systems are characterized by 50 Hz.

Not every country, however, follows strictly "North American" or "European" power system. One example of this is Japan, where the transmission system uses both frequencies, with the northern region of the country operating on

Figure 1.1-2 North American vs. European type power systems, based on 50- and 60-Hz systems throughout the world (*Energy Information Administration and CIA World Fact Book* 2002).

50 Hz, and the southern region operating on 60 Hz (see Figure 1.1-3).

China in 2004 experienced an explosion in new networks and growth. The network was constructed using the latest technologies and included integrated ac transmission and HVDC (see Figure 1.1-4).

For the two main types of power systems, the standard voltages are also different, as shown in Table 1.1-2.

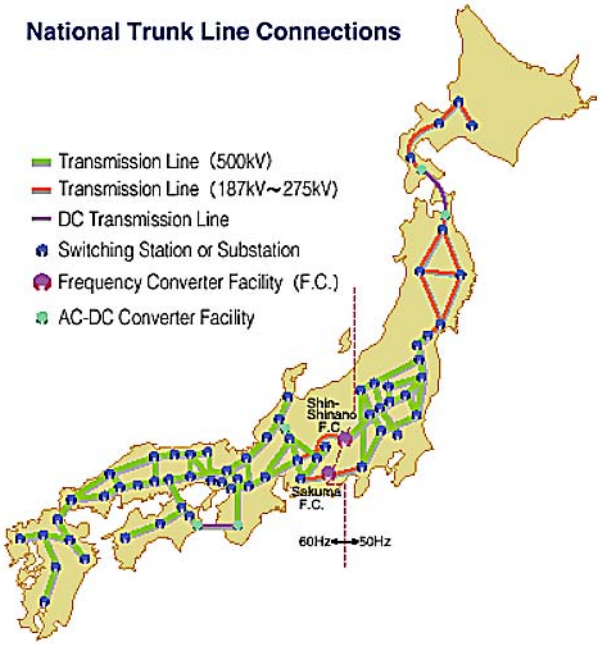

Figure 1.1-3 Japanese transmission system (EPRI 2004).

Figure 1.1-4 Transmission infrastructure in China (EPRI 2004).

The introduction of a new transmission voltage is prompted by the increase in power generation and distribution requirements within a region that cannot be efficiently handled using the existing transmission network. Generally, lower-voltage transmission networks are overlaid by a transmission network with voltages higher by a factor of two to three. In certain areas of North America, 115-161 kV transmission networks are overlaid by 345-kV network, and these by 765-kV networks. In other North America areas, 230-kV networks are overlaid by 500-kV network. Several European systems have 110 kV, 220 kV, and 400 kV (each approximately a factor of two from the next lower voltage).

The title for this edition of the Red Book reflects a clarification of the book's focus and a change from previous editions, as regards transmission system characteristics. Recognizing that most lines are in the voltage range of 230 to 345 kV, it was decided to lower the voltage range of the book. The choice of 200 kV was taken because this level is clearly in the transmission range. In addition, 200 kV is a "country-neutral" threshold. It represents neither the common North American standard of 230 kV nor the European standard of 220 kV. Also, because the Red Book focuses only on ac technology, and since EPRI has a separate handbook on dc technology (*HVDC Transmission Line Reference Handbook*), the term "ac" was added to the book's title.

1.1.3 Industry Trends Affecting Line Design

Starting in the late 1980s, there have been a number of broad electric industry trends that have had a profound impact on transmission-line design today in ways that extend far beyond the concerns of traditional electric design.

Foremost among these trends is the deregulation of the electricity industry in North America and various other parts of the world, and the associated unbundling of generation, transmission, distribution, and retail services. In some cases, the initial effects of deregulation have been a

Table 1.1-2 Standard Voltages

North American Transmission (kV)	European Transmission (kV)

115	110
138	132
161	220
230	275
345	400
500	
735–765	765
	1100 (not in general use)

lack of coordinated network planning to meet load, rapid increase in wholesale transactions, changes in grid flows and increased grid congestion, and low levels of infrastructure investment.

Other general industry trends in recent years with the potential to affect transmission-line design include increased legal and environmental requirements and high costs of rights-of-way, an aging infrastructure, lack of investment in maintenance, and growing needs for grid security.

Finally, at the time of this writing, a key concern for the industry is the loss of skills—a trend that may or may not be reversed. This loss is evident in the following areas:

- **Staff Reductions.** The focus on deregulation has meant major staff reductions. The uncertainty in the industry has seen the wide-scale loss of deep technical skills, with less attention on the technical and more on the financial operations of the industry (the standard comment being that the company is now run primarily by nonengineering managers).
- **Contracting.** Transmission companies are contracting out more and more of the day-to-day operations. (It is now typical for independent transmission companies with workforces of 300 employees to contract out nearly every day-to-day function.)
- **Hiring.** Since the late 1980's, hiring of graduates has been in decline. This trend has started to change, but in reality the poor job market has meant that potential graduates have turned to other industries for a career. Interestingly, the transmission industry now complains that there are now skilled positions available and that the universities are not producing the required supply of graduates to meet demand.
- **Graduates.** Universities have seen declining graduate numbers (although anecdotal comments indicate that the North American blackout of August 14, 2003, plus the decline in the luster of the "dot-com" industry, has made power engineering a more attractive career path).

The net result of these trends is that the practice of transmission-line design has undergone significant changes in the past 15 years. Accordingly, this edition of the Red Book reflects these changes in the breadth and content of its coverage. More detailed discussion of these trends is found in Sections 1.4 through 1.6.

1.1.4 Feedback of Experience

Another opportunity provided by this new edition of the Red Book is that, since the publication of the previous edition, more than 15 years of experience in line design, operation, and maintenance are available to today's designers. This edition, therefore, intentionally sets out to capture key areas of experience, including use of rights-of-way (servitudes), line maintenance, voltage uprating, and development of lines above 700 kV.

1.1.5 Organization of this Chapter

Section 1.2 reviews several basic concepts of electrical design that are relevant to line design, including voltage, impedance, and power limits, and the effects of standing waves and transients.

Section 1.3 discusses environmental factors pertinent to the design and siting of lines.

Given the profound changes in the electricity supply industry in recent years, Sections 1.4 and 1.5 examine issues related to the current state of the industry and its future direction that have the potential to shape the practice of transmission-line design.

Section 1.6 describes legislative and regulatory issues typically encountered during the siting and construction of new high-voltage transmission lines and ancillary facilities. This latter section provides extended discussion, because in recent years, it has been found that the majority of instances of delay or cancellation of new line projects are due to the permitting process.

Section 1.7 provides a mapping between the second edition and third edition of this Reference Book. Those familiar with the second edition will find this section useful when trying to locate information.

1.2 ELECTRICAL DESIGN

1.2.1 Voltage, Impedance and Power Limit

Some Basic Considerations

Under steady-state balanced ac conditions, a power line can be represented by the simple, Π equivalent-circuit shown in Figure 1.2-1.

In Figure 1.2-1, the subscript "S" on the voltage and current applies to the sending-end and the subscript "R" to the voltage and current at the receiving-end of the line. *R* is the series resistance, *L* the series inductance and *C* is half the

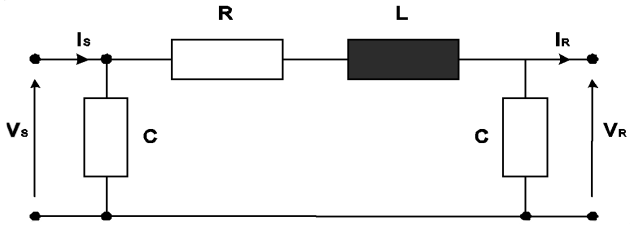

Figure 1.2-1 Π equivalent-circuit for a power line.

total shunt capacitance of the line. Shunt conductance provides a resistive path in parallel with both shunt capacitors. However, since the basic insulation for transmission lines is air, the shunt conductance is assumed to be zero and is ignored.

An analysis of a loaded line shows that, if line losses can be regarded as small in comparison with the power transferred by the line, the maximum power that the line can transmit is given by Equation 1.2-1 (Glover and Sarma 2002; Grainger and Stevenson 1994):

$$P_L = \frac{V_S V_R}{X} \qquad 1.2\text{-}1$$

Where:

P_L is the power limit of the line

V_S and V_R are the rms values of the sending-end and receiving-end voltages, respectively.

X is the series reactance of the line

This simple equation leads us to two very important limits on the performance of a line:

- **Voltage.** The maximum power that a line can transmit is directly proportional to the product of sending- and receiving-end voltages. In most transmission systems, these two voltages are more-or-less the same and hence the power limit is proportional to the square of the system voltage. This is why utilities move to higher voltages as the amount of power to be transmitted increases. The reactance of the line has a logarithmic dependence on the ratio between conductor size and phase spacing. It decreases with conductor size and increases with phase spacing. As the voltage increases, the change in reactance is generally small. Hence, as the system voltage is doubled, the power limit of the line approximately quadruples, provided the line length does not change.

  Increases in voltage require greater phase spacings and more insulation, necessitating wider rights-of-way, or servitudes. However, the relationship is not linear, and the economics of line design as well as the environmental impact are, usually, in favor of increasing the voltage instead of placing additional parallel lines in the same right-of-way. Chapter 15 describes the experiences of ten utilities that have developed transmission lines to operate above 700 kV.
- **Series Reactance.** The power limit is inversely proportional to the series reactance of the line. This reactance is directly related to the phase separation and the dimensions and configuration of the phase conductors as well as the line length (Glover and Sarma 2002, Chapter 4; Grainger and Stevenson 1994, Chapter 4). For a given length of line, the power limit can be increased by reducing the series reactance. This involves a reduction of phase spacing—realizable with compact structures and the use of large conductor bundles. With long lines, it is feasible to "tune out" the series inductance by means of series capacitive compensation. This involves placing series capacitor installations at appropriate positions along the line length and is economically viable for lines of approximately 800 km (500 miles) or longer. Frequently these installations are made at points of transposition.

  The electrical resonance produced by the series arrangement is always below power frequency so that resonance at power and harmonic frequencies will be avoided. Care must be taken to ensure that the resonant frequency chosen does not coincide with mechanical resonances in the generators. Where this has been the case, these subsynchronous resonances have caused severe damage to generators (Glover and Sarma 2002).

In addition, while the Red Book is an ac handbook, it is worth noting that high-voltage direct current (HVDC) is a viable alternative to ac for long-distance transmission because the conversion cost has decreased and reliability has increased. Also, high-capacity dc interties may be used to connect adjacent, asynchronous regions in order to resolve stability problems. Issues of long power transmission, coupled with improvements in converter technologies and increasing concerns about network stability, have meant that HVDC continues to receive consideration as a complementary technology to the existing ac transmission backbone in most countries and regions of the world.

Increasing the Power Transfer Capacity of a Line

The preceding section showed that the power limit of a line can be increased by increasing the operating voltage of the line or by reducing the series reactance of the line, neither of which are trivial issues.

To upgrade the voltage, the insulation to ground and between phases has to be increased. In addition, the conductor surface gradient must to be maintained below certain levels to prevent the generation of audible noise and radio and television interference. Frequently these requirements lead to larger towers and conductors. Voltage upgrading is addressed in Chapter 14, while corona is comprehensively dealt with in Chapters 8-11.

The reduction of series reactance can be addressed by changing the phase spacing and conductor geometries. This topic is addressed in Chapter 2. On long lines, the series reactance is frequently reduced through the installation of series capacitors. Shunt capacitors and inductors are installed on lines to improve voltage stability at the terminations, and this is referred to as shunt compensation. Power Electronics-based Controllers are used in conjunction with the compensation and the system is then referred to as a Flexible AC Transmission System (FACTS). They

are frequently used to provide dynamic compensation and control of line impedance. FACTS technology provides dynamic and flexible transmission compensation, which results in increasing transmission capacity while maintaining operation reliability of transmission grids (Edris 2000). Further information can be found in the book by Glover and Sarma (Glover and Sarma 2002).

The power transfer of a line can also be increased (uprating) by increasing the allowable current (ampacity) in the line, provided the total power remains below the power limit in Equation 1.2-1 and voltage drop criteria are adhered to. This can be achieved by employing probabilistic rating techniques, using real-time monitoring methods, increasing the height of the line above ground (increasing the design temperature of the line), or by changing the conductor on the line. High-temperature, low-sag conductors can operate up to above 200°C while not causing the conductor to sag below the allowable amount. Note that these conductors are not low-resistance conductors but rather low-sag conductors. These issues are addressed in Chapter 2.

1.2.2 Standing Waves

The lumped parameter networks used for representing a transmission line are approximations of a system with distributed resistance, inductance and capacitance. They are adequate for steady-state analysis of the voltages and currents at the terminations. However, if the voltage and current profiles along the length of the line are to be analyzed, the distributed nature of the line components has to be taken into account. This analysis can be found in any good text on transmission line theory or electromagnetics (Guile and Paterson 1977; Kraus 1953) and it shows that electricity is transmitted as a travelling wave. In steady-state ac conditions, this gives rise to a standing wave along the length of the line.

A standing wave is the envelope of the variation of the voltage or current with line length. If the line is terminated in its characteristic impedance, the voltage and current are constant. If the load is different from the characteristic impedance, the standing wave has a sinusoidal-like variation, with the distance between peaks or troughs being half of the power frequency wavelength. The distance from a peak to a trough is a quarter of a wavelength. A quarter of a wavelength is 1500 km at 50 Hz and 1250 km at 60 Hz, and the issue becomes very important when line lengths exceed about 700 km. Under normal operation, on a long radial line, there can be a significant difference in voltage between sending and receiving ends. This is one of the reasons that we have to design for temporary overvoltages, which are limited-duration power frequency voltages that can exceed the maximum ac voltage for which the line is designed. This issue is also discussed in Section 3.2.4 under "Ferranti Effect."

1.2.3 Transients

Lightning and switching operations produce transients that propagate along the line. They experience reflections at the terminations, and depending on the reflection coefficient, there may be an increase or a decrease of the total voltage on the line. The resistance of the line causes attenuation of the travelling waves, and where the transient voltage causes the line to go into corona, there is additional loss and attenuation. The effects of lightning and switching transients on line insulation are discussed in Chapters 5 and 6.

1.3 ENVIRONMENTAL CONSIDERATIONS

1.3.1 The Impact of a Line on the Environment

Visual impact is the most obvious intrusion that a transmission line makes into the environment. There is an onus on designers and surveyors to ensure that line design and routing are as least intrusive as possible, and that the route avoids environmentally-sensitive areas wherever possible (see Figure 1.3-1). Regulatory and legislative issues associated with line characteristics and siting are dealt with in Section 1.6 below.

The impact of a line on wildlife also needs careful consideration. Several bird species find the line structures ideal places for perching and nesting. Utilities have designed ingenious structures to either make the towers undesirable to birds for perching and nesting or have adapted their structures to encourage nesting and perching at positions where there will be no material hindrance to the normal operation of the line (see Figure 1.3-2) (Van Rooyan et al. 2003; Van Rooyan 2004; Vosloo and Van Rooyan 2001). Section 12.16 also addresses bird interactions with transmission lines.

Figure 1.3-1 Environmentally-sensitive transmission line tower structure. Architect: RFR and Gustavson. (Courtesy RTE).

The electric field at the conductor surfaces can cause the generation of corona and audible noise as well as radio and television interference. In addition to the high nuisance value to residents close to the line, the radio frequency noise may render carrier communication on the conductors useless. Chapters 8-11 cover these issues in detail.

Epidemiological studies conducted over the last 30 years have suggested that the electric and magnetic fields associated with power lines may cause childhood cancers. This is a very controversial topic, and despite the fact that medical scientists have not identified a mechanism associated with the field magnitudes typical of power lines, most regulatory bodies have adopted a prudent avoidance or cautious approach by setting appropriate magnitudes at the borders of the right-of-way. In general, permission to build new lines that do not conform to this approach is unlikely to be granted. Chapter 7 addresses the methods of calculating these fields, suggests mitigation methods, and reviews the literature on the health effects.

1.3.2 The Impact of the Environment on a Line

Environmental pollution is the most obvious manner in which the environment influences the performance of a line. Airborne pollution is deposited on the surfaces of the support insulation, and if this becomes conducting through condensation or light rain, a leakage current flows over the insulator surface. This current causes partial drying and local arcing, which can lead to complete flashover of the insulator. On the other hand, strong winds and/or heavy rain can inhibit the deposition of pollution and promote natural cleaning, thereby preventing the formation of a conducting layer on the insulator surfaces. Snow and ice also deposit on insulator surfaces and lead to a deterioration in performance. The design and selection of insulation to suit particular environments are complex issues. Chapter 4 presents the relevant background material, as well as practical approaches to address these issues.

Figure 1.3-2 "Bird guards" on a transmission tower positioned above the insulators (courtesy Eskom).

Ice also accumulates around conductors in severe weather, and the additional mechanical loading can cause towers to collapse. This phenomena caused very serious power outages in Quebec in 1998 (Hydro-Québec TranÉnergie 1998a and 1998b; Milton and Bourque 1999).

Lightning is responsible for very-high-voltage travelling waves on transmission lines. The containment and dissipation of these waves require careful design of the line and the earthing systems. Chapter 6 addresses the theory and modelling of lightning phenomena on power lines, and Chapter 3 suggests practical approaches for the design of lines where lightning is an issue.

The electric strength of air and of insulator surfaces in air varies with air density and hence inversely with altitude. Correction factors have to be applied in the design of insulation for altitudes above approximately 500 m. These factors are discussed for power frequency, lightning and switching voltage waveforms in Chapters 4-6.

Finally the interaction of wildlife, particularly birds, with power lines has to be considered. Many bird species choose to perch and nest on transmission-line towers. Their excreta is conducting and, if it sufficiently bridges the air gap between the line conductor and the tower, an immediate flashover may occur. If their excreta sufficiently pollutes the insulator, a flashover may occur in time. A variety of measures are available to discourage birds from perching on the towers at positions close to the insulators (see Figure 1.3-2), and are discussed further in Section 12.16.

Improving the integration of lines into their operating environment can lead to improved line performance. As shown in Figure 1.3-3, Eskom reported decreases in line faults over a six-year period in the late 1990s and early 2000s. The company attributed this improved performance to—

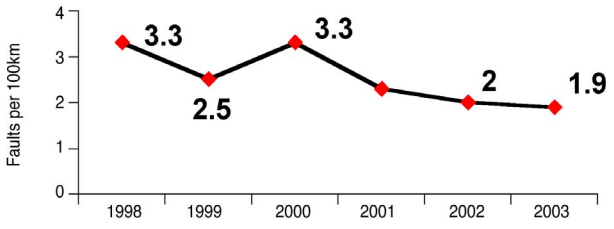

Figure 1.3-3 Line faults on Eskom transmission network showing the reduction as a result of intervention strategies (Naidoo et al. 2004).

among other things—the use of firebreaks for the management of planned fires on the right-of-way (servitude), installation of bird guards, and improved right-of-way maintenance programs (Naidoo et al. 2004).

1.4 TRENDS IN THE ELECTRICITY SUPPLY INDUSTRY

As the electricity supply industry grew in the middle of the twentieth century, it developed as a vertically integrated structure, comprising the major components of generation, transmission, and distribution. Since the late 1980s, however, the industry has undergone a process of deregulation and the associated unbundling of generation, transmission, distribution, and retail services. The drive in recent years has been to restructure the industry as a horizontally integrated industry—with the components of generation, transmission, and distribution being independent industries, and with further subdivisions within each of the component industries.

Deregulation, in turn, has brought about a number of developments, including a lack of coordinated network planning to meet load, rapid increases in wholesale transactions, changes in grid flows and increased grid congestion, and low levels of infrastructure investment.

In addition, in recent years, the industry has also witnessed a number of other important trends, including an aging infrastructure, lack of investment in maintenance, increased legal and environmental requirements and high costs of rights-of-way, and growing needs for grid security.

This section explores these trends by looking at their impacts on the three areas of the electricity supply industry: generation, transmission, and distribution.

1.4.1 Generation

Lack of Coordinated Planning

Under deregulation, the separation of generation and transmission entities into independent companies has had a negative impact on planning. Previously, under the vertically integrated structure, companies owning both generation and transmission could coordinate long-term planning for growth in generation capabilities with investment in transmission capacity. Likewise, companies could coordinate planned outages to conduct maintenance.

Today new generation is permitted to enter the market as desired. Normally transmission companies are not allowed to refuse access to any new generator, irrespective of where they wish to connect to the grid. There is also normally no requirement of the generating company to provide baseload or peaking power or auxiliary services.

In the late 1990s, the trend in the U.S. was to place "peaking" gas turbines at the intersection of natural gas pipelines and the transmission network. The rules of the market encouraged such investments. This generation can be installed and placed in operation within as little as nine months (whereas large coal-fired generation can take some ten years from conception to full generation). In the early 2000s, the rules of the market have matured, and also the price of natural gas has risen to a point where this practice is receiving much tighter review.

The lack of coordinated planning has meant that, in Europe for example, there is no obligation from any company to ensure security of supply. There is a lack of baseload generation due to the long payback periods and high initial cost. The benefits offered to renewable generation have resulted in most generation companies opting for wind generation, so much so that at least 15 GW is planned in Europe over the next few years. This has an adverse effect on grid operation due to the intermittent nature of this energy source.

For transmission company planners, the requirement to accept any generation at any part of the grid (requiring quotes within two weeks) has led to planners spending most of their time preparing quotations for the prospective generators. Grid designs have to be radically altered to allow for the new location of plants never before envisaged.

Load Growth

One effect of deregulation, and the separation of generation and transmission companies, is the decreasing ability to plan to meet loads. For example, in the United States, load growth from 2001 to 2002 was 2.8%, and from 2002 to 2003, it was 1.1% (EEI 2004). As noted below in Section 1.4.2, investment in transmission infrastructure, which is expected to average 0.5% per annum over the next 10 years, will be inadequate to meet this anticipated load.

In addition, the lack of coordinated planning between generation and transmission means that there are fewer capabilities for meeting daily peak loads. Figure 1.4-1 shows a

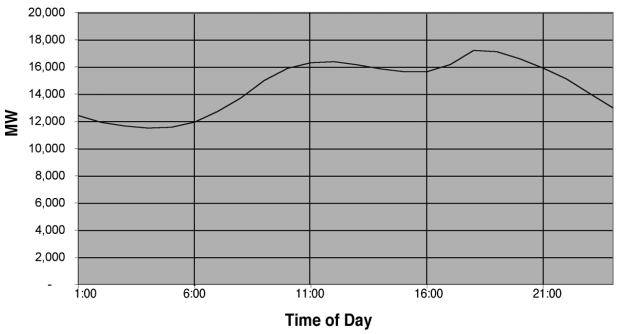

Figure 1.4-1 Typical daily load curve.

typical daily load curve. This is an aggregated load profile for 24 hours for the New England Independent System Operator (ISO) in the U.S. It shows the characteristic two daily peaks and the late-night trough. The best utilization of load would be to flatten the peaks and utilize 100% of line capacity 100% of the time. Previously, generation and transmission facilities were typically planned in unison to meet peak demands. However, with deregulation, and the creation of independent generation and transmission companies, there is no central coordination of measures to control peak load.

Figure 1.4-2 shows load factor as a percentage of the year. Load factor plays a major role in decisions with respect to the voltage of a particular network and also the networks' load-carrying capability. As a result, it is a key factor in the design of a network. Traditionally, load factor could be improved in several ways, including moving generation closer to loads or encouraging customers to change electricity usage patterns through demand-side management. However, under deregulation, generation companies have had little incentive to undertake steps to control load, and transmission companies have no control over the load factor. In an ideal world, the load factor would be flat, with the line running at 100% of load for 100% of the year. Running below 100% of load translates into unused or untapped capacity.

1.4.2 Transmission

Transmission companies are generally strictly regulated, because they are, by nature, monopolies. They plan and maintain networks according to established regulation. Transmission companies have been further divided into wires businesses and system operators, which are normally independent. The system operators are required to ensure that the network is stable under all operating conditions.

Initially, one impact of trading for transmission companies was to cause them to cut operating costs by outsourcing all engineering skills. This outsourcing led to a large reduction in skilled engineers within transmission companies (especially in the U.S.). The trend has since altered with utilities realizing the need to be informed buyers.

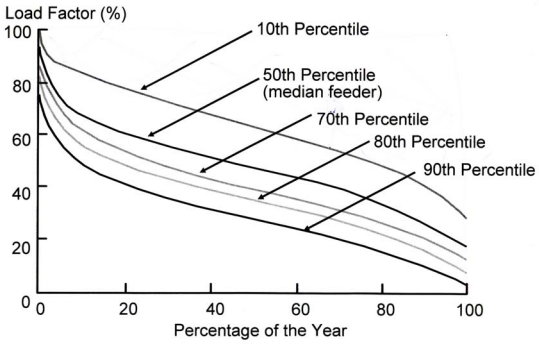

Figure 1.4-2 Feeder load duration estimates.

In North America, ISOs were formed under deregulation to operate the large control regions of the North American Electric Reliability Council (NERC). As of the writing of this book, there is discussion of forming Regional Transmission Operators (RTOs), which would have responsibility for overall system planning and coordination of generation and transmission planning.

Trading Practices

A further complication has been the introduction of traders who purchase from generators and sell to distributors or individual customers. The price traded can vary every 30 minutes, in some cases, and depend on the supply and demand.

Energy industry trading practices have forced system operators to push the networks to extremes never before thought possible. For example, from 1997 to 2001, the transaction volume in several NERC control regions in North America increased by more than 200%. Some large energy companies participated in as many transactions in an hour as they had once conducted in a day (EPRI 2001). This increase in volume is due to the high cost per MW that is realized in times of shortage. Amounts of $10,000 (USD) per MWh in some areas of the world are not uncommon. The high cost leads operators and transmission companies to attempt to increase power flow as much as possible. Attempts to increase power flow, coupled with the lack of skills in the companies, have been linked, in some cases, to blackouts in the U.S., Europe, and South America in recent years—which is discussed below.

One measure of the impact of deregulation—and the associated lack of coordinated network planning—is the current state of Transmission Loading Relief (TLR). As customers and generation companies contract to provide power, they may discover that the transmission network is not able to provide the required transport due to bottlenecks or network congestion. Figure 1.4-3 shows the rising

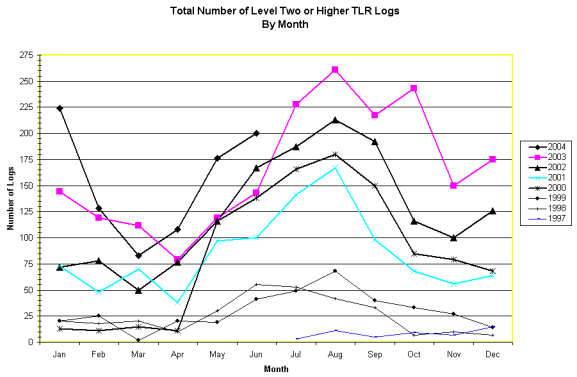

Figure 1.4-3 Transmission Loading Relief calls, Level 2 or higher, in North America, 1997-2004 (NERC 2004).

number of level-two or higher TLRs on the North American grid. This trend reflects the increasing inability of the transmission system, as built today, to accommodate open markets.

Grid Flows

Of major interest is the change in load flows as a result of the changing generation pattern. This change has resulted in some lines being overloaded, and others being under capacity. To deal with overloading, for example, in England, the National Grid first converted their transmission-line conductors from ACSR (Aluminium Conductor Steel Reinforced) to AAAC (All Aluminium Alloy Conductor), and then later to GTACSR (Gapped Thermal resistant Aluminium Conductor Steel Reinforced) conductors.

Figure 1.4-4 illustrates how the changing generation patterns following deregulation of the industry in England have led to a far greater flow from north to south and far less from east to west. The change in flow has resulted in lines running from north to south being overloaded, and lines running from east to west being underutilized. In addition, the rapid change of the generation pattern has meant that the response time that utilities have to deal with the situation has been reduced from approximately 10 to 3 years.

A similar situation occurs on the U.S./Canadian border. Traditionally, the trade has been predominantly in a north-to-south direction, utilizing the Canadian hydroelectric and nuclear generation capabilities. However, on occasion, there have also been significant flows in a south-to-north direction, particularly into Ontario (Barrie et al. 2003).

Investment in Infrastructure

The deregulation of the industry has also meant that now many different companies are owners of transmission grids. These companies are mainly focused on profit and increasing shareholder wealth. Many transmission grids are owned by companies that are not resident in the same country.

The result of these developments is that some transmission companies would rather increase utilization of the current assets, and thereby increase profit, than invest in new assets with long break-even periods and low initial returns.

Also delaying investment in transmission assets are the environmental and legal requirements for obtaining rights-of-way (servitudes), which result in long delays and high costs (see Section 1.6). In Europe, it may take 20 years to obtain the rights to build a transmission line. In the U.S., legal costs can exceed the cost of the line construction. Together with the high public profile (often negative) associated with obtaining the rights to build lines, these factors have resulted in under-investment in transmission networks over the past 20 years. These factors make it more attractive to add new lines in existing corridors, upgrade existing

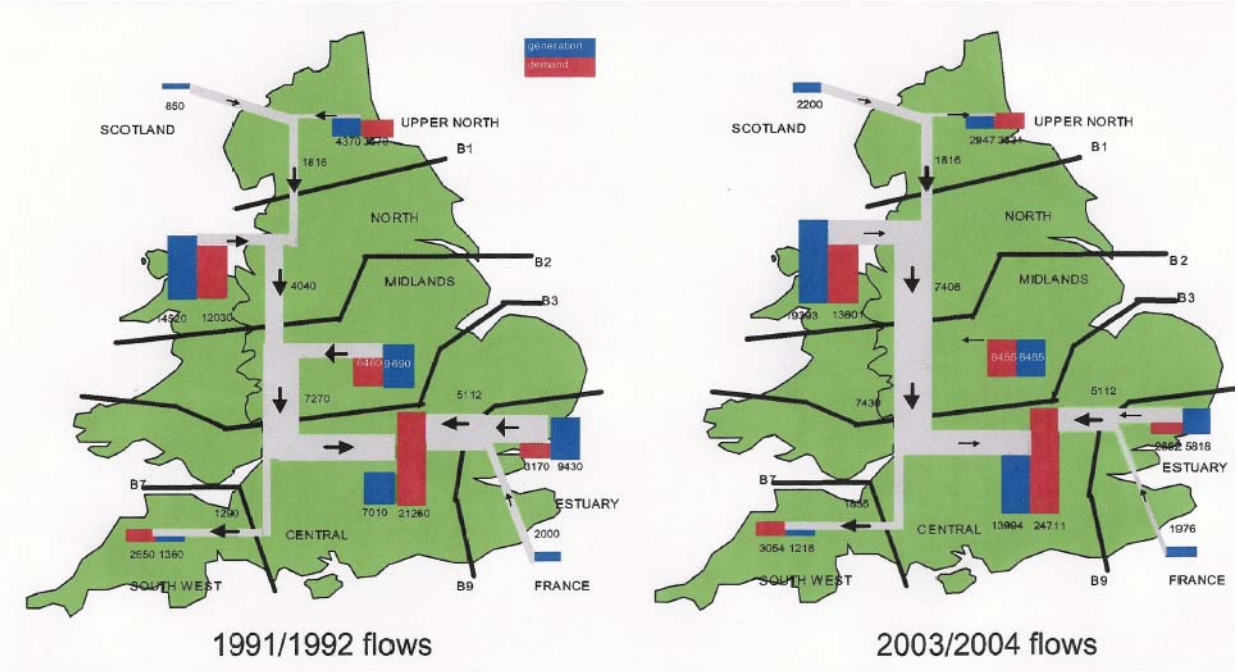

Figure 1.4-4 Changing flows in the UK network (CIGRE 2003).

lines, and even plan converting existing ac lines into dc lines in order to increase power transmission capabilities.

Figure 1.4-5 indicates the levels of capital invested in the U.S. transmission system as a percentage of U.S. electricity revenues. Of note is that the investment in the 1990s was about 12% of revenues, which is less than that experienced in the Great Depression in that country. An upward trend from 2002 to 2020 is envisaged but may not occur.

There are a few large-scale consequences relating to a lack of planned investment in transmission: In many developing countries, investment in transmission infrastructure is not meeting the massive growth in electricity demand (due to large-scale industrialization), and consequently networks are stretched. In addition, in the U.S., for example, from 1988 to 1998, total electricity demand rose by nearly 30%, but the capacity of the nation's transmission network grew by only 15%. Figure 1.4-6 shows the growth of system peak demand compared to the decline in transmission investment in the U.S. during the 1990s. The problem here is not so much a lack of planning, but rather a lack of incentives to investment in new transmission, coupled with a very lengthy and difficult process needed to secure rights-of-way.

For the future, this disparity is expected to increase—with demand anticipated to grow by 20% over the next 10 years, while the transmission system is planned to grow by only 3.5%.

Most developed countries have experienced, and are expecting to see, only limited growth in their transmission systems. For example, Figure 1.4-7 shows actual and projected increases in North American transmission circuit miles over the next 10 years. The per annum average increase in lines is 0.5%. In the U.K., transmission network expansion during the 1990s increased at about 0.5% per year. At the time of the writing of this book, no significant network expansion is being planned in England or Wales (Hoffmann 2004). In Australia, kilometers of transmission lines above 220 kV have grown about 1-2% per year from 1998 to 2002 (Gillespie 2004).

On the other hand, some developing countries are seeing higher levels of expansion. For example, in Thailand, lines above 230 kV grew about 7% in 1998 and 1999 (Booranasantigul 2004). In Brazil, expansion of transmission lines above 230 kV grew by about 17% from 1999 to 2003, and is anticipated to increase by about 19% from 2004 to 2008 (Esmeraldo 2004).

In sum, where there is a disparity between increasing electricity demand and declining investment in the transmission infrastructure, the system is, and will continue to be, inadequate to operate as needed.

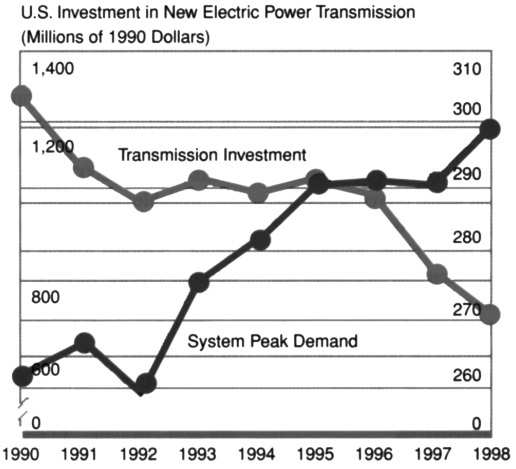

Figure 1.4-6 U.S. investment in new electric power transmission (Shahidehpour 2004).

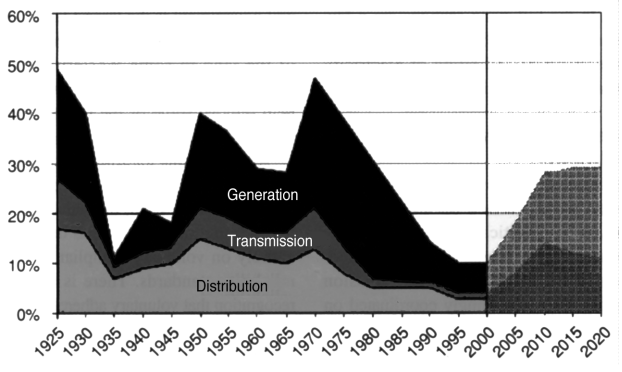

Figure 1.4-5 Capital invested as a percentage of electricity revenues (Shahidehpour 2004).

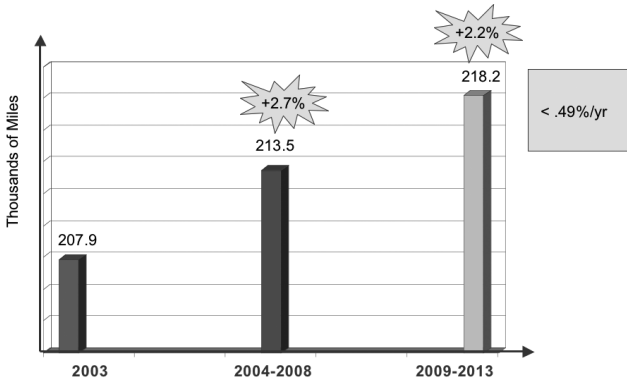

Figure 1.4-7 Projected growth in North American transmission (> 230 kV) (NERC 2004).

One offshoot of the lack of substantial capital investment in new transmission capacity is that some transmission companies, when required to add capacity, are doing so incrementally. This trend has spurred interest in transmission uprating of existing lines, which is described in Chapter 14. A similar situation pertains in Europe and most industrialized countries.

Maintenance

As noted in Section 1.1.1, the major expansion of the transmission network in the U.S. occurred in the 1950s to 1970s. Figure 1.4-8 shows the addition of ac circuit miles during this period. As a result, the bulk of the transmission assets in operation today have been in operation for 35 or more years, and are approaching or have exceeded their typical design life of 40 years.

Given this aging infrastructure, one might expect to see a focus in the industry on life extension of transmission assets. However, in recent years, there has been a steady decline in maintenance spending for transmission systems. Figure 1.4-9 shows the total transmission maintenance dollars spent in the U.S. during the 1990s and through 2002—a decline of about 20.5% over the 11 years. Figure 1.4-10 shows transmission maintenance spending in the U.S. in dollars per MWh sold.

Declining maintenance spending has several important implications. First, obviously, failure to adequately maintain lines, particularly with the current aging infrastructure, may cause a significant deterioration of the reliability of the system. Second, given the decreased levels of maintenance, it is important to design new lines in ways that require less maintenance.

Outages

The loss of transmission line power through an outage indicates the pivotal role that electricity transmission plays in world economies. Figure 1.4-11 provides a snapshot of recent outages around the world. At the time of the writing of this book, the largest blackout in North American history occurred in August 2003 in the Northeast U.S. and Canada. The outage affected approximately 50 million people in eight states and one province, and resulted in $6 billion of economic losses in goods and services ((U. S. DOE 2003, 2004; U. S.–Canada Power System Outage Task Force 2003).

1.4.3 Distribution

The distribution business has been split into two distinct parts, the wires business and the retail business. The wires business, responsible for the design, maintenance and, in some cases, the operation of the network, is normally strictly regulated in a similar manner to the transmission companies'. The retail business offers the customers many different types of product. Customers can choose the

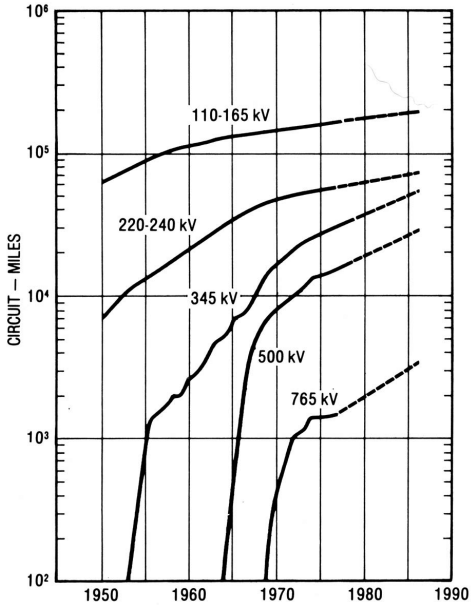

Figure 1.4-8 Circuit miles of overhead ac transmission lines in the United States (EPRI 1982).

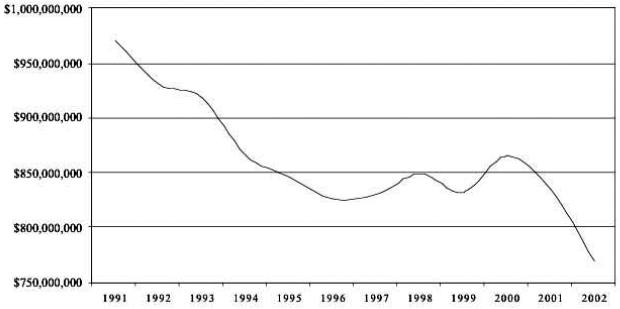

Figure 1.4-9 Transmission maintenance spending in the U.S., in total dollars, adjusted for inflation.

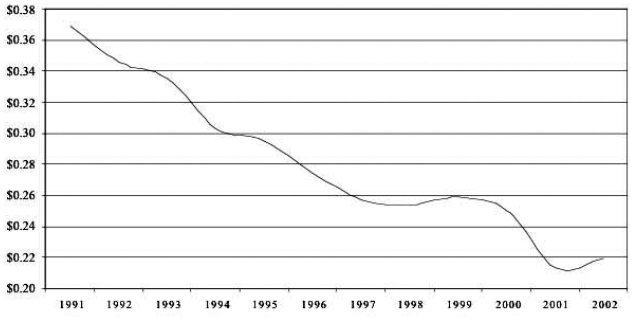

Figure 1.4-10 Transmission maintenance spending in the U.S., in dollars per MWh sold, adjusted for inflation.

retailer that they wish to take supply from depending on their needs. There is large competition between retailers, and this generally results in a lower cost.

The impact of this split on the distribution business was initially similar to the transmission industries with the outsourcing of technical staff. This trend has also begun to change. The advent of the retailers has led to wire companies being required to provide different products. This trend includes varying types of metering having to be used to accommodate the tariff types offered (e.g., Time-of-Use), as well as having to accommodate the different power flows on the network depending on customer response to the tariff options.

1.4.4 Overall Impact

Although much of the impact mentioned above appears to be negative, it is mainly as a result of the wires business not being able to respond rapidly or to fully understand the impact of the deregulation process. However, recent developments have resulted in the industry reviewing certain practices and strategies to counteract the negative effects experienced to date. This includes the initiatives of the U.S. government to increase investment in transmission infrastructure. In time, it is expected that the skills and operating practices will adequately meet the trading and customer requirements of the industry, and result in a more cost reflective service and possibly lower energy cost for customers.

1.5 FUTURE DIRECTION OF THE ELECTRICITY SUPPLY INDUSTRY

In response to the deregulation, organizations such as CIGRE and the IEEE have embarked on specific actions to provide guidance to the electricity supply industry in the face of future challenges.

1.5.1 Technical Strategies

The following strategies have been specifically identified as important fields of research in the future.

Analysis of Re-regulated Industry

This analysis will take place in three areas.

1. **Restructuring and Reliability.** The first area of study is the impact of the electricity supply industry restructuring on network reliability and loading. This realm explores the effect of competitive tariffs on load flows,

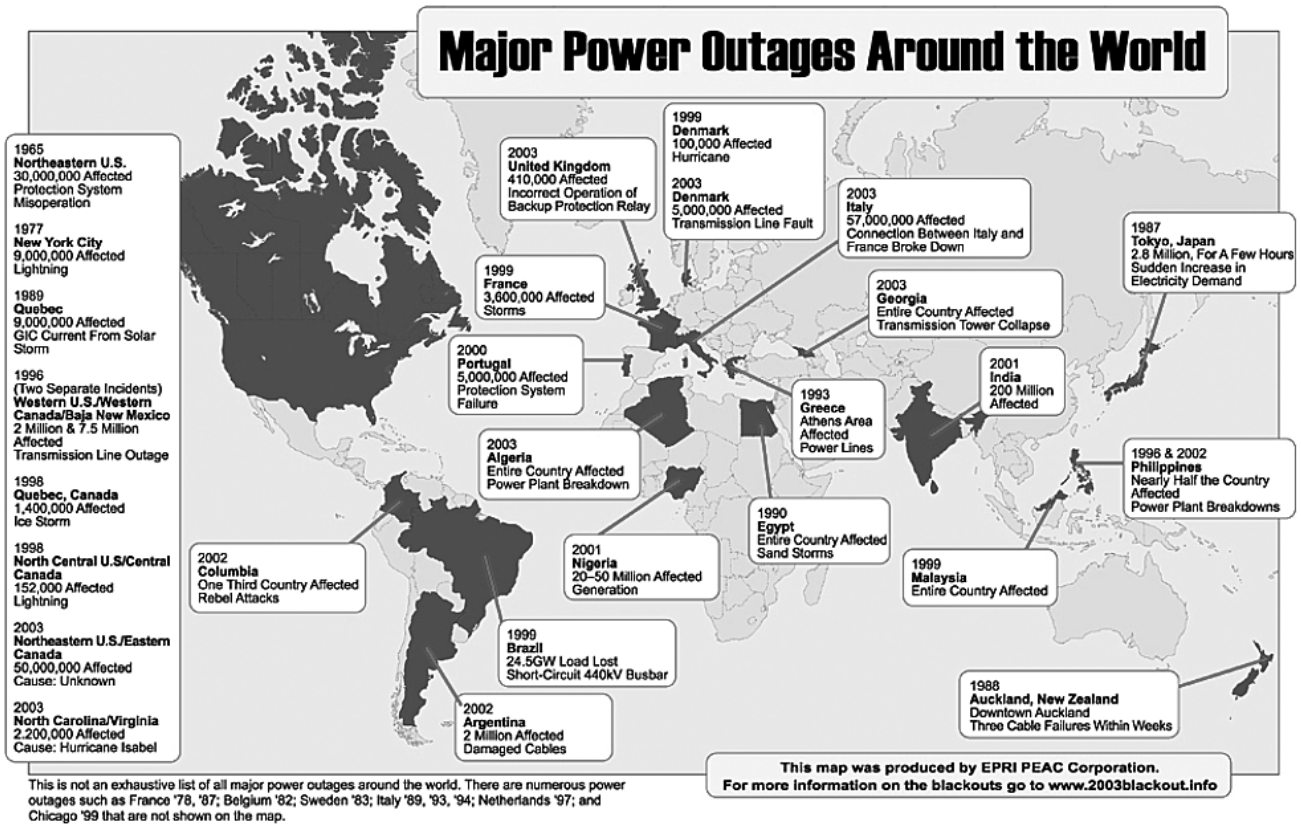

Figure 1.4-11 Major power outages around the world (EPRI 2004).

the resulting increased utilization of assets, as well as the potential catastrophic failures that can result once assets fault under high load transfer conditions. Examples include the blackouts in the Northeast U.S. and Canada, in Denmark, and to a lesser extent in England. This study also includes the need to build large interconnectors in Europe at the transmission level. At present, the inability to build transmission lines has forced the increased focus on cables.

2. **Distributed Generation and Storage.** The second area of study is to investigate the impact of dispersed generation and storage on the electricity supply industry. This area involves the advent of large-scale renewable (mainly wind) generators in Europe and the complexity of managing this type of generation when it becomes more than 20% of the total installed capacity. A further study will be undertaken on the ability of the deregulated environment to ensure security of supply (adequate generation) especially in Europe.
3. **Environmental Impacts.** The third area of study is the analysis of the impact of environmental issues on the industry (EMC, EMF, audible noise, visual impact, material recycling). An example of this study is the requirement to perform life-cycle assessment of each component in the network. This involves, for example in transmission lines, the evaluation of the impact of bauxite mining on the production of aluminium conductors.

1.5.2 Specific Issues to be Addressed

System Development

- There are conflicting needs relating to the electricity market and those of network reliability. The challenge is to meet both needs without jeopardizing one another.
- The other main area of focus is that of security of supply. The rules laid down by regulators and incentives offered by governments will determine the type of generation installed. For example, the large incentives for renewable power have resulted in the late 1990s and early 2000s in many GW of wind power being installed in Northern Europe.
- Electricity trading across many countries and large geographical areas, such as from Russia to England, leads to many challenges relating to the transfer capability of the network as well as system dynamics. This also involves studies related to removing the system congestion caused by power flowing in directions very different from that originally planned.
- There is also a need to determine the best manner in which to meet the need for high generation demand in developing countries.
- The developing countries also have sparse grids and loads remote from the closest supply point. The best method to supply these remote loads will also be studied.

System Operation

- The advent of the electricity trading market beyond geographical boundaries has implied that there is little meaning to the historical national grid. There is a need to ensure processes are in place to maintain optimum operation across national boundaries and to operate on an international basis rather than a national basis.
- The short-term generator shortages brought about by the lack of base generation will need innovative solutions to ensure the quality of supply is maintained.
- Operation of renewable and dispersed generation will require that different types of characteristics be studied.
- At the other end of the market, the customer demands are becoming increasingly severe, especially as customers move into the "digital society."
- The need to integrate the information and communication technology into the operations of the network is another field that will be studied. This field includes the use of the Internet to convey real-time rating data of circuits. Operators will need to determine the optimum level of information that is required to perform successfully.

Technology

- Technology developments will focus on development in materials that could affect breaker, transformer, generator, and even conductor design. These developments should, in turn, lead to components requiring less maintenance.
- The technology relating to control and protection engineering is developing extremely fast. There is also integration between the two areas. These areas need to be managed to ensure the important data and decisions made in real time are not jeopardized.
- The focus on HVDC will be intensified as converter technologies become more reliable and less costly. HVDC offers considerable network stability and security advantages over ac. These advantages have risen in importance as a result of deregulation.
- The new types of technology will also have to consider the environmental impacts at all stages of manufacture. One key driver has been the desire of the public to have transmission networks undergrounded. At this time, the costs of undergrounding are the biggest problem. Further, while the pubic wants an undergrounded system, they are not prepared to pay for it. In the interim, it is predicted that the industry will see new lines being a combination of overhead and underground technologies. This approach brings with it many new challenges—most of them involving changing network impedances and the associated inability of network protection to have complete visibility down the circuit. The transmis-

sion points between overhead and underground transmission also need further refinement.

- Transmission technologies including GIL (Gas-Insulated Lines) and HTSC (High-Temperature Superconducting) systems are starting to make an impact. GIL has been around for some 30 years, with the first systems being installed in 1974 in Germany, spreading a few years later to Japan (Nonjima et al. 1998) and many other parts of the world. The significant advantages of this technology are that the capacity of a line can readily be four times greater than what can be achieved with cable technology (Nonjima et al. 1998) and, because the ducts can be mounted in tunnels or even buried, they are much less intrusive than overhead lines. The proximity of the ducts also means that the electric and magnetic fields are much more confined than is the case with overhead lines. The restriction on their use has largely been related to the fact that the insulating medium is SF_6 (sulfur hexafluoride) and this is costly and is one of the greenhouse gases. Recent developments using mixtures of N_2 with SF_6, in the ratio of 15-20% SF_6 to 85-80% N_2, have proved very successful and are likely to become widely used in the future for special applications (CIGRE 2004b).
- At the time of this writing, EPRI and DOE (U.S. Department of Energy) had just completed a demonstration of an HTSC cable at the Detroit Edison Frisbie Substation. Further, three new HTSC cable demonstrations are presently in various stages of design. With each new pilot, new ground is broken.
- Also at the time of this writing, there is considerable discussion of the "Hydrogen Economy." Predictions are that, in time, energy in the form of hydrogen will be transported to the point-of-use, where it will be converted into either electricity or heat. As this thinking, and the associated technology, matures, it will challenge the traditional ac transmission backbone that presently exists in all countries.

Network Maintenance

- The main focus relating to all components will be the determination of the best method of asset management to minimize maintenance cost. This area will include the accurate assessment of life-cycle costs and life-extension techniques. The key, however, is to make sure that experiences gained during the life assessment and life extension phase make their way back into future designs.
- With the environmental pressures prohibiting lines and other new interconnectors to be built, it is necessary to upgrade or uprate the particular circuit. This upgrading involves condition assessment of the assets, determination of their remaining life, and the capability of the assets to be upgraded.

Technical Training

- With the increased reduction in staff and the retrenchment of skilled experts, it is necessary to focus on retention of existing knowledge, as well as ensuring new developments and solutions to problems are readily accessible to the engineers who remain in the industry.

1.6 LEGISLATIVE AND REGULATORY ISSUES

1.6.1 Introduction

Environmental permitting is increasingly the "critical path" for transmission-line siting, construction, and operation. The siting and permitting of new electrical infrastructure, including generation and transmission projects, can be one of the most challenging and often frustrating assignments that a utility's engineering and environmental personnel may undertake. Changing political climates, expanding environmental issues, increasing public concern and involvement, and established precedence often underlie many environmental review processes. Utilities have a broad range of corporate experience in environmental permitting, with many that have not permitted any significant projects in the last decade and may be unaware of new and changing environmental issues and approaches. For a smooth and streamlined project permitting process, it is imperative that a project applicant (e.g., utility) is informed of what will be specifically required; how the process works; what are the interrelated permitting requirements; and what are the new, upcoming issues.

In the present deregulated environment, it is no longer desirable or possible for utilities to construct lines by expropriating property. In most countries, permission is required from numerous authorities. Public involvement is critical for success. In addition, stringent environmental impact studies also are a prerequisite for approval to construct or (in some cases) modify overhead lines. The time taken to obtain the necessary permits has been increasing over the past two decades. In the United States, project permitting may require up to 10 years. In Europe, it has now extended to 20 years. Typically, this timeline means that the staff who originally plan the line are not involved at the construction phase, so that the process requires strict documentation and ongoing communication. It also is possible that the legal fees and the purchase of the rights-of-way could be in excess of the line itself. These factors limit the effect of line optimization and reduce the advantages of over-design on the line. In this section, the process whereby the line right-of-way and permission to construct are obtained is referred to as the "permitting process."

The permitting process, of course, varies from country to country, and the relevant agencies and applications are not standard in all countries. However, many of the lessons learned and types of agencies involved are common to

many countries and utilities. CIGRE WG14 and WG15 (SC B2) have completed documents on environmental assessments as well as best consulting practices (CIGRE 1999; CIGRE 2004a).

This chapter uses examples from the United States, primarily because the majority of project delays, cancellations, and increased costs for a utility have been attributed to the permitting process. It is assumed that most other countries have parallel processes where some of these examples would apply.

The following sections outline the environmental permitting processes and challenges typically encountered during the siting and construction of a new high-voltage transmission line and ancillary facilities to assist utilities in better understanding and resolving some of the more prominent issues. While each agency and environmental review process may have a unique set of well-defined and discrete steps, the process is fundamentally consistent in function and goals across many of these agencies. Each process typically has four primary steps or phases:

1. The applicant (i.e., utility) contacts the authorizing agency and submits the proposed project information, usually in the form of a permit application, for agency review.
2. The agency performs a preliminary assessment of the project and may request input from other governmental entities and the public.
3. The agency (or third-party contractor) prepares the environmental documentation under an established framework.
4. The agency uses this documentation as a decision-making tool on whether to issue or deny a permit to construct and operate the proposed project.

Understanding the key points of this process is particularly important, given the complexities associated with the applicable regulatory or land management agency review procedures. Further, public acceptance of a project can be integral to minimizing costs and maintaining project schedules.

Regulatory requirements, permitting processes, review procedures, and public participation mechanisms vary by country, state, province, county, and local municipality. Because of this variability, the following procedural discussion, insight, and recommendations applicable to environmental permitting for overhead transmission lines are relatively general. Some specific references to processes required in the United States and Canada are provided as examples to further illustrate these actions.

This section is designed to provide direction specifically to project engineers and managers who are responsible for siting considerations and project planning. It is not intended to be a comprehensive summary for transmission-line siting and permitting, but rather, the following information highlights the regulatory framework and primary issues that may be encountered, so that the utility project manager and/or engineer can effectively interface with his/her environmental staff or consultant and better understand the environmental permitting requirements and ever-evolving "political climates" that often surround environmental issues. Ultimately, the project manager or engineer should have the applicable tools to develop a project-specific plan that incorporates a standard approach to problem resolution, acknowledging the variables associated with different projects and planning scenarios. Because power generation is obviously associated with power transmission, a number of the following discussions on environmental permitting apply to both processes.

Whether permitting a line involving national, international, state, or local entities, it is imperative to maintain a clear approach to communicating and coordinating with the applicable agencies responsible for permitting oversight and project authorization. Developing an appropriate strategy for interagency and intergovernmental coordination and consultation, in addition to public notification and interaction, is often critical to a successful environmental permitting process, and lays the foundation for the entire permitting effort. An environmental permitting strategy should be developed in sufficient detail to be incorporated into an overall estimate of project costs and an overall timeline for project planning, permitting, and construction. The following sections outline and discuss specific permitting requirements, approaches, and suggested methods to streamline these processes, particularly as they relate to proactive communication, coordination, and problem resolution.

1.6.2 Examples of Inadequate Planning

The majority of project delays, cancellations, and cost overruns can be attributed to a few factors, including:

- Not addressing changing and evolving project economics.
- Not allowing sufficient time for project permitting.
- Not following the applicable process or integrating other environmental requirements.
- Not meeting the established "purpose and need" identified for a specific project through either the proposed project or its associated alternatives.
- Not developing a thorough and complete project description for a proposed project.

A few examples of project failures or costly delays are provided to underscore the importance of

1. understanding the applicable environmental permitting process;

2. applying that knowledge to both short- and long-term project planning, in advance;
3. implementing proactive communication, both internally and externally; and
4. developing strategies for problem resolution, when warranted.

Permit Review for an International Interconnection
A proposed transmission line between the United States and Canada required both federal review and a Presidential Permit because of the associated international interconnection. The utility's failure to firmly establish all project components necessary from a systems perspective at the start of the environmental process resulted in the need for a supplemental environmental permitting document and a total of four years to complete the environmental review process. The costs associated with this project delay were "significant."

Authorization by Multiple Agencies
A 200-mile (322-km) transmission line in the United States required certification of need and approval of a route by a state Public Utility Commission. The line also would cross 5000 feet (1524 m) of federal land, necessitating compliance with the United States' National Environmental Policy Act (NEPA) prior to granting a right-of-way (ROW). Both state and federal regulations encourage a consolidated permitting process; however, the parties involved were reluctant to request a ROW from the federal agency prior to the state certificating a route. Because a ROW application was not submitted, there was no "trigger" to bring the federal agency into the state's review process. Thus, the NEPA process was initiated after the state process was completed, adding about 2.5 years to the overall review process.

Substation on Native Tribal Lands
A rural U.S. utility had proceeded with standard environmental permitting processes for a proposed expansion of an existing substation less than 2 acres in size on native tribal lands without checking to determine whether additional permitting review would be required because of the land status. The utility's failure to recognize the additional environmental permitting review process required for facilities located on native tribal lands resulted in a 3-year project delay. In South Africa, although there are no "tribal" lands, there are areas still very much under control of traditional leaders. Some of these leaders respect the formal political structures and others do not. It is essential, as in the case mentioned in the U.S., that permission be obtained from the traditional leader before continuing the line construction.

Transmission-Line Routing
A utility's proposed routing of two parallel, double-circuit 345-kV transmission lines failed to recognize the political sensitivity of a designated nature preserve (e.g., siting constraint) during the corridor analysis phase of the project. This oversight resulted in rerouting of both ROWs with increased costs for eight additional 45-degree turning structures.

Many of these problems can be avoided or minimized by understanding the process and pitfalls that may be encountered and planning accordingly, as discussed below.

1.6.3 Regulatory Framework and Process for Transmission-Line Permitting

The following steps outlined for project permitting delineate not only the basic process, but also integral strategies for each process and how they are typically implemented. The chronology of a specific environmental permitting process can be important; therefore, it may be critical to understand what step depends on another or when these project stages should be initiated.

Initial Permit Planning Process
Strategic Planning

Most utilities conduct early strategic planning as part of their load growth and system capacity management. Once it is determined that a new transmission line is required in the system, preliminary economic feasibility and project design begin. However, strategic planning, as it relates to the environmental permitting process, is often overlooked or viewed as being of secondary importance. Early strategic planning for the project-specific environmental review process can avoid significant effects on a project's schedule, costs, and ultimate success.

One important planning strategy is to become familiar with regulatory and land management requirements for siting on both public and private lands. Although a standard strategic plan may apply to a number of development scenarios, it is important to acknowledge the variables and adopt a flexible, dynamic plan. This approach can greatly aid project planning and environmental permitting review. With the increased difficulty of obtaining ROW on both private and public lands and the overlap of system configuration, facility design, ROW acquisition, and environmental permitting considerations, it is critical to have all four specialties involved in early strategic planning.

Determining Whether an Environmental Permit Process Applies

One of the first steps necessary for new or proposed projects is to determine whether a regulatory review is applicable to that project. A screening process is typically applied to determine whether a project warrants a full environmental review or may be "categorically excluded" from further analysis. Different authorizing agencies have different screening processes or thresholds for environmental review. The key to this step is to initiate early dialog with the responsible agencies to identify what these thresholds

are and to become familiar with the criteria that may apply to this decision.

Route Selection and ROW Siting

Route selection and ROW siting can be complex and controversial, encompassing issues such as land-use conflicts, resource effects, public perception, and interagency coordination and communication. Environmental permitting processes and project-specific needs can be varied and are often confusing, and they differ internationally, nationally, and locally. They also may vary among the same types of projects, depending on project-specific issues and the degree of public participation. These differences can result in a frustrating effort for utilities to understand what is expected, how to proceed, and what are the associated costs and time restrictions. Addressing or avoiding many of these issues or possible problems in ROW siting typically involves understanding the:

- current environmental permitting "climate,"
- repercussions of certain approaches that may be used to site and construct a line, and
- components to subsequently develop and implement a project-specific planning strategy that proactively addresses these issues.

This knowledge aids in developing an effective mechanism to accurately estimate associated siting and line construction costs, and in developing a practicable and logical project schedule.

For large-scale transmission line projects, a routing study or siting analysis is often appropriate to better identify applicable siting constraints and define project-related issues. However, even smaller projects benefit from preliminary route selection, based on a number of site-specific variables. A routing study may either delineate general, broad corridors for transmission-line placement, or it may examine a more site-specific routing network. The appropriate approach typically depends on the length or the ROW (i.e., relative size of the proposed project). Within these corridors or routing alignments, site-specific constraints or opportunities should be identified and mapped. Possible constraints generally range among economic considerations, regional electrical needs and reliability, engineering constraints, land ownership and management, land access issues, environmentally sensitive areas or features, extreme topography or surface cover, land-use restrictions, and environmental justice concerns. Opportunities may include existing linear ROWs, existing public easements, compatible land uses, and topographical features (or lack thereof).

The identification of these objectives, opportunities, or sensitive areas is critical in the advanced project review and planning effort, in order to maintain the estimated project budget and timeline. Project engineering typically examines possible construction and operational options from electrical feasibility, line constructability, and overall economic perspectives; however, examples of specific siting issues that can result in increased costs, if caught unaware, could include ROW alignments crossing or located adjacent to the following:

- Natural areas, wildlife refuges, or environmentally sensitive areas that have been designated with either public or private protection criteria.
- Wetland systems or water bodies, particularly if used by large numbers of resident or migrating birds.
- Unknown, significant archaeological features.
- Sensitive plant or wildlife species' locations or associated habitats.
- Existing residential, commercial, or recreational areas.
- Urban interfaces.
- Agricultural lands.
- Areas planned for future development that may be incompatible with a transmission line.

The relative sensitivity of each resource item identified as a project constraint during the corridor selection process is typically compiled and compared among the alternative corridors and ROW alignments. Different resources have varying sensitivity to the construction, operation, and maintenance activities associated with a transmission-line project. These data may be categorized by specific corridor segment, possibly leading to the identification of other alternative routes, if warranted. Based on these siting constraints and opportunities, an applicant-preferred route is established and evaluated according to the applicable permitting requirements. Land ownership, funding sources, and the regulatory oversight often determine the type and extent of these permitting requirements.

Regulatory Review Process

Role of the Utility or Permit Applicant

New transmission-line construction or rebuild of an existing line generally requires some level of environmental review, which may address a wide range of issues and concerns. The utility responsible for this construction or expansion would be the "applicant" in this process. The utility (or applicant) then would be directly coordinating with the applicable reviewing or authorizing agency for environmental permit application and approval.

Role of the Authorizing Agency

Permitting agencies vary depending on their respective roles (e.g., land management versus regulatory, lead versus cooperating), the type of project proposed, and the applicable permitting process involved. It is vital to understand which agency or other governing entity may be responsible

for the environmental permit review. In addition, knowing when and how to initiate discussions with these agencies is fundamentally important.

Communication between the utility and applicable agencies cannot be overemphasized. Communication, or lack of, is often one of the more critical elements of environmental review. Proactive communication generally results in greater conflict resolution; whereas, uncoordinated processes often result in adversarial situations. Agency communication is discussed in greater detail below.

Because the United States' NEPA process encompasses a number of different types of federal, state, and local agencies that may be involved in moderate to large transmission-line projects, this Act is used as a representative example. For this example, there is always a federal agency responsible for reviewing the project in accordance with a mandatory set of guidelines that apply to earth, biological, and human resources. This agency is referred to as the "lead agency." In larger, more complex projects, there also may be one or more "cooperating agencies" that may be involved with project review.

Whether an agency is a "regulatory" versus a "land management" agency has no direct bearing on the role that an agency fulfills for project review under NEPA. In the United States, examples of "regulatory agencies" that may be involved in transmission-line projects include the Department of Energy (DOE), Rural Utilities Service (RUS), Environmental Protection Agency (EPA), U.S. Army Corps of Engineers (USACE), U.S. Fish and Wildlife Service (USFWS), Federal Aviation Administration (FAA), Federal Highway Administration (FHA), and Bureau of Indian Affairs (BIA). All of these agencies could be involved with a transmission-line project in a regulatory role. Representative "land management agencies" include Bureau of Land Management (BLM), U.S. Army Corps of Engineers (USACE), Bureau of Reclamation (BuRec), U.S. Forest Service, USFWS, and Sovereign Native Tribal Nations. Additionally, federal power marketing agencies are often involved in environmental permitting review of a project, particularly for proposed interconnects.

Any of these regulatory, land management, and oversight agencies may act as a "lead" or "cooperating" agency during an environmental review process. It is important to distinguish which agencies may be associated with a proposed project, what their respective roles may be, and what type of communication process will work the best in order to streamline the permit review.

Public Involvement and Perception

Most utilities have developed a standard approach to public relations, given the typical customer-based needs and demands. However, certain topics associated with transmission-line construction and operation can be volatile and highly emotional. The public's interest in a proposed transmission-line project can greatly differ from that associated with a typical utility–customer relationship.

For many environmental review processes, there is a public input component. The opportunity for the public to participate in the siting and permitting of a transmission-line project may be formal or informal, depending on the process and size of the project. Historically, the public has had a significant role in transmission-line placement. Public knowledge and level of sophistication on environmental issues have greatly increased, and at times, a project's success may largely depend on the level of public involvement. Accordingly, public demands for effective and timely participation in the decision-making processes also have increased.

Key to a successful public review process is

- becoming informed of the associated issues,
- understanding the public process that may apply to specific project types, and
- initiating proactive dialog.

Frustrated citizens, when treated as adversaries, often result in legal appeals and litigation, but acknowledging the public as project participants often establishes more of a working relationship. Ensuring public needs are met may involve public notice, public scoping meetings, and opportunity for public comment on a project. Using the public review process for scoping a project can be a valuable tool for identifying public and agency stakeholders; setting the spatial (geographical) and temporal (time) boundaries of the study; identifying key concerns and issues; delineating available data for the analyses; defining a reasonable range of alternatives; and providing a flexible mechanism for project modifications, if warranted.

Creating a partnership with the public requires more than holding public hearings and providing documentation, however. One tool that often can be advantageous is the use of small, breakout groups during public meetings. These groups, typically led by a utility or agency representative, may:

- allow citizens who are not as likely to speak in a large group the opportunity to voice any concerns;
- minimize the potential for emotional and disrupting outbursts that often are structured to monopolize meeting times;
- categorize issues and concerns in an efficient manner; and
- steer the group toward constructive discussions.

For those environmental review processes that do not require public review or comment, it may benefit the utility and authorizing agency to continue to provide information on the proposed project and make available opportunities for public comment to ensure that partnerships are forged with the surrounding community and interested stakeholders. This approach may avoid or minimize controversy, legal challenges, and increased costs and time.

Environmental Permit Documentation and Report Production

A variety of processes, approaches, and report types apply to the documentation of an environmental permitting process. Typically, this step or project phase is considered a tool or mechanism to document a process or disclose anticipated effects from proposed project implementation. Project documentation can be both internal and external to utility staff.

Project Scope and Alternatives Development

Delineating the project scope is closely associated with defining the project's purpose and need, and directly leads to identifying potential environmental effects from project implementation. An important aspect of many environmental review processes is the development of viable project alternatives that are reviewed parallel in timing and level of detail to the applicant's proposed project. In conjunction with practicable project alternatives, the environmental review process also may require that the "alternatives considered but eliminated from detailed analysis" be delineated. No detailed impact assessment is completed on these unrealistic or improbable alternatives, but they often must be disclosed to demonstrate the range of alternatives that have been examined.

Environmental Review and Impacts Analyses

Integral to a project's environmental review and impacts analyses is identifying and compiling relevant interdisciplinary or resource-specific information that is commensurate with the project scope, the anticipated project effects, and the degree of public concern (i.e., project complexity and level of volatility). When the environmental impact review and analyses are being completed, existing information should be used to the extent possible and appropriate. This approach builds on work already completed, avoids redundancy, minimizes additional project costs and expanded schedule, and provides a coherent and logical record of the analytical and decision-making process. As part of this process, it should be examined whether any existing analyses or other environmental documentation either partially or fully analyzes parallel resource issues that can be applied to the proposed project.

The types of resources examined vary, based on the project type and size, its location or setting, and the regulatory framework required for that area. For some analyses, impact significance thresholds must be identified, such as required for the preparation of an Environmental Assessment (EA) under the federal NEPA process in the United States. In the event that any of these significance thresholds are, or are anticipated to be, exceeded, the permitting review must be then taken to the next level, requiring an expanded Environmental Impact Statement (EIS), which is substantially greater in detail, time required, and associated costs. This example emphasizes the importance of understanding the process prior to initiating the environmental review.

Analyzing and disclosing the environmental consequences of a project are the main components of most environmental review processes. These analyses cover a broad range of topics and resource issues, such as earth resources (e.g., air quality, geology, soils, water quality and quantity, palaeontology, minerals); biological resources (e.g., vegetation, wildlife, sensitive species, wetlands, noxious weeds); and human resources (e.g., socioeconomics, transportation, land use, cultural resources, noise, aesthetics). The intent of the environmental documentation effort is to provide decision-makers and often the public with an objective evaluation of environmental impacts, both beneficial and adverse, that would be anticipated from implementation of the proposed project and reasonable project alternatives.

Cumulative Effects

For some projects, combining what may be individually minor, but cumulatively major, effects of multiple actions over time may result in a significant level of impacts. Analyzing the cumulative effects from a proposed project can be frustrating, confusing, and variable. The confusion and variability often can be attributed to the different approaches followed by different authorizing agencies. Some agencies and review processes require a cumulative assessment; others do not. A standard definition of cumulative impacts is those effects caused by the combination of past, present, and reasonably foreseeable future actions. It is important to note that the impact area, or "domain," varies from resource to resource. For example, a cumulative effects area to be examined for air quality differs greatly from that identified for sensitive plants, which, in turn, differs from that identified for mobile terrestrial wildlife species. A strategy to streamline the cumulative assessment for a project would be to initiate early dialog with the authorizing agencies on the potential cumulative actions to include in the analyses, refine the cumulative effects domains to reasonable and management sizes, and acknowledge that the information should provide the reviewing agencies with a tool to make an informed

decision and not necessarily be a "perfect" and "all-encompassing" analysis of cumulative effects.

Mitigation vs. Committed Environmental Protection Measures

Measures to minimize potential impacts to resources from implementation of a proposed transmission-line project can vary. Most applicants are familiar with "mitigation measures," which are typically developed as part of the environmental review process to minimize short- and long-term effects. Mitigation measures are assembled after the impacts analyses. Another category is the development of "committed protection measures." The applicant or utility commits to implementing these measures as part of the proposed project, and the impacts analyses are conducted with these measures in place. Identifying and applying committed protection measures early in the process, as part of the proposed project, can be advantageous. Although the utility has committed to the costs of implementing certain measures, this approach typically

- reduces the level of impact analysis required,
- streamlines the environmental permitting review and associated schedule,
- minimizes the potential for agency and public opposition, and
- enhances the potential for project authorization.

A common question relative to implementing mitigation measures is whether "monitoring" can apply as mitigation. By definition, monitoring is not a form of mitigation. Monitoring can be used as a tool to determine the need for, or relative effectiveness of, mitigation. Examples may include short-term monitoring (e.g., 2 to 4 years) of noxious weeds along a ROW. Based on the results of monitoring, an agency may determine if additional mitigation is warranted. The disadvantage of developing and implementing a project monitoring plan can be the additional costs, although this is not applicable for all scenarios. The advantages of developing a monitoring plan is it:

- ensures the adequacy of the mitigation measures, which is typically the intent of the plan;
- facilitates the environmental permitting process with the authorizing agency;
- may advance the project schedule; and
- may actually reduce environmental review costs by avoiding the need to answer all unknown questions prior to project implementation in order to gain project approval.

The decision to include a monitoring plan in a permit application is project specific and requires weighing all factors. Where resources are not likely to be appreciably affected in the long term, and there is an opportunity to reclaim or mitigate environmental damage, an adaptive environmental management approach may be appropriate, using monitoring to identify future mitigative measures.

Administrative Procedures and Agency Decision Records

Authorizing agencies issue a decision record following the environmental review of a proposed transmission-line project that requires regulatory oversight. This decision record varies, depending on the regulatory process, applicable agency, and type of project. Decisions can take the form of a permit, an ROW grant, or a certificate of public convenience and necessity, as examples. Ultimately, the decision record determines how the project may or may not proceed and what stipulations would apply to project construction and operation, if authorized. Understanding how a decision can be appealed, what procedural steps are involved in an appeal, and who has standing to appeal a decision is important. Project appeals result in increased costs and timelines for a utility and may ultimately threaten a project proceeding.

Other Legislative Acts and How They Are Integrated

A number of supplementary regulatory Acts often apply to a project's permit review and authorization. Some of this ancillary legislation can be equally as exacting as the overall environmental permitting requirements. Representative examples of this type of legislation that apply directly to transmission-line projects include the United States' Clean Water Act, Endangered Species Act, and National Historic Preservation Act. The Migratory Bird Treaty Act also applies to projects in Canada, the United States, and Mexico. The Endangered Species Act and Migratory Bird Treaty Act are discussed further in Section 12.16.

Once again, strategic planning and communication are key. Knowledge of how additional Acts may apply to a project is essential. For example, the wetlands analysis under the Clean Water Act, the federally listed species' analysis (i.e., Biological Assessment) under the Endangered Species Act, and the archaeological clearances under the National Historic Preservation Act are all powerful legislative requirements that can dramatically affect a project's costs and schedule, if the utility's staff is unaware of what these supplemental reviews entail. Allowing for these types of analyses is discussed in greater detail in Section Primary Issues for Transmission-Line Permitting for primary permitting issues.

1.6.4 Primary Issues for Transmission-Line Permitting

Project Purpose and Need

If a project does not begin with a solid base, credibility can become compromised. The public may assert that there is

no need for a new transmission line. If the utility or applicant has not developed a basic, understandable explanation of the need for the project, it can negatively influence the entire review process. It also may be important to examine potential system alternatives to the line being proposed. This type of analysis is as important for the regulators as it is for the public, because it is typically a component of a facility siting review.

Communication

The importance of open communications and understanding between the utility proposing to build new or expand existing transmission facilities (i.e., the applicant) and the associated regulatory and land management agencies involved in this often complex and mandatory process cannot be overstated. Proactive communication is key among the utility's project managers, design engineers, and environmental staff; technical specialists or other consultants; agency personnel; and the public. Communication affects all components of a utility's strategic plan for line permitting. It is important to understand who is responsible for what task and how the associated processes interrelate. One planning strategy is to develop a communication network among the applicable stakeholders, with a project core team for continuity. The communication network can be developed, using appropriate pathways (both internally and externally) to facilitate information transfer among engineering, environmental, management, and technical resources.

Overcommitted Agency Staff

Timeframes required for environmental permit review and authorization can be long, often because of the increased demands on federal, state, provincial, and local agency staff. Many agencies are understaffed and cannot process the number of regulatory and land management reviews that are proposed within their jurisdiction in a timely manner, often resulting in project delays. Another issue for projects requiring agency permitting review, authorization, and oversight is referred to as the "loss of institutional memory." Rapid personnel turnovers within an agency can result in a change in approach and direction mid-project, sometimes causing project delays or additional costs. As a result, applicants need to proactively plan for insufficient staff availability and changes in agency personnel by using their knowledge of the process and established communication mechanisms to achieve their goals in spite of these barriers. In addition, in planning schedules and budgets, applicants must anticipate delays, expect staffing changes, and plan accordingly.

Interagency Coordination

Approval processes for transmission-line projects typically fall into two general categories: (1) those that review and approve the entire project, and (2) those that are designed to protect a sensitive resource, primarily during facility construction, although some predominant issues associated with transmission-line operation are beginning to emerge. Both types of approvals can occur at varying levels (e.g., federal, state, provincial, county, local), and frequently there is overlapping interest. Federal and state (or provincial) regulatory agencies in a given region have usually developed procedures over the past few decades to integrate their review and approval processes so that they may run concurrently, but it is important to note that these are independent processes. For some projects, through lack of planning and coordination, different regulatory processes may run sequentially, typically extending the project schedule and increasing project costs. Timelines can be complicated further if approvals are also required at the county or local level. Historically, sequential reviews and approvals have had disastrous consequences for a project. It can be critical for a utility applicant to take the lead in developing consultation and coordination among agencies.

Due to staff turnover or the lack of previous transmission-line projects in an area, it should be expected that the applicant's team will have to work with agency personnel who have no understanding or very limited understanding of transmission lines and the unique challenges that they present for design, construction, and operation. These challenges and project impediments can be overcome through an honest and professional effort to educate the agency staff as the project progresses, as emphasized for general communication strategies. Situations still exist where federal, state, and local regulations require different degrees of environmental review for a proposal. It is recommended that a planning meeting be held at the beginning of the environmental permitting process, where all responsible agencies are invited. Each agency's regulatory responsibilities can be reviewed, and a method can be developed to integrate these requirements into a project-specific permitting strategy. An interagency agreement developed at the start of the planning process also can aid in coordinating timelines and resolving disputes. While each agency still requires its unique environmental permit application, the applicant (utility) can develop complete and consistent application documentation with maximum efficiency.

Baseline Information Availability

An environmental review process is based on the review and analysis of interdisciplinary resource information from many fields and sources in order to disclose potential short- and long-term impacts from project implementation, and provide the authorizing agency with a decision-making tool. Problems arise when sufficient data or resource information to make informed impact conclusions are unavailable prior to permit application submittal and review. Different interagency requirements and timelines can result in conflicts, such as the need to obtain sufficient field data for a federal corridor analysis when the local permit-

ting process prevents land access for data collection until a ROW centerline has been delineated.

One approach to mitigate these problems is to develop suitable "environmental indicators" (comparable to economic indicators) to provide more consistent resource information. New tools, such as the use of geographic information systems (GIS), help to provide sufficient resource information and focus the analyses. Finally, communication among the authorizing agencies is vital to resolving disputes regarding approaches to data collection, land access, and chronology of the different environmental permitting timelines, as discussed above for interagency coordination.

Public Perception and Opposition

For a new transmission-line project to be successful, it is also critical for the project applicant to be prepared for the opposition that may be encountered. It should be expected that some members of the public and possibly some regulators may have difficulty accepting a new transmission line, primarily due to the size of the structures involved, the visual intrusion they pose, and the effects of the ROW on property values and land uses. Other issues also may be raised as a means of opposing a project, some of which may have merit and some of which may not. For example, electric and magnetic field (EMF) concerns may be raised for a 69-kV line. Although EMF effects would not typically apply to voltage classes 69 kV or lower, utility personnel must be aware of high-profile and potentially volatile issues and be prepared to discuss these types of issues with the regulatory and land management agencies, organizations, and the public. Regardless of the project team's personal opinion about the issues raised by agency staff or the public, the team must be prepared to respond to the concern in a professional manner and act in an educational role. With the advent of the Internet, opposition groups can organize with surprising speed, and they have access to other groups across the country that are opposing similar projects. These groups should be expected to share issues and information.

A common tactic of opposition groups is to keep raising new issues over an extended period of time in hopes that the project will be cancelled or approval denied. Issues identified by the opposition groups may expand, and addressing the specific concerns can become a "moving target" for a utility. If the applicant is prepared to respond to the range of issues that may be raised in its initial permit application or submittal, delays can be avoided. While most issues will be environmental in nature, many will address other aspects of the project. The environmental staff will need to work closely with the design, engineering, and ROW staff to cover the range of issues. It also can be very helpful if someone with transmission-line construction experience is available to the team. Each project team will have to determine exactly how these issues may apply to the unique geography and design of the line that is being proposed.

The old adage states that "all politics is local," and that can certainly hold true for transmission-line permitting. Local agencies, generally counties, have permitting authority over land use and zoning. A difficulty for local agencies reviewing a proposed transmission line that would cross their jurisdictions is that they may not receive any direct benefit from the line, improved reliability not withstanding. This fact may result in local agencies reflecting the opinions of their constituencies by opposing a project that has substantial regional benefits. Again, an applicant must be sensitive to the perception of disproportionate impacts without benefits, be ready to address the system-wide benefits of the new line, and be prepared to accommodate local concerns to the extent that they are practical. Involving local agencies early in the planning process can have significant benefits in reducing local opposition.

Project Rebuild and Undergrounding New Lines

Agency and public perception of proposed new transmission lines is often that they are unnecessary, that existing lines should be rebuilt versus new lines constructed, or if new lines are warranted, they should be undergrounded. Addressing these issues is closely associated with the discussion for better defining a project's purpose and need. Many recent projects have been rebuilds of lines that were constructed in the 1930s and 1940s. It is common for these projects to increase the voltage class from 69 kV to 115 kV or 230 kV, for example. There may be good design reasons why the existing ROW or ROW width cannot be used for the new project. Paralleling an existing route also may be undesirable for reliability, land-use, or environmental reasons. These design considerations should be clearly explained, with specific references to conditions in the proposed project area or the applicant's service territory. Regulators and the public alike also often request that a line, or portion of a line, be placed underground, assuming that such an installation is as simple as constructing a pipeline. Design limitations, cost implications, and increased environmental effects of underground construction should be identified and communicated among the stakeholders.

Controversial and High-profile Resource Issues

The range of issues and concerns that the public or regulators may raise concerning transmission lines is broad, and a utility should be prepared to deal with those issues that may apply to its proposed project before they are raised. In September 2001, EPRI published Technical Report No. 1005189 titled, *Communicating with the Public About Rights-of-Way: A Practitioner's Guide*. Chapter 4 of this report, "Identifying and Addressing Issues," presents a comprehensive discussion of issues that were identified in

a research survey, in order of their ranking by the respondents. These issues were grouped into four categories dealing with local, regional, and maintenance topics. The reader is encouraged to refer to this technical report for discussion of each of the subjects presented below.

Local Public Issues Associated with ROW Corridors

- Property values.
- Equity/fairness (i.e., those who must live next to the line versus those who benefit).
- Compensations for easements/tax implications.
- Use of eminent domain.
- Impacts of construction (erosion, soil compaction, and mixing).
- Future corridor maintenance (e.g., use of herbicides, tree-trimming).
- Impacts of corridor on agricultural uses.
- Restrictions on use of easements.
- Local zoning/permits.

Local Issues Associated with Power Lines

- Visual impact/aesthetic appearance of the towers/poles.
- Electromagnetic fields.
- Need for the line (e.g., use of conservation or distributed generation instead).
- Impact of the presence of towers/poles on agricultural use.
- Stray voltage/current effects on animals.
- Stray voltage/current effects on humans.
- Electrical safety.
- Electromagnetic interference with equipment.
- Noise.
- Proximity to schools/daycare centers.
- Chemically treated poles.
- Ozone/odor.

Regional Environmental/Cultural Issues

- Impacts on the viewshed (scenic aesthetics).
- River/stream crossings.
- Wetland impacts.
- Impacts on archeological/historic sites.
- Co-location with other facilities (e.g., gas pipelines, railroads).
- Impacts on endangered species.
- Pesticide use.
- Biodiversity/habitat fragmentation.
- Avian interactions.
- Local zoning/permits.
- Environmental justice (relative impact on low-income or minority populations).

Issues Associated with ROW Maintenance

- Too much tree trimming/clearing within ROW.
- Illegal trespass (e.g., snowmobile, ATV use by outside parties).
- Removal/trimming of danger trees outside of ROW.
- Use of herbicides.
- Maintenance and use of access roads/routes (e.g., culverts, stream crossings, fences, gates).
- Method of herbicide application.
- Too little mowing.
- Pole/transformer maintenance (e.g., painting, replacement).
- Too little tree trimming/clearing within ROW.
- Too much mowing.

The following issues can be high-profile concerns associated with transmission-line permitting, and these topics are also often the catalyst for organized project opposition during the permitting review process. The following discussion includes a brief description of these issues and suggested approaches to streamlining a utility's response to them.

EMF

EMF (electric and magnetic fields) effects have been issues in transmission-line permitting for more than 30 years. Millions of dollars have been spent to investigate potential adverse health effects without a universally accepted conclusion on the existence or magnitude of risk presented by exposure to EMF in general and transmission lines in particular. Therefore, this issue is typically raised in opposition to new or upgraded transmission lines. A utility should be prepared to respond to concerns that are raised concerning EMF by both the public and regulators as part of the permitting review process. EPRI's *Electric and Magnetic Field Management Reference Book* presents the current understanding of EMF that can be incorporated into a utility's comprehensive policy statement on EMF. This issue is also discussed in Chapter 7 of this Reference Book.

Endangered Species Act and Other Sensitive Species

On an international level, endangered, threatened, and other sensitive plant and animal species attract some of the greatest attention and regulatory review. Federal, state, provincial, and local laws protect a number of terrestrial and aquatic species and the associated habitats upon which they depend. Undeniably, one of the more stringent endan-

gered species laws is the Endangered Species Act in the United States. This law requires an independent, yet interconnected, review of potential impacts to federally listed species and those proposed for federal listing through another regulatory agency, the U.S. Fish and Wildlife Service. Depending on the type of project, its location, and the species involved, a separate environmental review and associated documentation effort (e.g., Biological Assessment, Biological Opinion) must be completed. This process further supports the recommended approach for interagency communication and increased knowledge of a project. Since the Endangered Species Act maintains a very structured and mandatory process with established timelines, it is beneficial for the utility or applicant to "communicate well and communicate often." This strategy helps to ensure that the sensitive species' permitting review and authorization parallels and is incorporated into the overall permitting review process.

Bird Electrocution and Collision Risk

Bird electrocution is not typically an issue for transmission lines, given the dimensions phase-to-phase and phase-to-ground. However, Section 12.16 of this Reference Book summarizes potential electrocution and collision risks to birds on and near transmission-line structures. Impacts to birds continue to receive a great degree of attention and concern internationally. Permitting agencies are becoming more aware of avian-related issues and may require specific protection measures to minimize future effects. However, one existing problem is the lack of continuity among agencies, even those within the same region. Different agencies are requiring different approaches to making overhead power lines, including transmission, safer for birds. This concern is discussed further in Section 1.6.5 "New or Expanding Issues," in regards to new issues facing utility companies in the environmental permitting realm.

Bird Predation

Predation is the use of transmission-line structures by birds of prey to reduce the species of certain animals below that which would normally be expected. It may be necessary to reduce this effect by installing bird guards on lines that prevent birds of prey using towers as perches. This is a more difficult task than that mentioned previously where the birds are prevented from settling on certain parts of the tower in that the entire tower needs to be fitted with guards. Another point of note is that communication and links with environmentalists are essential.

These points are adequately illustrated by two examples prevalent at the time of writing of this book. For decades the predation of juvenile desert tortoises by the common raven has been problematic in the southwestern United States. The presence of both transmission and distribution lines across the desert habitats supporting the federally threatened desert tortoise has contributed to the overall population decline recorded for this tortoise species, thereby increasing the regulatory pressures on associated utilities in these areas.

More recently, two grouse species are beginning to receive greater scrutiny from federal, state, and local regulatory and management agencies based on the continued decline of sage-grouse populations in the western United States and Canada. These losses are typically attributed to a number of factors, predominantly habitat loss and fragmentation. In addition to surface disturbance and construction activity restrictions for power line corridors near grouse breeding sites (leks), a more recent and expanded concern for the utility industry is that transmission-line structures introduce possible perch sites for avian predators (e.g., golden eagles) near sage-grouse use areas.

Because of this issue, regulatory and land management agencies have recently begun to require perch deterrents on power line structures within a certain distance of active lek sites to try to discourage perching by eagles and other grouse predators. However, presently, there is no consistency among the agencies on this distance, the types of perch deterrents that should be used, or how they should be installed. It is commonly accepted that the scientific evidence is lacking on the determination of adequate distances or buffers between power lines and grouse use areas. Additional evidence is needed to determine whether the proximity of power lines to active sage-grouse use areas may result in increased grouse predation, what this level of this predation may be, if a buffer area is warranted, and what the appropriate buffer size should be. Finally, if perch management is warranted within a specific buffer area, the extent and efficacy of perch deterrents are also unknown

A number of "Working Groups" have been established to review the decline in grouse. One of the proactive strategies currently employed by the western United States' utilities is becoming more involved in these working groups that typically consist of government agencies, grouse researchers, environmental groups, and private citizens. Again, communication and participation are key to ensure that the environmental community is aware of the utility's position, willingness to cooperate, and the respective limitations for certain mitigation approaches.

Invasive and Noxious Weeds

Many parts of the world are experiencing the spread of undesirable plants. Many of these plants are exotic, or not native to a region or continent, and due to the absence of

natural controls, they may spread rapidly. Some plants are toxic to livestock or wildlife, and others are pests in agricultural or developed areas. There is a concern among land owners and managers that the construction of a transmission line will facilitate the spread of invasive or noxious weeds, either through seeds being transported on construction equipment or through weeds becoming established in disturbed areas, such as along access roads, at staging areas, or around structure sites. A utility should be aware of weed issues in the area crossed by its proposed ROW and have a weed control plan prepared that can be included with permit applications.

1.6.5 New or Expanding Issues

Historically, issues associated with siting, permitting, constructing, and operating a transmission line, associated generating facility, and other ancillary components have arisen and evolved. Some of these historical issues have been resolved or at a minimum addressed with standardized plans (e.g., cultural resources), while others continue to be problematic for utility planning and operations (e.g., EMF, land use conflicts, aesthetics).

Many of the new or expanding issues facing utilities today have been mentioned as part of the environmental permitting review information. It is anticipated that the following topics will continue to grow in depth and complexity in the near future:

1. **Generation Siting.** One evolving issue for the electric utility industry is that new generation will be located far from load, necessitating the construction of new transmission lines. As an example, power generation in the United States has always required proximity to fuel (or transportation), cooling water, and transmission, but the implementation and evolution of air quality regulations over the past 35 years continue to push new generation to less densely populated areas. Prevention of Significant Deterioration (PSD) requirements for Class I areas (primarily national parks and designated wilderness) further restrict the siting of new coal-fired power plants, particularly in the western portion of the country. Coupled with the increased difficulty of obtaining regulatory approval and securing ROW on both public and private lands, new transmission projects frequently miss their budget and in-service targets.
2. **Restrictions Near Load Centers.** Parallel to the project siting constraints discussed above, urban and suburban expansions worldwide restrict availability for new ROWs, limiting access to load centers. There are significant land-use issues associated with maintaining capacity and reliability in such areas.
3. **Conflicting Priorities**. Conflicting agency environmental permitting priorities and process chronologies are growing, particularly when combining federal, regional, and local processes.
4. **Necessary Security.** Security presence at public meetings due to increased issue volatility and public emotion is now required in some areas.
5. **Bird Predation.** Grouse predation and bird perch management in the western United States, and the interagency and interregional inconsistencies associated with this issue, will have to rely on extensive and thorough communication processes.
6. **Operational Issues.** Operational issues that pertain to wildlife concerns continue to evolve—e.g., bird streamer effects on high-voltage, steel structures (see Section 12.16).

In summary, an educated and informed approach regarding environmental permitting processes, resource issues, agency and public concerns, and the relative volatility of each will be the greatest aid to a utility's project managers, design engineers, environmental permitting personnel, and public relations staff. Because of the variability of each project, its location, the reviewing and authorizing agencies, and associated issues and concerns, this "education" must occur at the beginning of the project prior to any commitment of resources.

1.7 COMPARISON OF THE THIRD EDITION OF THE REFERENCE BOOK TO THE SECOND EDITION

The *Transmission Line Reference Book* had its origins in the 1960s, when General Electric established the Lenox Laboratory in Lenox, Massachusetts, to experiment with transmission lines on the order of 1 MV. Known as Project UHV, the Lenox Laboratory site designed and tested transmission lines at Ultra High Voltages. While the original edition of the Red Book was essentially a final report to Project UHV, the approach used to write it and present the information has proved to be very successful. Each chapter in the book is a refereed paper on a specific topic. However, over time, the theories and technologies related transmission-line design have advanced, and the Red Book has fallen behind.

This new edition of the Red Book is intended to preserve the style of previous editions and present the science and technology in the same depth as previous editions, while including the latest information on research, technologies, and materials. Accordingly, 10 of the chapters in the previous edition of the book have been extensively updated. Tables 1.7-1 and 1.7-2 show the corresponding chapters in the second and the third editions.

A copy of the second edition of this Reference Book is included on the CD associated with the third edition,

Table 1.7-1 Chapter Organization, Second Edition, *Transmission Line Reference Book: 345 kV and Above*

Chapter No., 2nd Edition	Chapter Title, 2nd Edition	Corresponding Chapter, 3rd Edition	Comments
1	Project UHV: A Transmission Research Facility	——	This chapter is dated and not directly applicable to the process of line design.
2	EHV-UHV Transmission Systems	Chapter 1	The content dealing with sample lines and structures was not carried over into the third edition. This information was considered too narrow and dated.
3	Electrical Characteristics of EHV-UHV Conductor Configurations and Circuits	Chapter 2	Many of the graphs on conductor and conductor bundles were deleted from the third edition and replaced by a software applet. The base cases were pulled out as an appendix in the third edition. Conductor tables and line parameters are now an applet in the third edition.
4	Corona Phenomena on AC Transmission Lines	Chapter 8	This chapter has been considerably enhanced with updated information, and with the support of applets to aid in modelling effects and performing calculations.
5	Radio Noise	Chapter 9	This chapter has been considerably enhanced with updated information, and with the support of applets to aid in modelling effects and performing calculations.
6	Audible Noise	Chapter 10	This chapter has been considerably enhanced with updated information, and with the support of applets to aid in modelling effects and performing calculations.
7	Corona Loss	Chapter 11	This chapter has been considerably enhanced with updated information, and with the support of applets to aid in modelling effects and performing calculations.
8	Field Effects of Overhead Transmission Lines and Stations	Chapter 7	This chapter has been considerably enhanced with updated information, and with the support of applets to aid in modelling effects and performing calculations.
9	Insulation—Design Criteria	Chapter 3	This chapter has been revamped with the focus on insulation co-ordination methodologies including consideration of line economics, the latest system operating experience, and the latest standards.
10	Insulation for Power Frequency Voltage	Chapter 4	This chapter has been totally revised to include developments in insulator materials and designs as well as the latest developments in contamination.
11	Insulation for Switching Surges	Chapter 5	This chapter has been considerably enhanced with updated information, and with the support of applets to aid in modelling effects and performing calculations.
12	Lightning Performance of Transmission Lines	Chapter 6	This chapter has been totally redrafted with considerable new information and supported by applets.
13	Planning and Electrical Design of Transmission Lines	——	Elements of this chapter are included in the relevant chapters within the third edition

Table 1.7-2 Chapter Organization, Third Edition, *AC Transmission Line Reference Book: 200 kV and Above*

Chapter No., 3rd Edition	Chapter Title, 3rd Edition	Corresponding Chapter, 2nd Edition	Comments
1	Transmission Systems	Chapter 2	This chapter introduces the subject of transmission-line design through a brief, high-level overview of fundamental concepts and industry issues bearing on the role of line design.
2	Electrical Characteristics of Conductor Configurations and Circuits	Chapter 3	This chapter reviews information about transmission conductors and the parameters that they influence. Included in the chapter are discussions of the common types of conductor and their characteristics, conductor surface gradients, transmission-line impedance and admittance parameters, types of unbalance, and induced voltages.
3	Insulation Design	Chapter 9	This chapter describes insulation coordination, or how overvoltage and line insulation performance are balanced in a transmission-line design at least cost. Guidance is provided for determining overvoltages (stresses), insulation levels (strengths), and the balance between them to achieve acceptable line performance.
4	Insulation for Power Frequency Voltage	Chapter 10	This chapter discusses transmission line insulator technologies, including ceramic and polymer (nonceramic or composite) insulators. Selection and dimensioning of insulation from a power frequency perspective is discussed from a range of perspectives including contamination performance and life expectancy.
5	Switching Surge Performance	Chapter 11	This chapter discusses the strength of phase-to-ground and phase-to-phase transmission line insulation when subject to switching surges.
6	Lightning and Grounding	Chapter 12	This chapter describes the mechanisms of lightning, the effects of those mechanisms on transmission-line equipment, and methods of mitigation of effects.
7	Electric and Magnetic Fields	Chapter 8	This chapter presents engineering issues related to electric and magnetic fields produced by high-voltage transmission lines and to their effects. It includes methods of calculations and measurements, and evaluations of currents, voltages, and energies induced on objects and assessments of their effects.
8	Corona and Gap Discharge Phenomena	Chapter 4	This chapter describes the basic physical processes involved in corona and gap discharges and their electrical characteristics.
9	Electromagnetic Interference	Chapter 5	This chapter describes the nature of electromagnetic interference produced by corona and gap discharges on high-voltage transmission lines. It outlines in detail the procedures for calculating the EMI due to corona from 100 kHz to 1 GHz produced by any practical line configuration.
10	Audible Noise	Chapter 6	This chapter describes the nature of this acoustic noise produced by corona on high-voltage transmission lines. It includes procedures for calculating the noise produced by any practical line configuration, and methods for measurements and criteria for assessing annoyance or compliance with noise regulations.
11	Corona Loss and Ozone	Chapter 7	This chapter describes the mechanism of generation and techniques for measurement of corona losses on transmission lines. The chapter outlines methods for calculation of corona losses in different weather conditions, as well as calculation of mean annual and maximum corona losses.
12	Shared Use of the Right-of-Way	——	This chapter reviews issues associated with shared uses of transmission-line corridors. Included is a discussion of the basic elements of electromagnetic compatibility and descriptions of 15 planned and incidental uses of the rights-of-way.
13	Considerations for Inspection and Maintainability	——	This chapter provides guidance on designing transmission lines for inspection and maintainability. It includes practical information, learned from experience, on design principles that will promote durability and longevity, and facilitate inspection, condition assessment, and maintenance activities.
14	Voltage Upgrading of Existing Transmission Lines	——	This chapter addresses the process of increasing the operating voltage of an existing transmission line (line upgrading). It includes a summary of items that need to be considered in an upgrading study.
15	Transmission Lines Above 700 kV	——	This chapter provides detailed case studies of nine 700-800 kV lines and two 1000-1200 kV lines. It also includes a brief review of the research and development efforts required for the design and construction of the lines.
Appendix 1	Base Case Line Configurations	——	The bases cases were included in the second edition, but not given the appropriate attention. This appendix allows for easy access to the base cases, which are used to help the reader. The base cases provide a balance between number of cases and diversity.
Appendix 2	Applets	——	This appendix identifies and describes the 50 applets that accompany this book.
	Glossary	——	New addition. The basis of the Glossary was the IEEE Dictionary augmented by definitions used in IEC and CIGRE.
	Index	——	New addition. The index offers a tool for quickly locating information.

thereby allowing the reader to review material in the second edition.

Examples of new information in these chapters are as follows:

- **Conductor Configurations.** The new chapter includes recent advances, international configurations, and configurations of shield wires.
- **Insulation for Power Frequency Design.** The new chapter has been expanded to discuss transmission line insulator technologies, including ceramic and polymer (nonceramic or composite) insulators. Selection and dimensioning of insulation from a power frequency perspective is discussed from a range of perspectives including contamination performance and life expectancy.
- **Lightning Performance.** The new chapter has been extensively rewritten to include information on NLDN, LPATS, FALLS, transmission-line surge arrestors, TFLASH, sizing of shield wires, shielding failure, and tower grounding and impedance issues.
- **Electric and Magnetic Fields.** The focus of this chapter is shifted to acknowledge the change in industry interest from electric fields to magnetic fields. Field mitigation techniques are also discussed in some detail.
- **Corona Phenomena.** This chapter is expanded to include information on corona onset, corona effects, corona and polymer insulators, gap discharges, and space discharges.
- **Radio Noise.** This chapter is expanded to electromagnetic interference (EMI) to cover the wide range of communication systems now in use.
- **Audible Noise.** This chapter is expanded to add information on the impact of conductors and fittings, background hum, increased gradients, correction factors for gradient and altitude, software models from BPA and TLW, noise regulations, and noise measurement and mitigation.

As shown in Table 1.7-2, the new edition also changed the sequence in which these chapters are presented in order to bring forward information on insulation design and stresses (power frequency, switching surge, and lightning), prior to sections on effects (EMF, corona, EMI, and audible noise).

The new edition also adds four new chapters—Chapters 12-15—on shared use of rights-of-way, inspection and maintenance concerns, voltage upgrading, and experience with lines above 700 kV. These new chapters reflect both the changing concerns over the past 15 years as well as the availability of experience in line design, operation, and maintenance.

In addition to the revised text, the new edition of the Red Book also includes applets, which are small software programs, or stand-alone calculation modules, that enable users to make specific calculations for transmission-line design parameters, with associated example and design features. Each applet has transmission-line data input screens, calculation results screens, and help files. The help file contains a sample problem that the user can load directly to calculate results. The user can also enter specific transmission-line information for a particular problem and then calculate specific results for that problem. Transmission-line parameters can also be modified and the result recalculated, thereby illustrating how the change in a particular parameter can affect the calculation results.

More than 50 different applets have been developed, with calculation capabilities related to conductor surface gradients, switching surges, lightning effects, electric and magnetic fields, radio noise and audible noise generation, and corona (see Table 1.7-3). Overall, the inclusion of these applets in the third edition offers users of the Red Book the advantages of software calculation, which were not available to users of the second edition, and enables rapid and accurate comparison of alternatives and understanding of effects.

1.8 CONCLUSION

Transmission lines embody a complex and deliberate balance between costs, energy to be transported, and electrical, mechanical, civil, performance, and environmental tradeoffs. Lines also need to operate within a system that has, in recent years, seen major changes driven by deregulation. Finally, lines are expected to operate for more than 40 years. Consequently, arriving at a "standard" design capable of serving all operating environments is nearly impossible. Considering the expansive system of lines that weave a mesh across the globe, it is hardly surprising that the vast system is considered one of the largest "structures" known to man.

As such a unique system, it is critical that engineers understand the many aspects of line design, construction and operation. The subject is so broad that one book cannot cover all electrical, mechanical, civil, and environmental aspects. This book covers only the electrical factors, but the reader is urged to understand the relationships between the mechanical, civil and electrical aspects that make up the line.

This chapter has endeavored to inform the reader on the basics of the electrical aspects of the line as well as to cover the dynamic environment (legal, social and political) that impacts on the line design engineer at present.

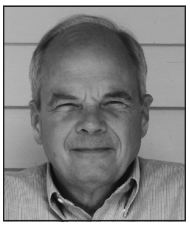
CHAPTER 2



Electrical Characteristics of Conductor Configurations and Circuits

Dale A. Douglass
James Stewart
Bernie Clairmont

This chapter reviews information about transmission conductors and the parameters that they influence. Included in the chapter are discussions of the common types of conductor and their characteristics, conductor surface gradients, transmission-line impedance and admittance parameters, types of unbalance, and induced voltages.

Dr. Dale A. Douglass is a Principal Engineer of Power Delivery Consultants, Inc. based in Niskayuna, New York. He has more than 30 years of experience in transmission line engineering and conductor design, having worked with Power Technologies, Inc., Kaiser Aluminum, and Bell Laboratories. He is presently the Vice Chairman of IEEE's Towers, Poles, and Conductors Subcommittee and the convener of CIGRÉ Working Group B2-12 on Electrical Aspects of Transmission Lines. He has been involved in studies of overhead line sag-tension, high temperature operation, and both current and voltage upgrading of existing lines. In 1996, he was elected a Fellow of the Institute of Electrical and Electronic Engineers for "contributions to understanding the characteristics and applications of overhead power transmission conductors."

Dr. James Stewart is an independent consultant based in Scotia, New York. He has more than 30 years of experience in power systems and transmission lines, having worked for Niagara Mohawk Power Corporation and Power Technologies, Inc. He has been involved in analysis and measurement of transmission line electrical parameters, including research contributions to compact and high phase order transmission line design. He taught circuit analysis at Syracuse University and taught power circuit analysis as part of the PTI Power Technology Course. He was elected a Fellow of the Institute of Electrical and Electronics Engineers in 1987 for "advances in transmission line theory and its reduction to practice through prototype demonstration." He is presently Chairman of the Transmission and Distribution Committee of the IEEE Power Engineering Society.

Bernie Clairmont has been a lead researcher at the EPRI laboratory in Lenox, Massachusetts for 18 years, following a six-year period of teaching physics at a nearby college. His research interests have included the corona and field effects of transmission lines, magnetic field management, application of fiber optics in high-voltage environments, and dynamic rating of overhead lines. He was the Principal Investigator of many EPRI and utility sponsored research projects. He worked on the development of several computer programs that are part of EPRI's workstations, such as the Transmission Line Workstation module for calculating field and corona effects, and authored or coauthored many published papers and EPRI reports, such as the *Magnetic Field Shielding Handbook.* As a Project Manager and Senior Research Engineer, he now leads the EPRI effort in the field of increased power flow of transmission lines.

2.1 INTRODUCTION

Many sizes and types of conductor are used in transmission lines at voltages above 200 kV, although most are at least 25 mm in diameter and are stranded with aluminum wires. This chapter provides information about conductors and the transmission-line parameters that they influence. The information supplied in this chapter is intended to be useful to those using the other chapters of this book and to those simply looking for basic information on transmission conductors.

Section 2.2 describes the various types of conductor that are in widespread use, describing their relative strength, weight per unit length, electrical resistance, and both inductive and capacitive reactance. The sag behavior of conductors under ice, wind, and high electrical loading is discussed as well as the reasons for limiting conductor temperature (annealing and electrical clearance). Thermal rating limits are also mentioned, since such limits are an essential part of line design and system planning.

Conductor surface gradients are explained in Section 2.3. The line's phase spacing and configuration, the number of conductors per phase bundle, and the subconductor diameter are all factors in determining the surface gradient. Applets concerning surface gradient calculations are discussed.

Section 2.4 concerns the calculation of basic line impedance and admittance parameters, the pi electrical equivalent, and the meaning and calculation of surge impedance and surge impedance loading. Examples are presented for typical line geometries.

Although modern power system circuits and their overhead transmission lines are intended for application in a balanced three-phase system, unbalances do occur and can be analyzed as described in Section 2.5. The importance of line "transposition" is discussed.

Section 2.6 concerns electric and magnetic field induction on de-energized circuits. Appropriate mention of applicable applets is included.

Appendix 2.1 includes several examples of conductor data tables for the most common transmission conductors. The conductor database applet allows the user access to types and sizes of transmission conductors.

A number of applets are provided with this book to assist in the calculation of conductor characteristics. These applets include the following:

- Applet CC-1, "Conductor Surface Gradients (2-D)." This applet provides the surface gradients of all the conductors (and subconductors) within a transmission corridor, and presents the results in tabular and graphical forms.
- Applet CC-2, "Conductor Surface Gradient (3-D)." This applet enables users to compute and plot the surface gradient (maximum and average) along a conductor's length. The applet accepts line geometry, voltage, objects, and terrain variation, and will provide surface gradients as a function of longitudinal distance down the line.
- Applet CC-3, "Corona Shield Surface Gradient." This applet computes the maximum surface gradient, as a single number, for toroids (and other simple objects).
- Applet CC-4, "Conductor Data." This applet allows users to access sizes and types of transmission conductors.
- Applet CC-5, "Transmission Line Parameters." This applet computes three-phase transmission-line phase and symmetrical component sequence impedance parameters including the effects of lossy earth.
- Applet CC-6, "Conductor Surface Gradient Base Case Curves and Effect of Line Parameters." This applet accepts base case number and the parameter to be varied, and will produce a plot of surface gradient versus varied parameter. Parameters that can be varied include conductor (or subconductor) diameter, phase spacing, and conductor heights above the ground.
- Applet CC-7, "Induced Voltages on Parallel Lines." This applet computes electric and magnetic field coupling from a three-phase transmission line to parallel wires.

2.2 BARE CONDUCTORS FOR OVERHEAD TRANSMISSION LINES

A wide variety of sizes and types of conductor have been used in transmission lines for voltages of 200 kV and above. In most cases, however, transmission phase conductors are at least 25 mm in diameter, and are stranded with aluminum wires and a stranded steel core for mechanical reinforcement. Because aluminum is highly conductive and the diameter is relatively large, transmission conductors typically have relatively low electrical resistance per unit length. This keeps electrical losses to a minimum.

Conductors used as shield wires are typically stranded with galvanized steel or aluminum-clad steel wires. They are, therefore, both strong and resistant to electrical arc damage. In recent years, shield wire conductors enclosing fiber-optic wires used for communications have come into widespread use.

This section concerns the electrical characteristics (and, to a lesser extent, the mechanical characteristics) of commonly used phase conductors and shield wires for transmission lines at 200 kV and above. The primary

characteristics of concern in these conductors are their electrical resistance as a function of temperature and current, the maximum allowable operating temperature, and the surface gradient as installed.

A variety of aluminum conductors with stranded steel reinforcing cores are available. Product specifications for many of these conductors exist either in IEC 1597-1995 or ASTM Volume 2.03 on Electrical Conductors. The conductors include:

- Aluminum Conductor Steel Reinforced, ACSR or A1/S1 (ASTM B-232 1992), and ACSR/TW (ASTM B-779 1991)
- Self-Damping Conductor, SDC (Livingston 1969; McCulloch et al. 1980; ASTM B-701 1991)
- T2 Conductor, T2/ACSR (Roche and Douglass 1981)
- Aluminum Conductor Steel-Supported, ACSS (Adams 1970; Thrash; 1999; ASTM B-856 1995) and ACSS/TW (ASTM B-857 1995)

The steel core wires used in these various ACSR conductors must all be galvanized GA, GB, or GC (ASTM B-498 1993), aluminized, AZ (ASTM B-341 1993), or aluminum-clad, AW (ASTM B-502 1993) to avoid electrolytic corrosion between steel and aluminum. The thickness of the galvanizing on steel core wires is usually Class A (the tables in Appendix 2.1 are for Class A galvanizing), but heavier zinc layers referred to as Class B and C galvanizing can also be specified when corrosion is severe. Greater thickness of galvanizing results in reduced strength for a given core wire diameter.

In addition to the ACSR family of conductors, conductors stranded entirely of aluminum, entirely of aluminum alloy (aluminum-magnesium-silicon) wires, or made of a combination of aluminum and aluminum alloy wires are available. All are relatively light in weight but more susceptible to loss of tensile strength and excessive creep elongation at temperatures in excess of 100^{o} C. The commonly available all aluminum conductors (ASTM B1 1991; IEC 1089 1991) include:

- All Aluminum Conductor (AAC, AAC/TW, A1)
- All Aluminum Alloy Conductor (AAAC, AAAC/TW, A2 or A3)
- Aluminum Conductor Alloy Reinforced (ACAR, A1/A2 or A1/A3)

Aluminum Conductor Alloy Reinforced conductors have outer layers of 1350-H 19 aluminum strands reinforced with a core of 6201-T81 aluminum alloy. These conductors are typically available with the same resistance as common ACSR conductors. Changing the ratio of 1350-H19 to 6201-T81 strands can vary the strength of ACAR. Common strandings for medium-sized transmission conductors include 30/7, 24/13, and 18/19. These are listed in order of increasing strength.

Special-purpose conductors have been developed and are utilized in many lines. These include:

- Expanded ACSR. These conductors generally use EC-H19 strand with a steel core. Expansion is by open helices of aluminum wire, flexible concentric tubes, or combinations of aluminum wires and fibrous ropes. Since there are no industry standards for these conductors, the data have not been included in this book. They are no longer in widespread use.
- Aluminum Alloy Conductor Steel Reinforced (AACSR [ASTM B-711 1993]). This conductor is used where very high strength is required. Typical applications are in long spans exposed to severe icing and wind loads.
- High-Temperature Conductors. On older lines that have been reconductored, certain high-temperature conductors are used, such as Aluminum Conductor Steel Supported (ACSS [ASTM B856 1995; Thrash 1999] or ACSS/TW [ASTM B857 1995]), "Gapped" ACSR with "Heat-Resistant" Aluminum Alloy (GTACSR [Kotaka et al. 2000; Tunstall et al. 2000]), High Temperature Aluminum reinforced with "Invar" steel (TACIR [Sasaki et al. 1985]), and high-temperature aluminum reinforced with various types of strong, lightweight composites.

Commonly used shield wires include "aluminum-clad-steel conductor" (Alumoweld), high-strength and extra-high-strength steel (EH and EHS), and optical ground wire (OPGW).

Choice of conductor type is primarily driven by mechanical considerations such as maximum ice and wind loads and maximum allowable conductor operating temperature and the corrosiveness of the line environment. Choice of conductor diameter is primarily driven by electrical considerations such as corona-induced radio and TV noise and, to a lesser extent, by electrical losses.

2.2.1 Conductor Materials

Table 2.2-1 summarizes the metal wire materials used in transmission conductors.

Copper wires are almost never used in conductors for high-voltage transmission lines, because the density of copper is three times that of aluminum, whereas its conductivity is less than twice that of aluminum. This makes it unattractive for use where the conductor is self-supporting but makes copper conductors quite attractive for use in high-voltage underground cables.

Table 2.2-1 Mechanical and Electrical Properties of Transmission Conductor Wire Materials

Name (ASTM/ IEC)	Tensile Strength (Ksi/Pa)	Minimum Elongation (%)	ASTM or IEC Specification	Temper	Conductivity (% I.A.C.S.)
1350/A1	24	1.5	B230/ IEC889	H19	61.2
1350	8.5	20	B609	H0	63.0
6201/A3	44-46/ 315-325	3.0	B398 IEC60104	T81	52.5
A2	295	3.5	IEC60104		53.0
Galvanized Steel/S	A-185 B-175 C-165	3.5 3.0 3.0	B498		
High Strength Galvanized Steel	A-205	3.0	B606		
Aluminized Steel (AZ)	160	3.5	B341		9.0
Aluminum-Clad Steel	175	1.5	B502		20.3

Most quantities in the conductor parameter tables of Appendix 2.1 have been calculated from the basic strand dimensions. The following is a summary of the formulae and procedures.

2.2.2 Areas and Diameter

The areas in kcmil and square millimeters are calculated from the strand dimensions. The area of an overhead conductor is typically described in terms of the aluminum area since this is the primary current-carrying conductor component. If the resistance of the conventional galvanized steel core is taken into account, the resistance of an ACSR conductor is reduced by 1 to 2%.

The conductor diameter is determined by the strand geometry. For example, Bluebird conductor is an ACSR with four layers of aluminum over two layers of steel. The steel core diameter is five times the diameter of the 0.0961-in. strand (0.480 in.). The total conductor diameter is then two times the four layers of 0.1602-in. aluminum strand, plus the core diameter, or 1.762 in.

2.2.3 Weight and Rated Strength

The weight and strength of those conductors that are included in Appendix 2.1, and those that may be accessed with Applet CC-4, "Conductor Data," are calculated from the ASTM or IEC manufacturing standards, and are generally consistent with the values in the Aluminum Association handbook (Aluminum Association 1989). The methods of calculation for both weight per unit length and "rated breaking strength" are described in detail in the appropriate ASTM or IEC standards. Essentially, the rated breaking strength (RBS) of stranded conductor is the sum of the strengths of the individual wires allowing for some reduction due to the helical stranding. For ACSR, the tensile "strength" of the steel core is calculated at the maximum elongation of the surrounding aluminum strands (1%), not the maximum elongation of the steel itself.

2.2.4 Electrical Resistance

For a bare, stranded, all-aluminum conductor, the electrical resistance depends on the aluminum conductivity, the lay length of each of the wire layers, the wire diameter, the temperature of the conductor, and the frequency of the electrical current.

The calculation process begins with the conductor's dc resistance. This is found from the strand conductivity, the wire diameter, and a correction factor for the lay length of each of the conductor layers. Since lay length varies with the position of the layer and with the particular manufacturer, correction factors for the helical stranding of the aluminum wires (2% for most transmission conductors) have been given by the American Society for Testing and Materials in Standard B232 (for ACSR), Standard 231 (for AAC), and Standard B524 (for ACAR).

If the lay length is known, then Equation 2.2-1 provides a method for a more exact calculation of the dc resistance of each layer:

$$R_i = \frac{\rho}{A} \cdot \sqrt{1 + \left(\frac{2 \cdot \pi \cdot r_i}{S} \right)^2} \qquad 2.2\text{-}1$$

R_i = Ohms per unit length of the ith layer at the reference temperature, $T_{REF.}$
ρ = Resistivity of aluminum strands at a standard reference temperature, $T_{REF.}$
S = Length of lay in i^{th} layer.
r_i = Stranded conductor radius to middle of i^{th} layer.
A = Area of aluminum strands in i^{th} layer.

The exact total dc conductor resistance, R_{dc}, is the parallel combination of the individual layer resistances, R_i:

$$R_{dc} = \frac{1}{\left(\frac{1}{R_1} + \frac{1}{R_2} + .. \right)} \qquad 2.2\text{-}2$$

This initial estimate of dc resistance must be further corrected for the temperature of the conductor, T_C, and the frequency of the electrical current through it.

DC Resistance as a Function of Temperature

The dc resistance of the conductor at temperatures other than T_{REF} is determined by using Equation 2.2-3 with the appropriate temperature coefficient of resistance, α_{REF}.

$$R_{dc}(T_C) = R_{dc}(T_{REF}) \cdot \left[1 + \alpha_{REF} \cdot \left(T_C - T_{REF}\right)\right] \qquad 2.2\text{-}3$$

where T_{REF} is the reference temperature in degrees Celsius, and T_C is the conductor temperature in degrees Celsius.

The thermal coefficient of resistance varies with wire metal alloy and with the reference temperature. The resistance of aluminum and copper wires increases approximately 3.5 to 4.0% per 10°C. The resistance of galvanized steel wires increases 3.2% and aluminum-clad steel wires about 3.6% per 10°C. The coefficient of resistance decreases as the reference temperature increases, going from 0.00403 for 61.0% I.A.C.S. aluminum at 20°C to 0.00360 at a reference temperature of 50°C.

In recent years, it has become common to reduce the resistance of steel core aluminum conductors (ACSR) by accounting for the conductivity of the galvanized steel wires. Including the conductivity of the steel core reduces the conductor's dc resistance by between 1% and 2% depending on the steel wire area. To do this, the resistance of the core is calculated with an equation like 2.2-1 with a conductivity of 8% I.A.C.S. The core resistance is combined with the aluminum layer resistances in Equation 2.2-2.

In correcting the dc resistance of ACSR, the steel wire resistance of the steel core must be corrected separately for temperature since its thermal coefficient of resistance is only about 2.9% per 10°C.

Adjusting Conductor (AC) Resistance for Frequency

Even after correcting the dc resistance for temperature, the ac resistance of bare stranded transmission conductors is greater than the dc resistance due to skin effect (i.e., the tendency of current density to be higher toward the outside of the conductor than in the middle due to magnetic field effects within). Except for steel-core aluminum conductor with an odd number of aluminum strand layers, the ratio of ac to dc resistance at 25-60 Hz is nearly 1.00 for transmission conductors less than 20 mm in diameter. For larger conductors, the ac/dc resistance ratio increases. The ac/dc resistance ratio for three relatively large all-aluminum conductors as a function of outside diameter is shown in Table 2.2-2.

The correction of ac resistance for skin effect may be accomplished by use of the graph shown in Figure 2.2-1. Note that R_{DC} is in ohms per mile. Other than that, the other dimensions can be SI or U.S. common units.

AC Resistance for 60 Hz Frequency with One- and Three-Layer ACSR

The ratio of ac to dc resistance due to skin effect is not dependent on the current magnitude. For aluminum conductors with a steel-reinforcing core, particularly those with one or three aluminum layers, however, ac resistance is dependent on both frequency and on current magnitude. Table 2.2-3 illustrates the dependence of ac resistance of three-layer 54/7 1033.5 kcmil (524 mm^2) Curlew ACSR (A1/S1) (Aluminum Association 1989).

The increase in effective ac resistance is even greater for single-layer ACSR, as shown in Table 2.2-4 (Aluminum Association 1989).

Complex models, to account for the increase in ac resistance of ACSR conductors, have been developed (Lewis

Table 2.2-2 Increased Resistance due to Skin Effect at 60 Hz (Dwight 1923)

and Tuttle 1959; Morgan et al. 1997; and Barrett et al. 1986). These models consider the increase in losses due to both iron losses in the core and uneven current densities between the helical aluminum wire layers. The increase in ac resistance due to the steel core depends on both the magnetic properties of the structural steel core wires and the lay lengths of the aluminum wire layers.

Practically speaking, the steel core and the lay lengths are chosen to assure sufficient strength and stiffness, and to assure proper handling characteristics of the composite conductor during tension stringing procedures. As a result, there is a good deal of variation in lay length and magnetic steel wire properties between manufacturers, and it is unlikely that the impact of core magnetization can be known exactly. The phenomenon of core magnetization is still under investigation, and the effects of core magnetization can only be determined in an approximate fashion.

The tables in Appendix 2.1 include ac resistance values for 25°C and 75°C. For single-layer ACSR (6/1, 7/1, 8/1, 12/7), as shown in Table 2.2-4, the resistance shows large changes with current as well as with temperature. For these small conductors, rarely used in transmission lines at 200 kV and above, the resistance values at high temperature must be calculated based on laboratory measurements (Aluminum Company of America 1960). For three-layer ACSR, however, which is commonly used in transmission lines at 200 kV and above, the resistance can be calculated as follows:

- Calculate the resistance at the desired temperature and correct for skin effect, as described in the preceding part of this section.
- Correct for magnetization losses by multiplying the resistance by the core magnetization multiplier shown in Figure 2.2-2.

If the details of the ACSR conductor construction and core magnetic properties are known, the methods suggested by Barrett (Barrett et al. 1986) and Morgan (Morgan et al. 1997) may be used and a more precise estimate of ac resistance obtained. The method outlined in these two papers incorporates a more precise estimate of the core losses and recognizes that the current density in the aluminum wires varies between layers due to mutual inductance rather than skin effect.

2.2.5 GMR of Stranded Conductors

The geometric mean radius (GMR) is the name given the quantity used in calculating the inductive reactance from the conductor dimensions. The GMR for a solid cylindrical nonmagnetic conductor with uniform current density is:

$$\text{GMR} = e^{-1/4} D_s / 2 \cong 0.7788\, R_s \qquad 2.2\text{-}4$$

Where:
D_s = strand diameter
R_s = strand radius

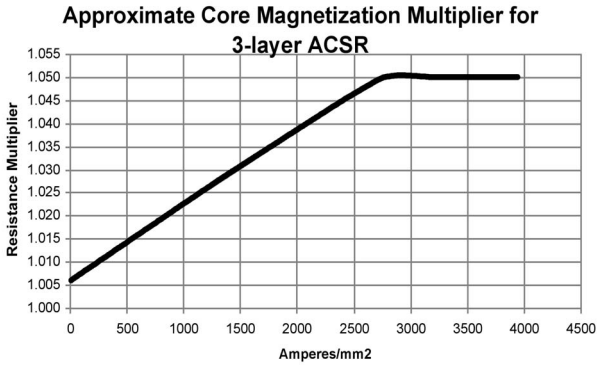

Figure 2.2-2 Core magnetization resistance multiplier for three-layer ACSR (Douglass).

The GMR of a composite conductor (Figure 2.2-3), such as ACSR and AAC, which consists of strands of equal diameter and conductivity regularly spaced in concentric layers, is calculated in the following:

For a single cylindrical conductor with uniform current density (dc, no skin effect), the GMR is

$$\text{GMR} = (e^{-\mu_r/4})r \qquad 2.2\text{-}5$$

Where:
r = radius of the conductor.
μ_r = relative permeability of the conductor (approximately equals 1 for aluminum and copper).
GMR $\cong$ 0.7788r for copper and aluminum

The GMR of transmission conductors is typically equal to between 75% and 80% of the conductor radius. Thus for a stranded conductor that is 28 mm in diameter, the GMR is typically about 21 to 22 mm. The exact value of GMR depends on the numbers of layers of aluminum strands and the presence or absence of a steel core. GMR values are included in the conductor tables of Appendix 2.1 and in Applet CC-4.

The calculation of the GMR for conductors where the strand diameters are sometimes unequal, as in expanded designs or in designs where the conductivity varies, is accomplished with the procedure outlined by Lewis and Tuttle (Lewis and Tuttle 1959).

2.2.6 Inductive and Capacitive Reactance "to One Meter (Foot)"

The positive sequence inductive reactance, X_1, of a three-phase transmission line is a function of both the properties of the individual conductors and the line geometry (as presented in Section 2.4). Many authors have traditionally split the equations for reactance into two parts, so the total reactance becomes the sum of two terms:

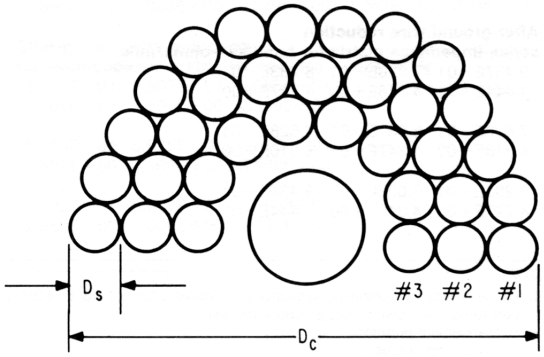

Figure 2.2-3 GMR diagram for an ACSR conductor.

- The reactance of the conductor itself, X_a, called the reactance to one meter in metric units and the reactance to one foot in English units. The reactance to one foot or one meter is a property of the individual conductor. The reactance to one foot is given in the conductor tables in Appendix 2.1.
- The spacing factor term X_d, as described in Section 2.4.

This division into two terms is possible because ln (A/B) = ln (A/1) + ln (1/B), where the number "1" represents 1 meter or 1 foot, depending on the dimensions employed.

A complication arises because different, but equivalent, forms of the equations have been used in different parts of the world. Both give identical answers, but superficially look different. The metric form uses the fundamental physical quantities ω and μ, the frequency, *f*, and the natural logarithm, ln. The English form is traditionally presented with a coefficient *k* that assumes a 60-Hz frequency and uses the logarithm to the base 10, log. Both forms of the equation are given because both are in common use in different parts of the world.

The metric form of the equation for inductive reactance at one-meter spacing in ohms per meter is:

$$X_a = 2\pi f \frac{\mu_0}{2\pi} \ln\left(\frac{1}{GMR}\right) \qquad 2.2\text{-}6$$

Where:
μ_0 = permeability of free space $4\pi \times 10^{-7}$ H/m.
f = frequency in Hz.
GMR = geometric mean radius of the conductor in m.
ln = natural logarithm.

The English form yields inductive reactance at one-foot spacing in ohms per mile as:

$$X_a = k \log\left(\frac{1}{GMR}\right) \qquad 2.2\text{-}7$$

Where:
k = 4.657×10^{-3} *f* = 0.2794 at 60 Hz.
f = frequency in Hz
GMR = geometric mean radius of the conductor in ft.
log = logarithm to the base 10.

The derivation of the positive sequence capacitive reactance follows the same pattern as that of the inductive reactance, allowing for the similar differences of form found in different parts of the world. The positive sequence capacitive reactance, X_{C1}, of a three-phase transmission is given as the sum of the reactance to one meter (foot) term *X*'a and the spacing factor term *X*'d, as described in Section 2.4.

The metric form of the capacitive reactance at 1-m spacing in ohm-meters is:

$$X'_a = \left(\frac{1}{2\pi f}\right) \bullet \left(\frac{1}{2\pi\varepsilon_0}\right) \bullet \ln\left(\frac{1}{r}\right) \qquad 2.2\text{-}8$$

Where:
ε_0 = permittivity of free space 8.854×10^{-12} F/m.
f = frequency in Hz.
r = radius of the conductor in m.
ln = natural logarithm.

In contrast to inductive reactance, where the conductor is characterized by GMR, for capacitive reactance the conductor is characterized by its spatial radius, *r*.

The English form of the capacitive reactance at 1-ft spacing in megohm-miles is:

$$X'_a = k' \log\left(\frac{1}{r}\right) \qquad 2.2\text{-}9$$

Where:
k' = $4.093/f = 0.06822$ at 60 Hz.
f = frequency in Hz.
r = radius of the conductor in ft.
log = logarithm to the base 10.

For background and further information, see one of the standard works.

2.2.7 Annealing of Aluminum Stranded Conductors

Normally overhead transmission lines are designed such that maximum conductor tension under heavy ice and wind loading does not exceed a certain percentage of the conductor's RBS. A significant reduction in the RBS can lead to a tensile failure during subsequent high ice and wind loading events. To avoid this, energized conductors are typically not allowed to operate at a high enough temperature for a long enough period of time to reduce their breaking strength by more than 10% over their expected lifetime.

The ASTM or IEC standards specify the minimum tensile strength of new aluminum and copper wires, which is the stress at which the wire breaks. At temperatures above 75°C, the tensile strength decreases with time. Even for moderately long exposures to temperatures as high as 300°C, however, the tensile strength of galvanized, aluminum-clad, or copper-clad steel wires is not reduced (though the galvanizing may deteriorate). Extended exposure of conductors with little or no steel reinforcing core to temperatures above 75°C can, therefore, lead to tensile failures during high ice and/or wind loading events.

Figure 2.2-4 shows typical tensile strength reduction data for 1350-H19 "EC" hard drawn aluminum wire (Aluminum Association 1989). In general, tensile strength reduction of aluminum wires at temperatures of less than 90°C is considered negligible. At 100°C, the tensile strength of the wire is reduced by 10% after 5000 hours and at 125°C, the tensile strength is reduced 10% after 250 hours.

When compared to copper, aluminum appears to anneal somewhat more slowly.

In applying these curves, the cumulative strength reduction for multiple exposures at the same conductor temperature may be found by simply adding up all the hours and calculating the residual strength. However, for multiple exposures at different conductor temperatures, the calculation process is more complex. To determine the cumulative strength reduction for a series of high-temperature exposures at different temperatures and times, all exposures must be expressed in equivalent time at the highest temperature before adding.

If the hard-drawn aluminum strand is raised to 125°C for 100 hours and then at a later time for 50 hours, then the strength reduction can be calculated for 150 hours at 125°C. With reference to Figure 2.2-4, the remaining strength is then approximately 91%. If the same conductor is raised to 125°C for 100 hours and then at a later time is raised to 150°C for 50 hours, then the following calculation must be performed: Again, with reference to Figure 2.2-4, the remaining strength after 100 hours at 125°C is approximately 93%. This is equivalent to 3 hours at 150°C. After the next 50 hours at 150°C, the remaining strength is equivalent to 53 hours at 150°C, or approximately 85%.

A similar but more accurate estimate of remaining strength can be obtained by using the formulas given in (Harvey 1972). Harvey's paper also considers 6201 aluminum alloy and the change in composite strength of various strandings of ACSR. As shown in his paper, conductors with a relatively large steel reinforcing core are less susceptible to annealing. For example, consider Table 2.2-5.

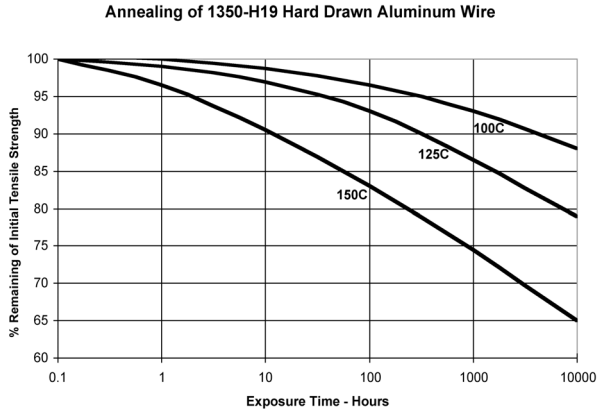

Figure 2.2-4 Annealing of 1350-H19 hard-drawn aluminum wire (Aluminum Association 1989).

The rate of loss of strength also depends on the amount of "cold work" imparted to the wires in drawing them to size from their 3/8-in. rod form. Aluminum wires drawn from rod produced by the Properzi continuous cast process exhibits slower annealing rates than wire drawn from "rolled" rod. Most conductors manufactured in the last 30 years have aluminum strands drawn from Properzi rod.

2.2.8 Sag Tension of Overhead Lines

In the design and maintenance of power transmission lines, the concern of primary importance is public safety. Other than designing the supporting structures such that they remain standing under even the most severe weather conditions, the safety of a line is essentially determined by the position of its energized conductors relative to people, buildings, and vehicles that are nearby. Maintaining minimum distances to nearby objects and people is primarily a matter of limiting the sag of the energized conductors under either high-mechanical load or high-temperature conditions.

In addition to making lines safe, other important constraints are the level of electric and magnetic fields produced (e.g., electric fields increase as the conductor gets closer to the ground), the maximum structure loads during occasional high wind and ice loads, and the maximum temperature at which the energized conductors are allowed to operate. Given standard "worst-case" rating weather conditions, the maximum allowable conductor temperature determines the thermal rating of an existing line.

Figure 2.2-5 is a basic sag-clearance diagram, which illustrates how minimum ground clearance must be maintained under both heavy loading and high-temperature events over the life of both new and re-rated transmission lines. The

Table 2.2-5 Reduction in Conductor Rated Strength (Due to Annealing of Aluminum Strands) as a Function of the Size of Steel Reinforcing Core. All Three Conductors Have an Aluminum Cross-sectional Area of 400 mm^2.

Conductor Type	% Steel by Area	Residual Strength after 1000 hrs@100°C (%)	Residual Strength after 100 hrs @150°C (%)	Residual Strength after 1000 hrs@ 150°C (%)
Arbutus AAC	0	97.7	82.5	75.6
Tern ACSR	6.5% [Type 7]	100	91.1	86.4
Drake ACSR	14.0% [Type 16]	100	98.6	96.0

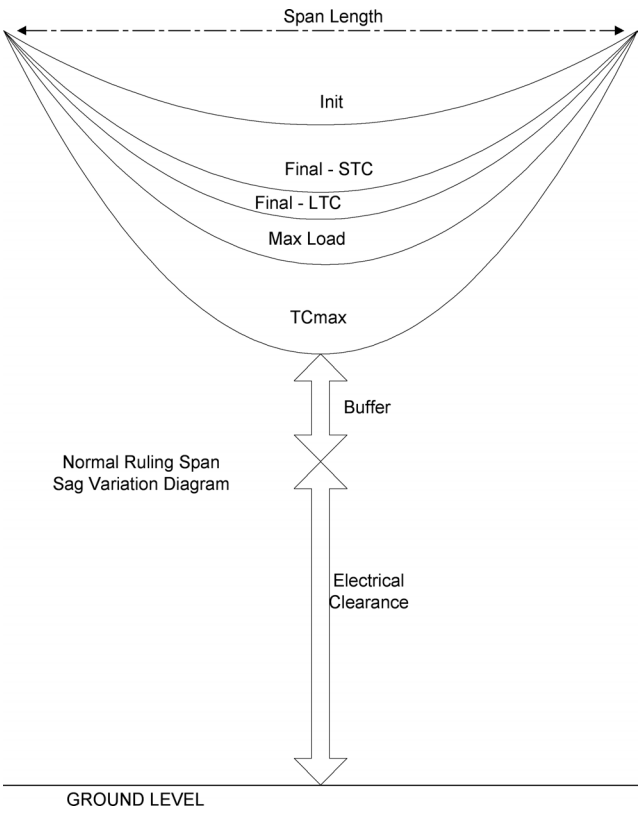

Figure 2.2-5 Sag diagram showing sags for various times and loading conditions.

figure shows ground clearance and line sags under normal, high ice/wind load, and high-temperature conditions for a ruling (or "equivalent") span. Note that the sum of the minimum ground clearance, the buffer, and the sag at maximum temperature is the minimum attachment height, which determines structure height and spacing. In a detailed line design that has many different spans, this sort of sag-clearance calculation must be developed for all spans (Varney 1927; Winkelman 1959).

Definitions of the labels in Figure 2.2-5 are as follows:

- **"Init"** is the initial installed unloaded (with no ice or wind) sag of the conductor. It is typically at a conductor temperature of 10°C to 25°C (50°F to 80°F). This is also typically referred to as the line "ruling span stringing sag."
- **"Final – STC"** is the final sag of the conductor at 15°C (60°F) after an ice/wind-loading event has occurred for a short time—typically an hour. STC stands for "short-time creep."
- **"Final – LTC"** is the final sag of the conductor at 15°C (60°F) after an extended period—typically 10 years—where the conductor simply persists at a conductor temperature of the order of 15°C (59°F) without ice or wind. "LTC" stands for "long-time creep," which occurs even if heavy ice and wind loads never occur.
- **"Max Load"** is the sag of the conductor during the specified maximum ice and wind loading at a reduced temperature—typically –18°C to 0°C (0°F to 32°F). Note that the sag prior to this event is normally assumed to be the Init sag, and the sag after this event is the Final – STC sag.
- **"TCmax"** is the sag of the conductor when its temperature is the maximum for which the line is designed—typically 50°C to 150°C. The final sag at 15°C (60°F), prior to this high-temperature event, is assumed to be the larger of the Final – STC and the Final – LTC sags.

Figure 2.2-5 shows typical behavior of transmission conductors where the sag under maximum ice and wind load conditions is less than that at the maximum temperature. For small or weak conductors experiencing heavy ice loads, this may not be true.

Note that the diagram illustrates the "snapshot" nature of traditional sag-tension calculations. The actual conductor sag position at any time in the life of the line depends on the actual mechanical and electrical load history of the line. If the high load event is more severe or persists for a longer time than assumed in determining the Max Load condition, then the corresponding sag at Max Load and the sag increase will be greater. The use of buffers is required because of such uncertainties.

For transmission conductors made primarily of aluminum strands under tension, sag never stops increasing with both time and high-loading events throughout the life of the line (Harvey 1972). That is, the sag at a given conductor temperature (e.g., 15.5°C, or 60°F) increases steadily over the years after construction. However, with moderate unloaded and loaded conductor tensions (typically 15% and 50% of rated strength), the rate of change in sag with each such event decreases over the life of the line. Thus, if a heavy ice load event occurs 10 years after installation, the permanent increase in sag is much smaller than if it occurred in the first 6 months after construction. Similarly, under everyday unloaded conditions, the rate of change in sag will decrease with time, over the life of the line.

2.2.9 Thermal Rating (Ampacity) of Bare Conductor

The electrical power conductors of overhead transmission lines carry relatively large electrical currents, and are self-supporting and energized at high voltage. As the current flowing through a conductor increases, the conductor's temperature increases, and it elongates. This elongation increases the sag of the conductor between support points, decreasing the clearance to people, ground, other conduc-

tors, buildings, and vehicles under the line. Beyond a certain "maximum allowable" sag, the line may flashover, resulting in either a power supply outage or injury to the public. If the conductor temperature remains high for an extended period of time, the strength of the conductor and tensioned connectors may decrease, resulting in mechanical failure during the next occurrence of ice or high wind loading.

Maximum Conductor Temperature

Modern transmission conductors are typically stranded from aluminum wires with a steel core added where increased strength is required. The temperature limit on all-aluminum or ACSR conductors is based on the maximum sag or maximum loss of strength in the aluminum. Temperature limits for normal ACSR conductors in use today range from 50°C to 150°C (122°F to 302°F). The temperature limit is normally selected at the time the line is designed. The higher this temperature, the higher the thermal capacity of the line, the higher maximum conductor sag, and the higher (or closer) the structures required to maintain ground clearance.

If aluminum or copper conductor temperatures remain high (above 95°C, or 203°F) for an extended period of time, the strength of the conductors and tensioned connectors may decrease, which eventually results in mechanical failure during the next ice or high wind occurrence. Generally, rating durations are kept short if maximum conductor temperatures are high (e.g., 4 hour maximum at 115°C (239°F) and 15 minutes at 125°C (257°F)).

Weather Conditions for Rating Calculation

Traditionally power utilities use fixed "worst-case" weather conditions in order to calculate (static) line ratings using heat balance methods (IEEE 738 1993b). The impact of changes in these weather parameters upon thermal line ratings depends on the specific rating situation. Consider an overhead line with 795 kcmil (402 mm^2 of aluminum), 26/7, "Drake" ACSR conductor, whose static rating is based upon a maximum allowable conductor temperature of 100°C with an air temperature of 40°C, full summer sun, and a wind blowing perpendicular to the conductor axis at 2 ft/sec. The static rating under these conditions is 1000 amp.

Clearly, if the current in this conductor is 1000 amp with the assumed weather conditions, the conductor temperature is 100°C. Table 2.2-6 shows how the conductor temperature is affected by small changes in weather conditions. For example, the conductor temperature drops to 92°C if there is no solar heating. The table also shows how the thermal rating (i.e., the current that yields a temperature of 100°C) changes with small changes in weather.

Note that, with the conductor at a reasonably high temperature and near "worst-case" heat transfer conditions, the overhead line rating and conductor temperature are very sensitive to wind direction, modestly sensitive to changes in wind speed and solar heating, and less affected by small changes in air temperature. Other minor factors are gradual changes in emissivity and absorptivity of the conductor with age and seasonal shifts in solar heating.

How Line Design Temperature Affects Line Ratings

Line design temperature is the maximum allowable conductor temperature for a particular line. As noted previously, for normal conventional ACSR, it varies from 50°C to 150°C. The impact of changes in the line design temperature upon thermal line ratings depends on the specific rating situation, but certain observations are possible.

Until the early 1970s, the National Electric Safety Code (National Electric Safety Code 1997) suggested that minimum electrical clearances were to be met at conductor temperatures up to 120°F (49°C). Line thermal capacity was typically calculated by conductor manufacturers for a conductor temperature of 75°C, a temperature sure to avoid possible annealing problems with aluminum and copper.

In the 1970s, the NESC changed and stated that the electrical clearances listed were to be met at "the maximum conductor temperature for which the line was designed to operate, if greater than 50°C, with no wind displacement" (excerpted from Rule 232.A.2). Thus the maximum allowable conductor temperature used in line rating calculations may vary from 50°C to 200°C according to available ground clearance and consistent with concerns about loss of tensile strength at temperatures above 90°C.

2.2.10 Transient Thermal Ratings

The need for increased thermal capacity in overhead lines is often driven by occasional sharp increases in load after

Table 2.2-6 Variation in Conductor Temperature and Rating with Weather Conditions (for 795 kcmil, 26/7, "Drake" ACSR conductor with a maximum allowable conductor temperature of 100°C, an air temperature of 40°C, full summer sun, and a wind blowing at 2fps perpendicular to the line)

Change in Assumed Weather Conditions	Line Rating @ 100°C (amperes)	Conductor Temperature at 1000 amps	
		(°C)	(°F)
None	1000	100	212
Air temp = 39°C	1010	99	210
No sun	1070	92	198
3ft/sec (0.91m/sec)	1090	90	194
Parallel wind	750	133	271

certain system contingencies. For example, an HV line might only reach high current levels after the loss of an EHV line or a critical generating facility. Since these occasions of high load occur infrequently and may persist for short time periods, it is often useful to consider transient thermal ratings for lines.

The temperature of an overhead power conductor is constantly changing in response to changes in electrical current and weather. With regard to transient rating calculations, however, weather parameters (wind speed and direction, ambient temperature, etc.) are assumed to remain constant; and any change in electrical current is limited to a step change from an initial current, I_i, to a final current, I_f, as illustrated in Figure 2.2-6 (IEEE 738 1993b).

Immediately prior to the current step change, the conductor is assumed to be in thermal equilibrium. That is, the sum of heat generation by ohmic losses and solar heating equals the heat loss by convection and radiation.

Immediately after the current step change, the conductor temperature is unchanged (as are the conductor resistance and the heat loss rate due to convection and radiation), but the rate of heat generation due to ohmic losses has suddenly increased. Therefore, the excess heat goes into heating the conductor to a higher temperature.

As time passes, the conductor temperature increases, yielding higher heat losses due to convection and radiation and somewhat higher ohmic heat generation due to the increased conductor resistance. After several "thermal time constants," the conductor temperature approaches its final steady-state temperature (T_f).

The transient thermal rating of an overhead line is dependent on the duration of the elevated current, the maximum temperature that the conductor is allowed to attain during the rating period, and on the starting temperature of the conductor. For example, with the Drake ACSR that was used for rating calculations previously, the transient ratings for various rating durations, maximum temperatures, and starting temperatures are shown in Table 2.2-7.

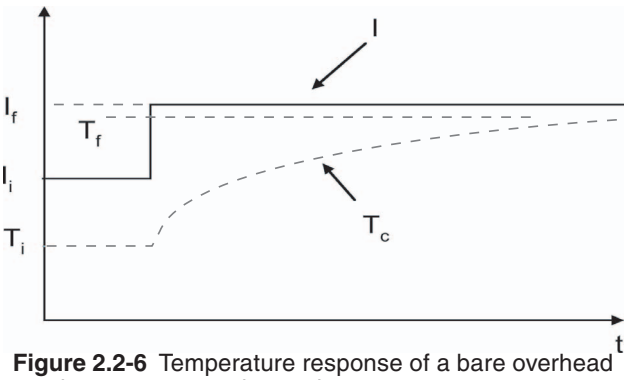

Figure 2.2-6 Temperature response of a bare overhead conductor to a step-change in current.

The advantage in using transient ratings is that the line can be loaded above its continuous rating without violating the constraints on sag clearance or annealing. The drawback is that the load must be reduced to the continuous rating or below within a short time (15 to 30 minutes). See, for example, references (Black and Rehberg 1985; Davidson et al. 1969).

2.3 CONDUCTOR SURFACE GRADIENTS

2.3.1 Introduction and Overview

The electric field at the surface of overhead transmission conductors (and other nearby conductive objects such as hardware, wood poles, trees, etc.) is an important quantity to the transmission engineer because it is the driving force behind all corona activity. As described extensively in Chapter 8, corona activity is the source of audible noise, radio noise, TV interference, ozone production, and some power loss. For HVDC lines, it also produces space charge. (Space charge is also produced by HVAC lines, but it tends to stay in the immediate vicinity of the conductors. There are claims that space charge has been measured downwind of HVAC lines, but the issue remains controversial.) In fact, the magnitude of this electric field is frequently used as a surrogate for the corona-related phenomena.

Because electric field is equal to the *gradient* of the space potential, i.e.,

$$\vec{E} = -\nabla V_{sp} \qquad 2.3\text{-}1$$

the electric field at the surface of conductors (and other objects) is referred to as the *surface gradient*. (The negative sign represents the fact that electric fields, by definition, point in the direction of decreasing potential.)

The exact, actual surface gradient around the periphery of a conductor is complicated by the non-uniformity of the surface caused by conductor stranding and by protrusions such as insects and raindrops. Also, corona itself affects the surface gradient (particularly on HVDC lines).

Table 2.2-7 Transient Ratings versus Rating Duration

Rating Duration (Min.)	Maximum Temperature (°C)	Starting Temperature (°C)	Rating (amps)
continuous	100	N/A	1040
60	100	50	1045
30	100	50	1090 (+ 4.8%)
15	100	50	1230 (+ 18.3%)
15	100	75	1135 (+ 9.1%)

Consequently, it has become standard practice to compute and specify the surface gradient of conductors as though they were smooth cylinders with diameters equal to their nominal diameters, and in a corona free environment. This is sometimes referred to as the *nominal surface gradient*.

The surface gradient of an overhead transmission conductor (or any conductive object) is perpendicular to the conductor everywhere over its surface. For a single conductor in free space (i.e., far from a ground plane), the surface gradient is constant around its periphery, as depicted in Figure 2.3-1.

However, the presence of a ground plane or other conductors causes the magnitude of the surface gradient to vary around the periphery (see Figure 2.3-2). Therefore, the surface gradient cannot be completely specified by a single number. The surface gradient varies around the periphery of a conductor with circular cross section, approximately

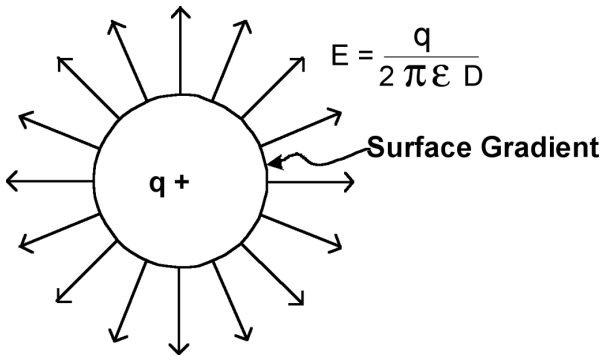

Figure 2.3-1 A positive line charge, q (C/m), and its resulting electric field lines. In general, D is the distance from the line charge, and at the conductor's surface, it is equal to the conductor's radius.

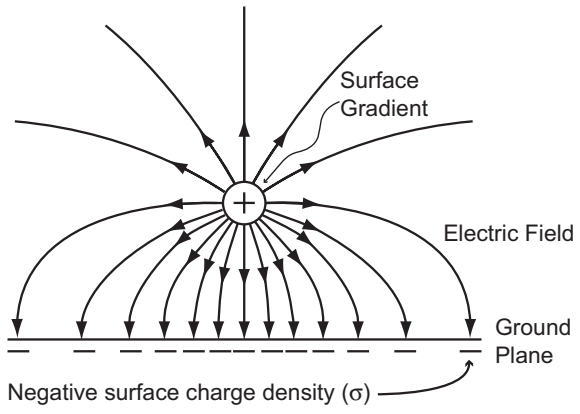

Figure 2.3-2 A positive line charge, q, above a ground plane. Note that a negative surface charge, σ, is induced on the ground plane, which causes the surface gradient to vary around the conductor's periphery.

following a sinusoidal relationship (see Equation 2.3-7). The average and the maximum surface gradients, and the point on the periphery where the surface gradient reaches its maximum value, fully characterize the electric field not only on the conductor surface but also in the immediate vicinity of the conductor where ac corona phenomena take place. The *maximum surface gradient* is the quantity chosen to characterize the corona effects of bundled conductors, together with diameters of the individual conductors, number of conductors in a bundle, and bundle diameter (see Subsection 2.3.4).

For a given conductor, the maximum surface gradient is simply the maximum value of the surface gradient around its periphery. However, for a bundle of two or more subconductors, the individual subconductors may have maximum surface gradients that differ from each other. This situation led an IEEE committee to define surface gradient terminology for bundled conductors as follows (IEEE Standard Definitions):

> *Maximum bundle gradient*: The highest of the maximum surface gradients of the individual subconductors in the bundle. For example, for a three-subconductor bundle with individual maximum surface gradients of 16.5, 16.9, and 17.0 kV/cm, the maximum bundle gradient is 17.0 kV/cm.
>
> *Average-maximum bundle gradient*: The simple arithmetic average of the individual maximum surface gradients of the individual subconductors in the bundle. For example, for a three-subconductor bundle with individual maximum surface gradients of 16.5, 16.9, and 17.0 kV/cm, the average-maximum bundle gradient is 16.8 kV/cm.

In most practical cases, the difference between the maximum bundle gradient and the average-maximum bundle gradient is about 1-4%. It was the practice at Project UHV and in previous editions of this reference book, and is the practice within IEEE, to use the average-maximum bundle gradient to characterize corona effects, and to simply use the term *maximum gradient*, *maximum surface gradient*, or just the term *gradient* in its place.

Various methods of calculating conductor gradients have been developed. An IEEE subcommittee has compared the results of several different methods and in general has found all to give comparable results (IEEE Subcommittee Report). The method discussed below is considered to be very accurate, and is the method used in previous editions of this reference book, in EPRI's Transmission Line Workstation (TLW), and in the applets.

2.3.2 Single Conductor

When a voltage, *V*, is applied to a single overhead conductor, it becomes charged due to the capacitance of the conductor to ground. This charge, *q*, is characterized by the charge-per-length (i.e., C/m) distributed along the conductor. For the commonly used 2-D approximation of the situation (infinitely long, straight conductor running parallel to a ground plane), *q* is constant along the conductor's length. The electric field at all points in space, including at the conductor's surface (the *surface gradient*), is due to this charge, and the induced charge on the ground plane below.

For calculation of the electric field, it can be assumed, to a very high degree of accuracy, that the charge *q* is distributed along a line running down the center of the conductor. Hence, the equivalent problem becomes that of a line charge above a ground plane. This problem is commonly treated in undergraduate textbooks on the subject (Reitz and Milford 1967).

The electric field at a distance *D* from a line charge *q* in free space is given by:

$$E = \frac{q}{2\pi\varepsilon D} \qquad 2.3\text{-}2$$

and is in a direction radially outward from the charge (ε is the permittivity of free space). Figure 2.3-1 shows a line charge *q* (assumed to be positive in polarity) running down the middle of a cylindrical surface coincident with that of the conductor it is representing, and its associated electric field lines emanating from that surface.

When a line charge resides above a ground plane, a surface charge density, σ (C/m^2), is induced on the plane below. The magnitude of the induced surface charge is greatest directly under the overhead line charge, and diminishes off to the sides. This surface charge is opposite in polarity to *q*. The electric field at all points in space is a vector superposition of the electric fields from *q* and from σ. The resulting electric field lines are depicted in Figure 2.3-2.

Solving for the numerical values of the charge densities *q* and σ, and then solving for the corresponding electric fields at points above the ground plane, is relatively difficult. However, a common method used to solve this problem is the *method of images* (Reitz and Milford 1967). In this method, the ground plane is conceptually replaced with a second line charge, -*q*, which is a "mirror image" of *q*. Because of the location of this image charge, every point on the ground plane is equidistant from a positive charge and a negative charge of equal magnitudes. Hence the potential on the plane remains zero, and is, therefore, still a "ground" plane. This concept is depicted in Figure 2.3-3.

As far as all points above the ground plane are concerned, the situations of Figure 2.3-2 and Figure 2.3-3 are identical. However, solving the two-line charge problem of Figure 2.3-3 is much simpler than solving the problem of Figure 2.3-2. Once the magnitude of the charge *q* is determined, Equation 2.3-2 can be used to determine the electric field at all points in space from each of the two charges.

The space potential, V_{sp}, at any point in space at distances D_1 and D_2 from charges *q* and –*q*, respectively, is given by:

$$V_{sp} = \frac{q}{2\pi\varepsilon}\ln\frac{D_2}{D_1} \qquad 2.3\text{-}3$$

If the charge q is placed in the center of the conductor, the points at the conductor surface are only approximately at the same potential. The approximation is acceptable when the conductor diameter is much smaller than the height above ground. In this case, applying Equation 2.3-3 to the surface of a real overhead conductor results in:

$$P = \frac{1}{2\pi\varepsilon}\ln\frac{4H}{D} \qquad 2.3\text{-}4$$

Where:

D = the conductor diameter.
H = height of the conductor above the ground plane (assumed to be large compared to *D*).
V = voltage applied to the conductor.

For a given problem, Equation 2.3-4 can be solved for the charge *q*, and Equation 2.3-2 can then be used to determine

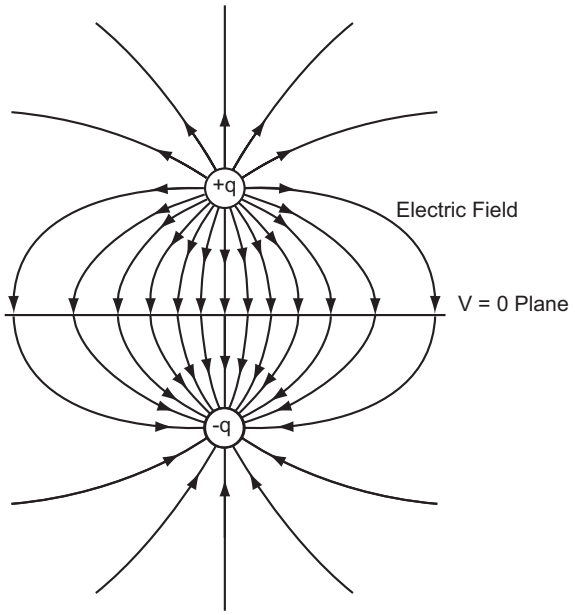

Figure 2.3-3 A positive line charge, *q*, its image, -*q*, and their resultant electric field lines.

the electric field at the conductor's surface—i.e., the surface gradient.

In addition, the ratio of voltage to charge is frequently referred to as the Maxwell potential coefficient, *P*. From Equation 2.3-4:

$$P = \frac{1}{2\pi\varepsilon}\ln\frac{4H}{D} \qquad 2.3\text{-}5$$

This variable has units of m/F, and its inverse is the capacitance-per-length of the conductor to ground (refer to Chapter 7 for greater detail).

As a simple example, consider the case of a single overhead conductor that is 3.42 cm in diameter, located 7.5 m above a level ground, and energized at a system voltage of 230 kV (132 kV to ground).

With Equation 2.3-5, the Maxwell potential coefficient is:

$$P = 1.219\times10^{11}\,\text{m/F}$$

Its inverse is:

$$1/P = 8.205\times10^{-12}\,\text{F/m}$$

This latter term represents the capacitance-per-length of the conductor to ground.

Using Equation 2.3-4 to determine the charge yields:

$$q = 1.09\times10^{-6}\,\text{C/m}$$

This charge is conceptually placed down the middle of the conductor. The magnitude of the electric field produced by this line charge, at a distance away equal to the radius of the conductor, represents the average electric field around the periphery of the conductor (i.e., the *average surface gradient*). With Equation 2.3-2, this average surface gradient is:

$$E_{AVG} = 11.46\ \text{kV/cm}$$

The electric field at any single point around the periphery of the conductor is due to the vector sum of the electric field due to the charge *q*, and its image *-q*. If the radius is much smaller than the height above ground, the contribution of the image charge may be neglected and the gradient may be considered the same all around the periphery. In reality, the surface gradient is maximum at the bottom of the conductor. To calculate the maximum gradient, the line charge must be placed not in the center of the conductor, but at a point just below the center such that the conductor surface under the action of the charge and its image becomes an equipotential. This point is a little below the center by a distance, *x*, such that $(2H\text{-}x)\cdot x = r^2$, (therefore, $x \approx r^2/2H$), where *r* is the conductor radius. This relationship is derived by applying Equation 2.3-6 to the top and bottom of the conductor.

For an example, consider the electric field at the very bottom of the conductor's surface, where the surface gradient is at its maximum around the conductor's periphery (i.e., the *maximum surface gradient*). The situation is illustrated in Figure 2.3-4. The net electric field is, according to Equation 2.3-2:

$$E_{MAX} = \frac{q}{2\pi\varepsilon(r-x)} + \frac{q}{2\pi\varepsilon(2h-r)} = 11.486\ \text{kV/cm}$$

The surface gradient around the periphery of the conductor can be obtained from Applet CC-1. This applet provides plots of surface gradient versus the angle θ (θ being measured counter clockwise from the right-side horizontal as shown in Figure 2.3-4). A corresponding plot of *E* (i.e., surface gradient) versus θ is shown in Figure 2.3-5. Note that the range on the vertical axis in Figure 2.3-5 is very small, and the sinusoidal variation is very small for this case. In some cases, particularly for individual subconductors of a bundle, the peak-to-peak variation can be much larger.

2.3.3 Multiple Conductors

The general method for calculating surface gradients for multiple conductors is similar to that above for a single conductor, although the mathematics becomes tedious and the need for a computer is obvious. The case of multiple conductors includes the conductors of multiple phases (including ground wires), as well as the individual subconductors of conductor bundles (i.e., the method applies to all the individual conductors for a given transmission corridor).

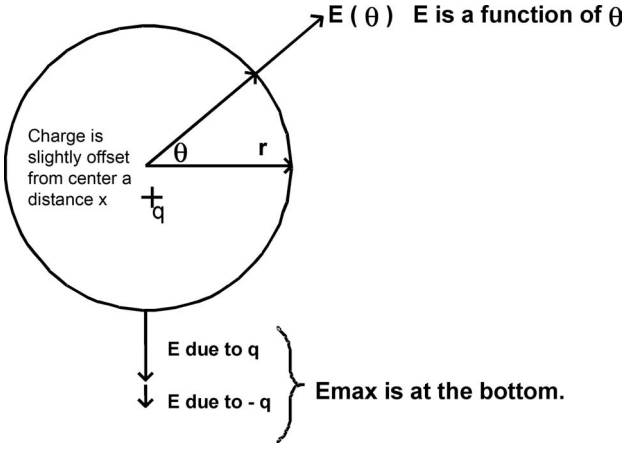

Figure 2.3-4 The surface gradient is a function of position around the conductor's periphery; for a single conductor above a ground plane, the maximum surface gradient is on the bottom.

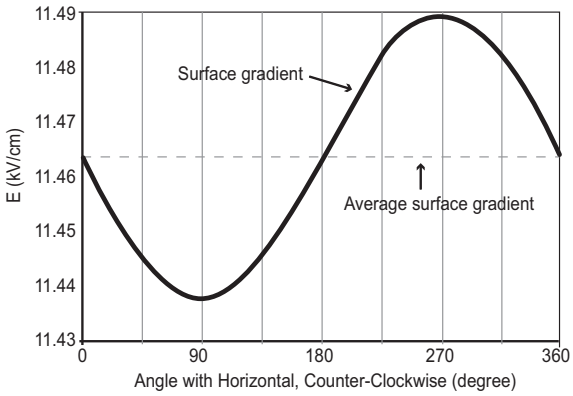

Figure 2.3-5 Surface gradient of a single conductor above a ground plane as a function of position, θ, around its periphery. The maximum surface gradient is at the bottom (θ= 270 degrees).

However, there is one important difference between the simple case of a single overhead conductor, and the case of multiple conductors. In the single-conductor case, a single image charge was required. But for the multiple-conductor case, each conductor requires the introduction of several image charges (this approach is referred to as the method of successive images).

To explain the method, an example is described below in some detail for the simple case of two conductors. The same method can be extended to include any number of conductors. However, it is useful at this point to digress a little to discuss the concept of equipotential surfaces for a pair of parallel line charges that are equal in magnitude and opposite in polarity.

It is a fact, commonly presented in textbooks, that the equipotential surfaces for a pair of parallel line charges, equal in magnitude and opposite in polarity, are cylindrical surfaces, as depicted in Figure 2.3-6 (Reitz and Milford 1967). This figure shows a positive line charge, q, parallel to a second line charge, $-q$, and a few of the resulting cylindrical equipotential surfaces (in fact, the ground plane midway between the two charges can be thought of as the surface of an equipotential cylinder infinite in diameter). The requirement for any of the equipotential surfaces is that the space potential calculated with Equation 2.3-3 remains constant over the surface, which requires that

$$D_1 / D_2 = \text{constant} \qquad 2.3\text{-}6$$

where D_1 and D_2 are the distances from the two line charges.

Each equipotential surface is cylindrical. If the distance between the charges is L, and the center of an equipotential surface is at a distance x from the charge $+q$, the following relations exist (in order to satisfy Equation 2.3-6) between the charge, the radius of the equipotential cylinder, r, and the cylinder potential, V.

$$x \cdot (L + x) = r^2 \qquad 2.3\text{-}6a$$

$$V = \frac{q}{2\pi\varepsilon} \ln \frac{r}{x} \qquad 2.3\text{-}6b$$

This fact is the reason why a line charge and its image can be used to represent an energized conductor for the single-conductor case above. The surface of such a conductor is an equipotential surface (as is the entire surface of any conductor), and it is cylindrical in shape. Therefore, the potential throughout space can be obtained by defining a pair of line charges (plus and minus q) such that the equipotential surface representing the conductor's surface is at the conductor's voltage. Also, it can be shown that the solution for the electric field throughout the region of concern is unique once the potentials at the surfaces of the conductor and ground plane are set (Jackson 1975).

However, when a second conductor is introduced, along with its image, the situation is altered. Now there are four line charges, and the surface of the first conductor is no longer an equipotential surface. However, the problem can

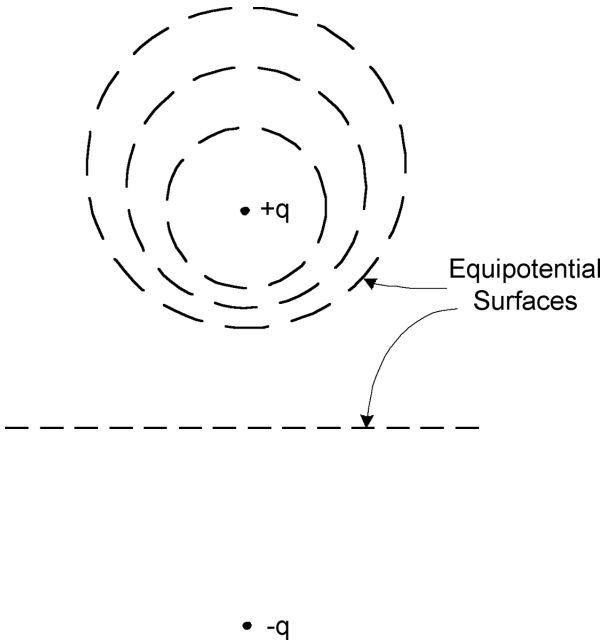

Figure 2.3-6 Two infinitely long parallel line charges of equal magnitude and opposite polarity, q and $-q$, and their resultant cylindrical equipotential surfaces.

be solved using the method of successive images (Maruvada and Janischewskyj 1969). The lack of equipotentiality can be remedied by adding within the surface of the first conductor two more "second-order" images that are equal in magnitude and opposite in polarity to the line charge representing the second conductor and its image, and located such that pairs of line charges hold the surface at equipotential by satisfying Equation 2.3-6. An example of this method is illustrated in Figure 2.3-7, and explained below.

Referring to Figure 2.3-7, two energized parallel conductors, with surfaces labeled S1 and S2, are placed above a ground plane. The linear charge densities along these conductors, q_1 and q_2, respectively, are placed at distances x_1 and x_2 below the centers of the conductors. Their "first-order" images, $-q_1'$ and $-q_2'$, are placed at the respective mirror locations below the ground plane.

The pair of charges, q_1 and $-q_1'$, will cause the surface S1 to be an equipotential. However, the pair of charges, q_2 and $-q_2'$, does not create an equipotential on surface S1. Hence, to maintain the equipotentiality of surface S1, two "second-order" image charges, $-q_2''$ and q_2'', must be introduced. Note that this procedure is allowed because it is consistent with reality. After all, q_2 and its image do exist, and S1 is an equipotential, therefore, q_2 and $-q_2'$, must have images, $-q_2''$ and q_2'', within S1. The positions of the second-order images are such as to satisfy Equation 2.3-6.

Note that the introduction of $-q_2''$ and q_2'' does not change the net charge on S1, since they are equal in magnitude but opposite in polarity, nor does it change the average gradient on the surface S1. It will, however, change the maximum surface gradient on S1 and will not maintain the ground plane and S2 as equipotentials. In order to maintain the ground plane as an equipotential line, images of $-q_2''$ and q_2'' must be placed below the plane. In order to maintain S2 as an equipotential, line images of $-q_2''$ and q_2'' must be placed inside S2. These third-order images will increase the accuracy. Higher-order images may be introduced, and the process can be carried out until the error in the definition of equipotential surfaces becomes negligible. In practice, consideration of second-order images is amply sufficient for transmission-line configurations where the conductors' diameters are significantly smaller than their spacings. This limitation should be considered if

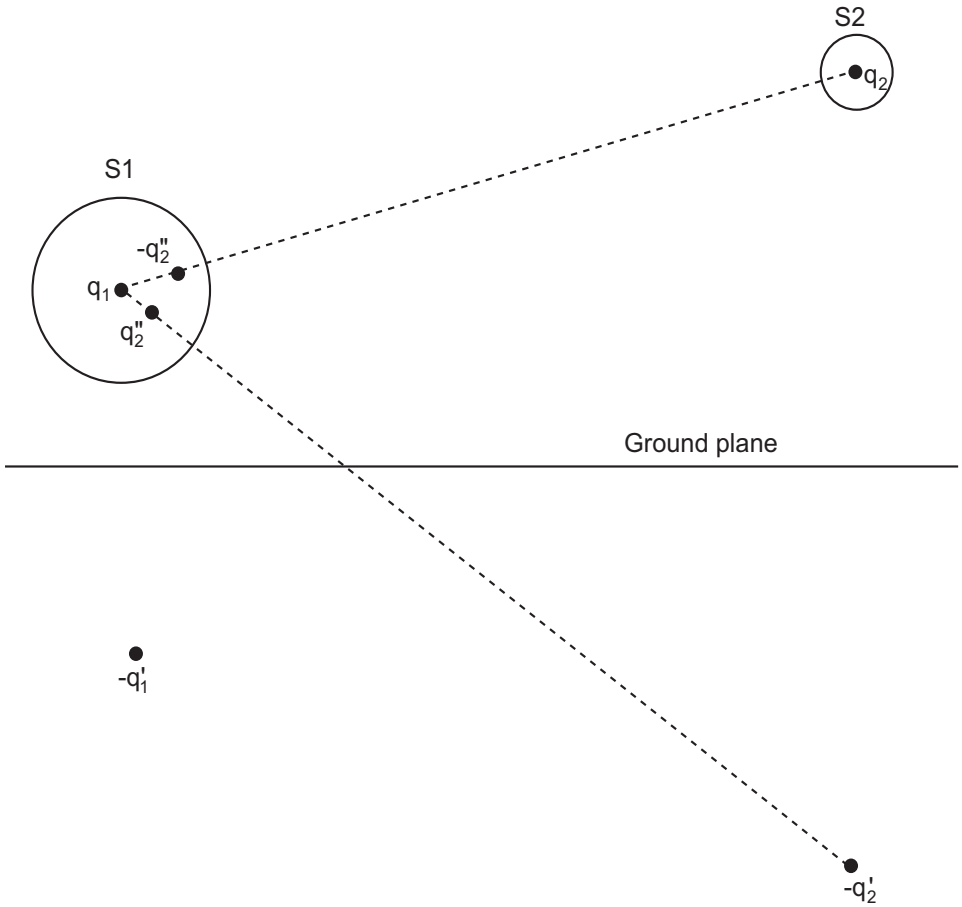

Figure 2.3-7 Two parallel conductors above a ground plane, with surfaces S1 and S2, and all the line charges used to calculate the surface gradient at all points around the periphery of S1.

this technique is applied to unusual conductor configurations with very small spacings.

To summarize, the charge pairs, (q_1, $-q_1'$), (q_2, $-q_2''$), and ($-q_2'$, q_2'') each produce an equipotential on the surface S1. Also, the position of all the images must be such that Equation 2.3-6 is satisfied (can be easily done by applying Equation 2.3-6 to opposite sides of the equipotential cylinder).

The entire procedure outlined above for S1 also holds for S2. In fact, this procedure is extended to include all conductors that may reside within a transmission corridor.

These line charges are conceptual constructs; however, they do represent the capacitive charge that is distributed on the surface of conductors. In the example of Figure 2.3-7, the line charge q_1 represents the magnitude of the capacitive charge and is solely responsible for the average surface gradient around S1. The contributions from all the other charges represent the nonuniform distribution of charge (and, therefore, nonuniform surface gradient) around the periphery of S1 due to the presence of the ground plane and other conductors.

2.3.4 Conductor Bundling

The term *conductor bundle* (sometimes simply referred to as *bundle*) is used above and elsewhere throughout this reference book. Conductor bundling is a common technique used by transmission-line designers to control certain performance parameters, especially for higher voltage lines. A conductor bundle is an assembly of two or more conductors used for a single phase of an overhead transmission line, employing spacers to maintain a predetermined configuration. The individual conductors are called subconductors. Figure 2.3-8 shows a photo of a 500-kV line utilizing conductor bundles of four subconductors each.

Using a conductor bundle increases the effective size of a transmission line's phase without having to use a single larger conductor. A larger phase conductor offers several advantages, along with some obvious disadvantages (cost, weight, wind and ice loading, etc.). These advantages include:

- Greater surge impedance loading (SIL)
- Greater current-carrying capacity
- Lower surface gradient

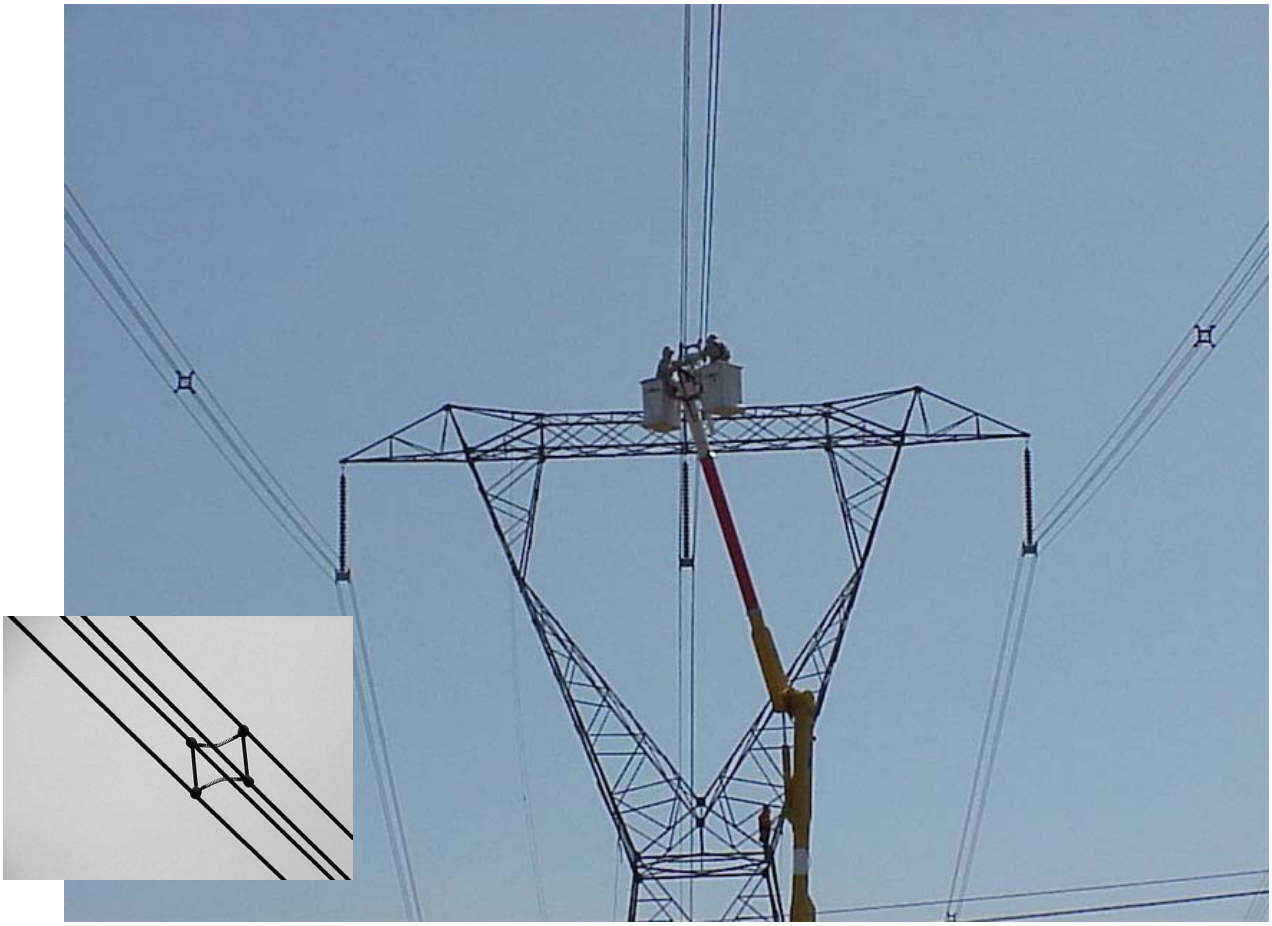

Figure 2.3-8 500-kV line with three four-subconductor bundles (and inset).

Employing conductor bundles can be an effective means for maximizing the advantages relative to the disadvantages, including surface gradients, which is the focus here.

As described above, the subconductors of a conductor bundle each have their own individual surface gradients, which vary around their periphery with the following sinusoidal relationship:

$$E(\theta) = E_{av}\left[1 + \frac{d}{d_b}(n-1)\cos(\theta)\right] \qquad 2.3\text{-}7$$

Where:

E_{av} = average subconductor surface gradient (given by Equation 2.3-2).
d = subconductor diameter.
d_b = bundle diameter (diameter of an imaginary circle on which the subconductors lie).
n = number of subconductors.
θ = angle as defined in Figure 2.3-9.

From Equation 2.3-7, it can be seen that the maximum surface gradient around a subconductor is at $\theta = 0$.

It is an interesting fact that, everything else being the same, the surface gradient depends only on the outside diameter of a conductor (a result deduced from Equations 2.3-2 and 2.3-4). Therefore, a hollow pipe or a solid pipe of the same diameter would have the same surface gradient. Conductor bundling is a useful method for increasing the effective size of a transmission line's phase without increasing the amount of conductor material required. Another tool that has been used in some rare cases is the so-called air-expanded conductor (see Figure 2.3-10). In this case, the diameter of a conductor is increased by leaving voids inside.

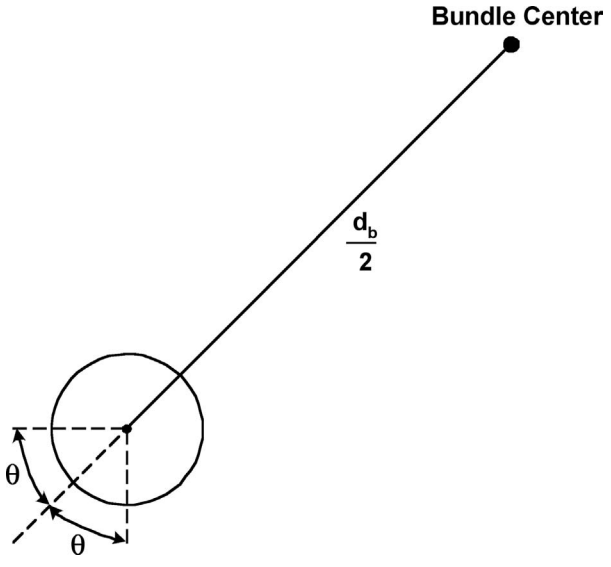

Figure 2.3-9 Definition of terms for a subconductor of a conductor bundle.

2.3.5 Toroidal Shielding Electrodes (Corona Rings)

The analysis of conductor gradients to this point has been limited to collections of long, parallel conductors over a ground plane. At the ends of these conductors, and at the ends of bushings and other station equipment, electrodes in the shape of toroids are often used to lower the surface gradient there. Because these "ends" are relatively "pointed," surface gradients there would be elevated and corona may result. As such, these toroidal electrodes are commonly referred to as corona rings. Figures 2.3-11 and 2.3-12 show photographs of corona rings on station equipment and conductor bundles, respectively.

Although these devices are used to prevent corona on conductors, it is possible for them to be configured such that they experience corona themselves due to their surface

Figure 2.3-10 An air-expanded conductor. This can be used to increase the outside diameter of a conductor without increasing its weight.

Figure 2.3-11 Toroidal corona rings on station equipment.

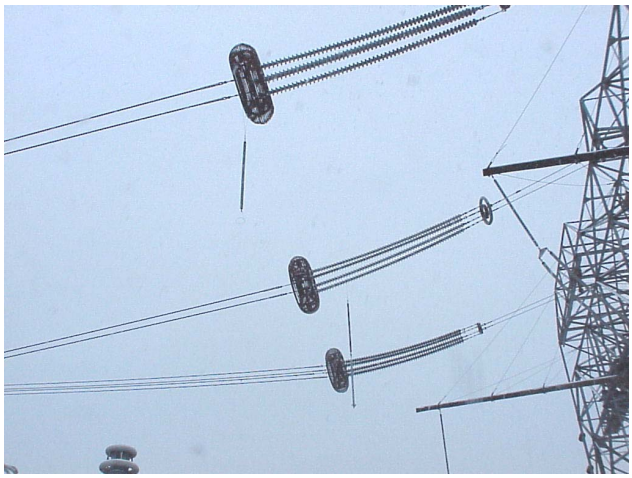

Figure 2.3-12 Toroidal corona rings at the ends of conductor bundles.

gradients. The surface gradient of a toroidal corona ring is characterized by the maximum value on its surface. The maximum surface gradient depends on the voltage applied to the toroid, its size, and its position in space with respect to other objects. Its size is specified by its inner and outer diameters, and its position in space is specified by the location of its center and the orientation of its axis.

Applet CC-3 is for computing the maximum surface gradients on toroids (as single numbers) and other simple objects. Refer to Chapter 8 for discussions on the evaluation of corona performance based on maximum surface gradients.

2.3.6 Variation of Surface Gradient with Design Parameters—Applets and Examples

While the theoretical foundation to calculate surface gradients is quite simple, the need for computer programs can be appreciated. Four applets are included with the reference book to help the user evaluate surface gradients. These applets are named CC-1, CC-2, CC-3, and CC-6. Below are brief descriptions of each of these applets, including examples. The purpose here is not only to introduce the reader to the applets, but also to help the reader understand some of the relationships between surface gradients and transmission-line design parameters.

Applet CC-1: Conductor Surface Gradients (2D)

Applet CC-1 provides the surface gradients of all the conductors (and subconductors) within a transmission corridor, and presents the results in tabular and graphical forms. The graphs are plots of surface gradient versus angle. The angle is defined counterclockwise from the right-side horizontal (see Figure 2.3-4). The conductors can be lone, or part of a bundle. The calculations are performed using the 2D approximation that the conductors are straight, infinitely long, and parallel to each other and the ground plane.

Consider the simple case of a three-phase 230-kV transmission line with single-phase conductors 3.42 cm in diameter, phase spacings of 4.5 m, and a height above ground of 16 m. Figure 2.3-13 shows the graphical result for the center phase conductor provided by Applet CC-1.

This graph clearly shows the sinusoidal nature of the surface gradient around the outside perimeter of the conductor (although the variation is typically very small for single conductor phases). It can be seen that the maximum surface gradient is 14.298 kV/cm, and occurs at the bottom of the conductor, and the minimum surface gradient is 14.268 kV/cm at the top of the conductor. Every conductor or subconductor within a transmission corridor will have its own surface gradient characteristics; however, they all are sinusoidal around the conductor's perimeter.

Applet CC-2: Conductor Surface Gradients (3D)

The surface gradient not only varies around the periphery of a conductor, but it also varies along the length of a conductor due to change in its elevation, change in terrain, change in relative position to other conductors, and the presence of objects. Applet CC-2 lets the user compute and plot the surface gradient (maximum and average) along its length. This applet accepts line geometry, voltage, objects, and terrain variation, and will provide surface gradients as a function of longitudinal distance down the line.

Applet CC-6: Sensitivity Analysis

This applet *accepts base case number*, and the *parameter to be varied*, and will produce a plot of *surface gradient* versus *varied parameter*. Parameters that can be varied include conductor (or subconductor) diameter, phase spacing, and conductor heights above ground. Below are graphical examples for the same 230-kV base case as described above for Applet CC-1.

Figure 2.3-14 shows how the surface gradient of the example varies with diameter of the conductors. It is interesting

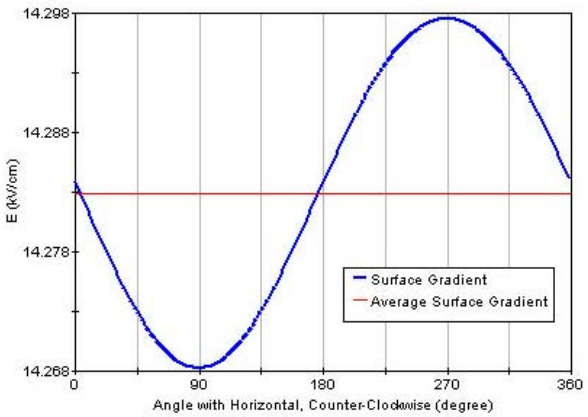

Figure 2.3-13 Plot of surface gradient around the outside perimeter of a conductor, as provided by Applet CC-1.

to note that with a greater size conductor, the net charge on the conductor increases (see Equation 2.3-4) and, therefore, the electric field on the ground increases, but the surface gradient decreases.

Figure 2.3-15 shows how surface gradient of the example varies with phase spacing. As the phase spacing increases, the surface gradient decreases. Note that this is not true if the phases are of the same phase, such as in a double-circuit case.

Applet CC-3: Surface Gradient on Corona Toroidal Shields

Applet CC-3 computes the maximum surface gradient, as a single number, for toroids (and other simple objects). A toroid is specified by its voltage, its inner and outer diameters, the location of its center, and the orientation of its axis (refer to Figure 2.3-16). Refer to Chapter 8 for discussions on the acceptable levels of surface gradient for corona performance.

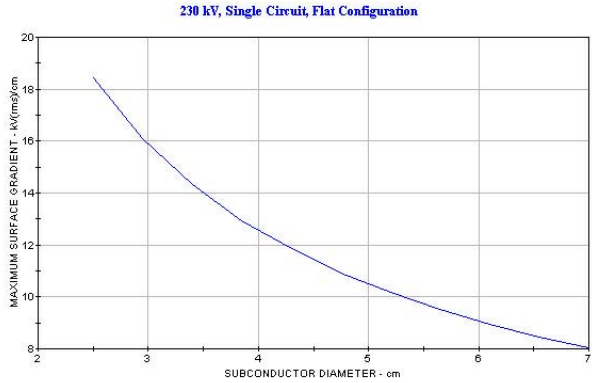

Figure 2.3-14 Plot of surface gradient versus conductor diameter as provided by CC-6.

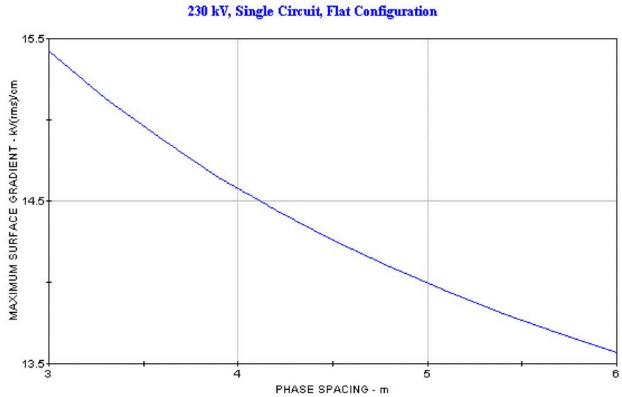

Figure 2.3-15 Plot of surface gradient versus phase spacing as provided by CC-6.

2.4 BASIC TRANSMISSION LINE IMPEDANCE AND ADMITTANCE PARAMETERS

2.4.1 Introduction

Knowledge of impedance and admittance parameters of transmission lines is essential for power system studies such as power flow, stability and fault investigations. These studies generally rely on a lumped parameter pi equivalent circuit representation for short lines, as given in Figure 2.4-1, where R represents conductor resistance and X_L represents series inductive reactance. Half of the line shunt capacitance C is placed on each side of the circuit, or $2X_C$ on each side.

A complete impedance representation of a three-phase power transmission line requires 3 x 3 complex matrices of self and mutual series and shunt impedances. This level of detail is not necessary for many system analysis purposes. In order to simplify the analytical representation, a matrix transformation has been developed to transform the phase impedances into "symmetrical component" impedances, called positive sequence, negative sequence, and zero sequence. Each sequence network is a single-phase circuit

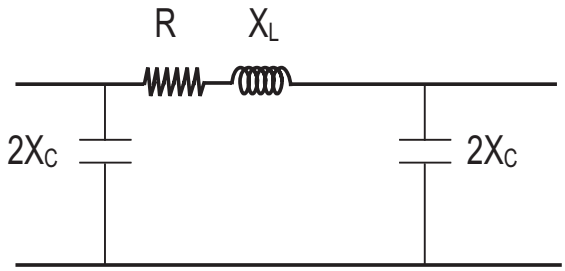

Figure 2.4-1 Pi equivalent circuit for transmission line.

representing certain aspects of the system behavior. Positive sequence values represent the normal steady-state operation of the power system, and are adequate by themselves for many studies when it is sufficient to consider the line to be in balanced, steady-state, three-phase operation. This section presents a brief overview of positive sequence inductive and capacitive reactance of transmission lines. Because balanced phase currents sum to zero, earth return effects are usually negligible in a positive sequence analysis. For a detailed exposition of symmetrical components, see one of the standard texts (Gross 1979; El-Hawry 1983; Grainger and Stevenson 1994).

In order to analyze cases of unbalanced construction or operation, it is usually necessary to know the zero sequence impedance and admittance in addition to the positive sequence. The zero sequence impedance includes the effects of the current return path in the earth. The negative sequence impedance of a passive element, such as a transmission line, is equal to the positive sequence impedance. For some purposes, either a complete matrix of self and mutual phase inductive and capacitive impedances, or a complete matrix of self and mutual sequence inductive and capacitive impedances is required. These additional terms in the inductive reactance matrix include the effects of conducting earth and are addressed in Section 2.5. Ground effects and conductor skin effects are frequency-sensitive. Thus, when knowledge of line parameters for surge propagation or other transient studies is required, it is necessary to determine how the impedance or admittance elements vary with frequency.

Applet CC-5 contains calculations for phase and sequence inductive and capacitive reactances. This section presents a hand calculation method for positive sequence inductive and capacitive reactance for transmission lines with symmetrical phase conductor bundles. Impedances of transmission lines with asymmetrical phase conductor bundles can be calculated with Applet CC-5.

2.4.2 Positive Sequence Inductive Reactance

The positive sequence inductive reactance X_1 of a three-phase transmission line is customarily given as the sum of the reactance-to-one-meter (foot) term X_a and the spacing factor term X_d. The "one-meter" and "one-foot" terms were defined in Section 2.2.6.

The relation between the one-meter (foot) and spacing factor terms is given in Equations 2.4-1 through 2.4-3.

$$X_1 = k \log (\text{GMD} / \text{GMR}) \qquad 2.4\text{-}1$$

Expanding Equation 2.4-1 gives

$$X_1 = k \log (\text{GMD}) + k \log (1 / \text{GMR}) \qquad 2.4\text{-}2$$

$$X_1 = X_d + X_a \qquad 2.4\text{-}3$$

$$X_d = k \log (\text{GMD}) \qquad 2.4\text{-}4$$

$$X_a = k \log (1 / \text{GMR}) \qquad 2.4\text{-}5$$

where in SI units:

k = $2.895 \bullet 10^{-6} f = .0001737$ at 60 Hz.
f = frequency in Hertz.
GMD = geometric mean distance between the phase conductor bundles in meters (Equation 2.4-6).
GMR = geometric mean radius of the phase conductor bundle in meters from Equations 2.4-9 and 2.4-11 for single or bundled conductors.
X_d = inductive reactance spacing factor in ohms per meter (Equation 2.4-4 and Table 2.4-1).
X_a = inductive reactance at one-foot spacing in ohms per meter (Equation (2.4-5).

In English units for use with the conductor tables:

k = $4.657 * 10^{-3} f = 0.2794$ at 60 Hz.
f = frequency in Hertz.
GMD = geometric mean distance between the phase conductor bundles in feet (Equation 2.4-6).
GMR = geometric mean radius of the phase conductor bundle in feet from conductor data tables or Equations 2.4-9 and 2.4-11 for single or bundled conductors.
X_d = inductive reactance spacing factor in ohms per mile (Equation 2.4-4 and Table 2.4-1).
X_a = inductive reactance at one-foot spacing in ohms per mile (Equation 2.3-5).

The geometric mean distance (GMD) is the geometric mean of the distances between the phase conductor bundles

$$\text{GMD} = \sqrt[3]{D_{12} D_{23} D_{31}} \qquad 2.4\text{-}6$$

where D_{12}, D_{23}, and D_{31} are the distances between centers of the three-phase bundles of a three-phase circuit. X_d can then be expanded as:

$$\begin{aligned} X_d &= k \log (\text{GMD}) \\ &= (1/3)(k \log D_{12} + k \log D_{23} + k \log D_{31}) \end{aligned} \qquad 2.4\text{-}7$$

The reactance to one meter (foot) spacing X_a is:

$$X_a = k \log (1 / \text{GMR}) \qquad 2.4\text{-}8$$

where the geometric mean radius (GMR) is the geometric mean radius of the phase conductor bundle. For a single conductor per phase, GMR is given in the conductor data in the tables in Appendix 2.1. For a single cylindrical conductor with uniform current density (dc, no skin effect), the GMR is:

$$GMR = (e^{-\mu_r/4})r \qquad 2.4\text{-}9$$

Where:

r = radius of the conductor.

μ_r = relative permeability of the conductor (approximately equals 1 for aluminum and copper).

$$\text{GMR} \cong 0.7788\, r \quad \text{for copper and aluminum} \qquad 2.4\text{-}10$$

For a symmetrically bundled conductor:

$$\text{GMR}_B \cong [n(\text{GMR}_C)\, r_b^{(n-1)}]^{1/n} \qquad 2.4\text{-}11$$

Where:

n = number of subconductors per phase.

GMR_B = geometric mean radius of the conductor bundle.

GMR_C = geometric mean radius of each subconductor.

r_b = bundle radius.

When the bundle size is described by bundle spacing (the distance between adjacent subconductors of a symmetrical bundle) then:

$$r_b = s / \left[2\sin(\pi / n)\right] \text{ when } n > 1 \qquad 2.4\text{-}12$$

$$r_b = 0 \quad 0^0 = 1 \text{ when } n = 1 \qquad 2.4\text{-}13$$

s = bundle spacing.

Table 2.4-3 shows the effect of conductor bundling on X_a, and consequently on the line series inductive reactance for the same phase geometry (same X_d for each case). For approximately the same total cross section area of aluminum in the conductor bundle, dividing up the aluminum into a greater number of smaller subconductors decreases the line series reactance. This has been a factor in the decision to use a larger number of subconductors per phase in designing long transmission lines.

Conductor resistance from the conductor data tables is vectorially added to the inductive reactance to give the complete positive sequence series impedance.

16	2683	Pigeon	—	60	-0.182	0.464	0.282	0.35

Example:
Consider the 345-kV single-circuit flat configuration from the list of cases given in Appendix 2-1. Data for the line are:

- Twin 954 kcmil Cardinal subconductors per phase
- Flat configuration, 7.5 m phase spacing, 12.5 m average conductor height

This simplified calculation ignores the shield wires, which have a negligible effect on positive sequence inductive reactance.

The first step is to calculate the geometric mean distance of the three phases from Equation 2.4-4. $D_{12} = D_{23} = 24.6$ ft and $D_{31} = 49.2$ ft, giving GMD from Equation 2.4-4 = 31.015 ft. From Equation 2.4-5 $X_d = 0.4167$ Ω/mile.

Each phase consists of a bundle of twin Cardinal subconductors of 1.196 in. diameter. From Table A2.1-1 in Appendix 2.1, GMR_C for Cardinal is 0.0404 ft. For a two-subconductor bundle of bundle radius 0.75 ft, the bundle GMR is given by $GMR_B = [(2)(0.0404)(.75)]^{1/2} = 0.2462$ ft. From Equation 2.4-7, $Xa = 0.1701$ Ω/mile.

The positive sequence reactance is given by Equation 2.4-3: $X_1 = X_d + X_a = 0.5868$ Ω/mile.

Applet CC-5 gives the same positive sequence reactance.

2.4.3 Positive Sequence Capacitive Reactance

A development parallel to that for inductive reactance can be given for positive sequence capacitive reactance of a three-phase transmission line is given by:

$$X_c = k' \log (GMD / r) = k' \log (GMD) + k' \log (1/r) = X'_d + X'_a \quad 2.4\text{-}14$$

where in SI units:
k' = $6.588 \bullet 10^9 / f = 109.8 \bullet 10^6$ at 60 Hz.
f = frequency in Hertz.
GMD = geometric mean distance in meters (same value as for inductive reactance).
r = effective radius of the conductor in meters.
X_C is in ohm-meters.

In English units for use with the conductor tables:
k' = $4.093/f = 0.06822$ at 60 Hz.
f = frequency in Hertz.
GMD = geometric mean distance in feet (same value as for inductive reactance)
r = effective radius of the conductor in feet.
X_C is in megohm-miles.

The capacitive reactance spacing factor (values are given in Table 2.4-2):

$$X'_d = k' \log (GMD) \quad 2.4\text{-}15$$

The capacitive reactance at one-meter (foot) spacing is:

$$X'_a = k' \log (1/r) \quad 2.4\text{-}16$$

The effective radius, r_{eq}, for symmetrically bundled conductors is:

$$r_{eq} = (n r r_b^{n-1})^{1/n}$$

Where:
n = number of subconductors per phase.
r = radius of each subconductor.
r_b = bundle radius.

When the bundle size is described by the bundle spacing (the distance between adjacent subconductors of a symmetrical bundle), then;

$$r_b = s / \left[2 \sin(\pi / n)\right] \text{ when n } > 1 \quad 2.4\text{-}17$$

$$r_b = 0 \quad 0^0 = 1 \quad \text{when n} = 1 \quad 2.4\text{-}18$$

s = bundle spacing.

Table 2.4-4 shows the effect of conductor bundling on X'_a, and consequently on the line shunt capacitive reactance for the same phase geometry (same X'_d for each case). For approximately the same total cross-section area of alumi-

Table 2.4-4 Effect of Bundling on Capacitive Reactance

No. of Conductors	Total (kcmil)	Conductor Code Name	Bundle Spacing (in.)	Bundle Diameter (in.)	X'_a (megohms-miles)	X'_d (megohms-miles)	X_c (megohms-miles)	X_c (per unit)
1	2515	Joree	—	—	0.0755	0.1134	0.1889	1.00
2	2544	Pheasant	18	18	0.0363	0.1134	0.1497	0.79
3	2625	Crane	18	20.5	0.0223	0.1134	0.1357	0.72
4	2544	Grosbeak	18	25.5	0.0120	0.1134	0.1254	0.66
6	2392	Ibis	—	36	-0.0020	0.1134	0.1114	0.59
8	2400	Ostrich	—	40	-0.0078	0.1134	0.1057	0.56
12	2539	Penguin	—	50	-0.0168	0.1134	0.0966	0.51
16	2683	Pigeon	—	60	-0.0236	0.1134	0.0898	0.48

num in the conductor bundle, dividing up the aluminum into a greater number of smaller subconductors decreases the line shunt reactance, and increases the line-charging current.

Example:
Consider the same 345-kV single-circuit flat configuration used for calculation of inductive reactance in the previous section. This simplified calculation ignores the effect of shield wires and the ground plane, which have a minor effect on positive sequence capacitive reactance.

The geometric mean distance of the three phases is the same as calculated from Equation 2.4-4 for inductive reactance. $D_{12} = D_{23} = 24.6$ ft and $D_{31} = 49.2$ ft, giving GMD from Equation 2.4-4 = 31.015 ft. From Equation 2.4-12, $X'_d = 0.1018$ megohm-mile.

Each phase consists of a bundle of twin Cardinal subconductors of 1.196 in. diameter. Capacitance calculations use the outer conductor diameter rather than the conductor GMR used for inductance calculations. This is because the electric field is zero inside the conductor, while a nonzero magnetic field exists within the conductor. Thus, the radius to use for capacitance calculation is 0.0498 ft. For a two-subconductor bundle of bundle radius 0.75 ft, the bundle GMR is given by $GMR_B = [(2)(0.0498)(.75)]^{1/2} = 0.2733$ ft. From Equation 2.4-13, $X'a = 0.0384$ megohm-mile.

The positive sequence reactance is given by Equation 2.4-11: $X_{C1} = X'_d + X'_a = 0.1402$ megohm-mile.

Repeating the same calculation with Applet CC-5 (including the shield wires) gives $X_{C1} = 0.137$ megohm-mile, or about 2% less capacitive reactance than the simplified calculation. The difference is due to the effect of the conducting earth and shield wires. Removing the shield wires and moving the phase conductors far from earth gives the same capacitive reactance as the simplified calculation.

2.4.4 Surge Impedance and Surge Impedance Loading

The surge impedance of any transmission line, whether power frequency or radio frequency is:

$$Z_0 = \sqrt{X_L \cdot X_c} \qquad 2.4\text{-}19$$

where X_L and X_c are the inductive and capacitive reactances per unit length, respectively. Surge impedance is thus a parameter determined by the design of the line, since it depends only on the line impedances. When positive sequence inductive and capacitive impedance are used in Equation 2.4-19, the resulting value is the positive sequence surge impedance. Surge impedance is a real number, representing a resistance. Surge impedance is the special case of the more general characteristic impedance, when series resistance and shunt conductance are assumed to be zero (lossless condition). When any line is terminated in its characteristic impedance, the voltage and current are pure forward traveling waves with no reflections at the termination. This is the desired termination condition for radio frequency transmission lines.

"Surge impedance loading" (SIL) is that loading when the transmission line is terminated in a wye-connection of resistors, each resistor having the value of the line surge impedance. This is the case of the line terminated in its own impedance with pure forward traveling waves. In the case of a lossless line, this is the power loading where the reactive power generated by the line capacitance exactly compensates the reactive power absorbed by the line inductance. This equality of capacitive and inductive vars is correct to a good approximation for practical values of conductor resistance.

Positive sequence surge impedance of a power transmission line has long been used as a "rule of thumb" measure of the loadability of the line under practical conditions (Bergen 1986; Gutman 1988). Since the line is a part of a larger power system, surge impedance loading is insufficient by itself to determine a line's rating. However, it is a useful basis of comparison of different line designs and different operating voltages, and serves as a check on the practicality of a given line loading. The use of surge impedance loading in assessing transmission lines is shown in Figure 14.2-1.

For a three-phase line, the surge impedance loading is:

$$\mathrm{SIL}(3\Phi) = (\mathrm{kV}_{LL})^2 / Z_0 \ \mathrm{MW} \qquad 2.4\text{-}20$$

Comparison of the series and shunt impedance values in Tables 2.4-3 and 2.4-4 shows that both series and shunt reactances decrease as the phase conductor material is divided into a greater number of subconductors. This reactance decrease reduces the surge impedance and increases the surge impedance loading as given in Table 2.4-5. For this particular example, dividing the conductor material from a single subconductor to twin-subconductor bundles increases surge impedance loading 27%. Further subdividing into a quad-subconductor bundle increases surge impedance loading 53% compared to a single subconductor per phase.

Table 2.4-5 Effect of Bundling on Surge Impedance

No. of Conductors	Total (kcmil)	Conductor Code Name	Bundle Spacing (in.)	Bundle Diameter (in.)	Surge Impedance (Ohms)	Per Unit Surge Impedance Loading

2.5 GENERAL TRANSMISSION-LINE PARAMETERS

In addition to the positive sequence impedance developed in Section 2.4, it is frequently necessary to know the zero sequence impedance and admittance for analysis of faults and unbalanced conditions. For a passive circuit element, such as a transmission line, the positive and negative sequence impedances are equal, leaving positive and zero sequence impedances to be determined. More detailed studies may require either a complete matrix of self and mutual phase inductive and capacitive impedances, or a complete matrix of self and mutual sequence inductive and capacitive impedances. Terms in the inductive reactance matrix include the effects of conducting earth. Ground effects and conductor skin effects are frequency-sensitive. Thus, when knowledge of line parameters for surge propagation or other transient studies is required, it is necessary to determine how the impedance or admittance elements vary with frequency.

A frequent concern is the degree of line impedance unbalance produced by asymmetrical placement of line conductors above the ground plane. This unbalanced condition leads to generation of negative and zero sequence voltages and currents in an otherwise balanced system. These negative and zero sequence voltages and currents may have adverse effects sufficient to require line transposition to balance the line impedances. Generators, motors, shunt reactors, and relay performance may be affected by negative- and zero-sequence values. For example, manufacturers give generators negative sequence current limits, expressed as a percentage of rated current. Exceeding the negative sequence current limit can result in excessive heating of the machine rotor. Mutual coupling in the zero sequence between parallel circuits is a consideration in design of ground fault protection.

Transmission-line impedances can be balanced by line transposition, where the phase conductors occupy different structure positions for different portions of the line length. For example, conductor placement on the structures may be a-b-c for one-third of the line length, b-c-a for one-third of the line length, and c-a-b for the remaining third of the line length. The effect of line transposition on the phase impedance matrix is to make all the diagonal terms equal, and all the off-diagonal terms equal, leaving the self impedance Z_S for all the diagonal terms, and the mutual impedance Z_M for all the off-diagonal terms. Transformation to sequence components results in a diagonal matrix where the diagonal terms are the zero, positive, and negative sequence impedances and all the off-diagonal terms are zero. The sequence networks are decoupled by transposition, and the positive sequence network by itself represents the balanced operating condition with no interaction from the other two sequence networks. For a more detailed exposition, see one of the standard texts (Gross 1979; El-Hawry 1983; Grainger and Stevenson 1994). Development of component transformations as a special case of the general matrix transformation is given in Long and Gelopulos 1982.

The single-circuit series and shunt impedance matrix equations presented in this section are incorporated in Applet CC-5. Applet CC-5 gives both phase impedance and sequence impedance matrices. Another approach to calculation of unbalanced voltages and currents on transmission lines is by use of a phase matrix technique such as the electromagnetic transients program EMTP.

2.5.1 Capacitive (Electric Field) Unbalance

There are two ways to mathematically represent the capacitive (electric field) unbalance. The first is in terms of phase quantities, while the second is in terms of symmetrical components.

Phase Quantities

The capacitance equations in terms of phase voltages and charges in matrix notation are:

$$\begin{bmatrix} V_1 \\ V_2 \\ \cdot \\ \cdot \\ \cdot \\ V_m \end{bmatrix} = \begin{bmatrix} P_{11} & P_{12} & \cdots & P_{1n} \\ P_{21} & P_{22} & \cdots & P_{2n} \\ \cdot & \cdot & & \cdot \\ \cdot & \cdot & & \cdot \\ \cdot & \cdot & & \cdot \\ P_{m1} & P_{m2} & \cdots & P_{mn} \end{bmatrix} \begin{bmatrix} q_1 \\ q_2 \\ \cdot \\ \cdot \\ \cdot \\ q_m \end{bmatrix} \quad 2.5\text{-}1$$

where q is the conductor charge in coulombs per-unit distance, V the conductor potentials in volts with respect to ground, and P the "potential coefficients" defined in Equations. 2.5-2, 2.5-3, 2.5-4, and 2.5-5.

$$P_{mm} = 1.7975 \times 10^{10} \ln(D_{mm'} / r_m) \text{miles / farad} \quad 2.5\text{-}2$$

or

$$P_{mm} = 2.5718 \times 10^{7} \log(D_{mm'} / r_m) \text{miles / farad} \quad 2.5\text{-}3$$

when $m \neq n$

$$P_{mn} = 1.7975 \times 10^{10} \ln(D_{mn'} / D_{mn}) \text{miles / farad} \quad 2.5\text{-}4$$

or

$$P_{mn} = 2.5718 \times 10^{7} \log(D_{mn'} / D_{mn}) \text{miles / farad} \quad 2.5\text{-}5$$

Where:

r_m = radius of each conductor.

D_{mn} = distance between conductors m and n.

$D_{mn'}$ = distance between conductor m and the image conductor n' (See Figure 2.5-1).

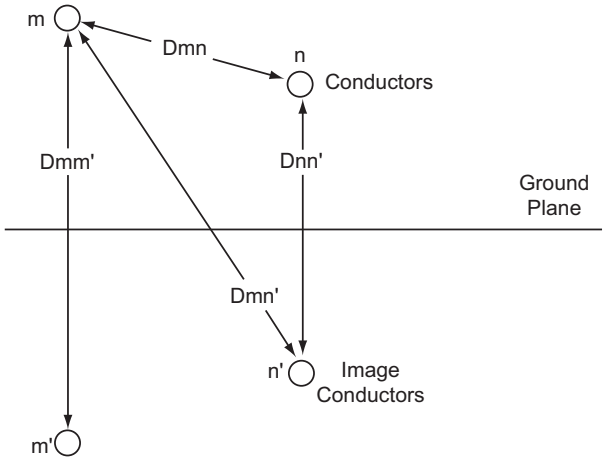

Figure 2.5-1 Conductor and image geometry symbols.

Dimensions for r_m, D_{mn} and $D_{mn'}$ must be in the same units. The notational form of Equation 2.5-1 is:

$$[V] = [P][Q] \quad 2.5\text{-}6$$

In order to calculate the current flow, it is necessary to write Equation 2.5-1 in terms of currents rather than electric charges. First recall that:

$$q_n(t) = Q_{n(\max)} \sin \omega t \quad 2.5\text{-}7$$

and that

$$i_n(t) = d[q_n(t)]dt \quad 2.5\text{-}8$$

Then:

$$i_n(t) = \omega Q_{n(\max)} \cos \omega t = \omega Q_{n(\max)} \sin(\omega t + 90°) \quad 2.5\text{-}9$$

In phasor form, Equation 2.5-9 becomes:

$$I_n = j\omega Q_n \quad \text{or} \quad Q_n = (1 / j\omega) I_n \quad 2.5\text{-}10$$

Thus Equation 2.5-6 can be written as:

$$[V] = (1 / j\omega)[P][I] = [Z][I] \quad 2.5\text{-}11$$

or in expanded form as:

$$\begin{bmatrix} V_1 \\ V_2 \\ \cdot \\ \cdot \\ \cdot \\ V_m \end{bmatrix} = \frac{1}{j\omega} \begin{bmatrix} P_{11} & P_{12} & \cdots & P_{1n} \\ P_{21} & P_{22} & \cdots & P_{2n} \\ \cdot & \cdot & & \cdot \\ \cdot & \cdot & & \cdot \\ \cdot & \cdot & & \cdot \\ P_{m1} & P_{m2} & \cdots & P_{mn} \end{bmatrix} \begin{bmatrix} I_1 \\ I_2 \\ \cdot \\ \cdot \\ \cdot \\ I_m \end{bmatrix} \quad 2.5\text{-}12$$

It is often desirable to determine the currents in terms of the voltages. In this case, premultiply each side of Equation 2.5-12 by Z^{-1} to obtain:

$$I = Z^{-1} V = j\omega P^{-1} V = j\omega C V = Y V \quad 2.5\text{-}13$$

or in expanded form:

$$\begin{bmatrix} I_1 \\ I_2 \\ \cdot \\ \cdot \\ \cdot \\ I_m \end{bmatrix} = j\omega \begin{bmatrix} C_{11} & C_{12} & \cdots & C_{1n} \\ C_{21} & C_{22} & \cdots & C_{2n} \\ \cdot & \cdot & & \cdot \\ \cdot & \cdot & & \cdot \\ \cdot & \cdot & & \cdot \\ C_{m1} & C_{m2} & \cdots & C_{mn} \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \\ \cdot \\ \cdot \\ \cdot \\ V_m \end{bmatrix} \quad 2.5\text{-}14$$

where the matrix C is called the capacitance matrix, and Y the admittance matrix. It should be noted that each element of the capacitance matrix is an involved expression that cannot be readily determined from physical dimensions. It is best to determine the potential coefficients, P, and then find the capacitance coefficients, C, as the elements of the inverse of the P matrix.

Sequence Quantities

The symmetrical component transformation is a matrix transformation based on the eigenvalue analysis for diagonalization of a matrix. (Long and Gelopulos 1982; Bellman 1960) The usefulness of the symmetrical component transformation is the ease with which it allows understanding of unbalance phenomena. For a three-phase transmission line, the shunt capacitive matrix given in Equation 2.5-13 becomes:

$$\begin{bmatrix} I_0 \\ I_1 \\ I_2 \end{bmatrix} = j\varpi \begin{bmatrix} C_{00} & C_{01} & C_{02} \\ C_{10} & C_{11} & C_{12} \\ C_{20} & C_{21} & C_{22} \end{bmatrix} \begin{bmatrix} V_0 \\ V_1 \\ V_2 \end{bmatrix} \qquad 2.5\text{-}15$$

It is important to keep in mind the different significance of the terms in Equations 2.5-14 and 2.5-15. In the phase impedance matrix of Equation 2.5-14, the off-diagonal terms represent mutual coupling between phases, where a voltage on one phase results in a current in another phase. In the sequence impedance matrix of Equation 2.5-15 the off-diagonal terms represent mutual coupling between *sequences*, or the degree of unbalance in the line impedances.

The significance of off-diagonal terms in the sequence impedance matrix is shown in that, for a perfectly symmetrical or perfectly transposed transmission line, the capacitance matrix is a diagonal matrix with all the off-diagonal terms equal to zero. In this case, a positive sequence voltage results in only a positive sequence current; a negative sequence voltage results in only a negative sequence current; and a zero sequence voltage results in only a zero sequence current. For a normal, untransposed transmission line—for example, a horizontal configuration line above earth—the off-diagonal terms are not zero. The interpretation of off-diagonal terms can be seen by injecting a purely positive sequence voltage into Equation 2.5-14.

$$\begin{bmatrix} I_0 \\ I_1 \\ I_2 \end{bmatrix} = j\varpi \begin{bmatrix} C_{01} \\ C_{11} \\ C_{21} \end{bmatrix} V_1 = j\varpi \begin{bmatrix} C_{00} & C_{01} & C_{02} \\ C_{10} & C_{11} & C_{12} \\ C_{20} & C_{21} & C_{22} \end{bmatrix} \begin{bmatrix} 0 \\ V_1 \\ 0 \end{bmatrix} \qquad 2.5\text{-}16$$

Currents result in all three sequences from a voltage of only one sequence. The three resulting currents are determined by the middle column in the capacitance matrix. A similar analysis can be conducted by injecting pure zero or negative sequence voltages.

An alternative approach to capacitive unbalance is use of three unbalance factors defined as follows (Gross and Weston 1951; Gross and Chin 1968):

1. Ground displacement d_0

$$d_0 = \frac{V_0}{V_{ph}} \qquad 2.5\text{-}17$$

V_0 = voltage from neutral to ground.
V_{ph} = voltage from phase to neutral.

2. Zero sequence unbalance factor d'$_0$

$$d'_0 = \frac{Q_{a0}}{Q_{a1}} = \frac{I'_{a0}}{I'_{a1}} \qquad 2.5\text{-}18$$

Q_{a0} = zero sequence charge.
Q_{a1} = positive sequence charge.
I'_{a0} = zero sequence charging current.
I'_{a1} = positive sequence charging current.

3. Negative sequence unbalance factor d_2

$$d_2 = \frac{Q_{a2}}{Q_{a1}} = \frac{I'_{a2}}{I'_{a1}} \qquad 2.5\text{-}19$$

Q_{a2} = negative sequence charge.
Q_{a1} = positive sequence charge.
I'_{a2} = negative sequence charging current.
I'_{a1} = positive sequence charging current.

2.5.2 Single-Circuit Inductive (Magnetic Field) Unbalance

The inductive unbalance may be presented in terms of phase quantities or in terms of symmetrical components.

Phase Quantities (Carson Form)

The inductive matrix may be calculated by using the equations developed by Carson and modified by Clarke and Calabrese (Carson 1928; Clarke 1943; Calabrese 1959). In matrix form, the equations are:

$$\begin{bmatrix} V_1 \\ V_2 \\ \cdot \\ \cdot \\ \cdot \\ V_m \end{bmatrix} = \begin{bmatrix} Z_{11} & Z_{12} & \cdots & Z_{1n} \\ Z_{21} & Z_{22} & \cdots & Z_{2n} \\ \cdot & \cdot & & \cdot \\ \cdot & \cdot & & \cdot \\ \cdot & \cdot & & \cdot \\ Z_{m1} & Z_{m2} & \cdots & Z_{mn} \end{bmatrix} \begin{bmatrix} I_1 \\ I_2 \\ \cdot \\ \cdot \\ \cdot \\ I_m \end{bmatrix} \qquad 2.5\text{-}20$$

In notational form, Equation 2.5-20 is:

$$[V] = [Z][I] \qquad 2.5\text{-}21$$

when $m = n$,

$$Z_{mm} = R_m + 4\pi\, 10^{-7} f \left[\begin{matrix} j \ln(D_{mm'} / \mathrm{GMR}_m) \\ + \ 2(P + jQ) \end{matrix} \right] \text{ohms / meter} \quad \text{2.5-22}$$

or

$$Z_{mm} = R_m + j0.004657 f \log(D_{mm'} / \mathrm{GMR}_m) + 0.004043 f (P + jQ) \text{ ohms / mile} \quad \text{2.5-23}$$

when $m \neq n$,

$$Z_{mn} = 4\pi\, f\, 10^{-7} \left[\begin{matrix} j \ln(D_{mn'} / D_{mn}) \\ + \ 2(P + jQ) \end{matrix} \right] \text{ohms / meter} \quad \text{2.5-24}$$

or

$$Z_{mn} = j0.004657 f \log(D_{mn'} / D_{mn}) + 0.004043 f (P + jQ) \text{ ohms / mile} \quad \text{2.5-25}$$

Where:

f = frequency, Hertz.

$\mathrm{GMR_m}$ = geometric mean radius for conductor m.

D_{mn} = distance between conductors m and n.

$D_{mm'}$, $D_{mn'}$ = distance between conductors m and image conductor m' or n' (see Figure 2.5-1). The dimensions for $\mathrm{GMR_m}$, D_{mm}, $D_{mm'}$ and $D_{mn'}$ must be in the same units.

R_m = ac resistance of conductor m, ohms/meter, for Equation 2.5-22 and ohms/mile for Equation 2.5-23.

The terms P and Q are defined by the following expressions:

$$P = \frac{\pi}{8} - \frac{1}{3\sqrt{2}} k \cos\theta + \frac{k^2}{16} \cos 2\theta \left(0.6728 + \ln \frac{2}{k} \right) + \frac{k^2}{16} \theta \sin 2\theta + \frac{k^3 \cos 3\theta}{45\sqrt{2}} - \frac{\pi k^4 \cos 4\theta}{1536} \quad \text{2.5-26}$$

$$Q = -0.0386 + \frac{1}{2} \ln \frac{2}{k} + \frac{1}{3\sqrt{2}} k \cos\theta - \frac{\pi k^2}{64} \cos 2\theta + \frac{k^3 \cos 3\theta}{45\sqrt{2}} - \frac{k^4 \theta}{384} \sin 4\theta - \frac{k^4 \cos 4\theta}{384} \times \left(\ln \frac{2}{k} + 1.0895 \right) \quad \text{2.5-27}$$

The terms P and Q have different values for the impedance coefficients Z_{mn}, when $m = n$ and $m \neq n$.

In the case of $m = n$,

$$k = 2.81 \times 10^{-3} D_{mm'} \sqrt{f\rho} \quad \text{2.5-28}$$

$$\theta = 0 \quad \text{2.5-29}$$

In the case of $m \neq n$,

$$k = 2.81 \times 10^{-3} D_{mn'} \sqrt{f / \rho} \quad \text{2.5-30}$$

$$\theta = \arcsin(H_{mn} / D_{mn'}) \quad \text{2.5-31}$$

Where:

f = frequency, Hertz.

ρ = resistivity of earth, ohm meters.

H_{mn} = horizontal distance between conductors m and n in meters.

D_{mn} = image distance for Equation 2.5-30 as shown in Figure 2.5-1 in meters.

The computer calculation of the Z matrix is described by Hesse (Hesse 1963).

Approximating Equations

Electromagnetic calculations have been made with approximating Equations 3.5-32 and 3.5-33 (Westinghouse 1964; Lawrence and Povejsil 1952).

The impedance for $m = n$ is:

$$Z_{mm} = Z'_{mm} + Z_g - 2Z_{mg} \quad \text{2.5-32}$$

and for $m \neq n$ is:

$$Z_{mm} = Z'_{mn} + Z_g - Z_{mg} - Z_{ng} \quad \text{2.5-33}$$

where:

Z'_{mm} = self-impedance of conductor.
= $r_m + j4\pi f 10^{-7} \ln(1/\mathrm{GMR_m})$ ohms/meter.
= $r_m + j4.657 * 10^{-3} f \log(1/\mathrm{GMR_m})$ ohms/mile.

Z'_{mn} = mutual impedance between conductors.
= $j4\pi f 10^{-7} \ln(1/\mathrm{D_{mn}})$ ohms/meter.
= $j4.657 * 10^{-3} f \log(1/\mathrm{D_{mn}})$ ohms/mile.

Z_g = $9.865 * 10^{-7} f + j0$ ohms/meter.
= $0.001588 f + j0$ ohms/mile.

Z_{mg} or

Z_{ng} = mutual impedance between conductor and ground.
= $j2\pi * 10^{-7} f \ln(1/660\sqrt{\rho}/f)$ ohms/meter.
= $j2.3283 * 10^{-3} f \log(1/2160\sqrt{\rho}/f)$ ohms/mile.

r_m = resistance of conductor in ohms/meter or ohms/mile as applicable.

D_{mn} = distance between conductors in meters or feet as applicable.

ρ = resistivity of the earth in ohm meters.

f = frequency in Hertz.

Sequence Quantities

The representation of inductive unbalance in a single-circuit, three-phase system by symmetrical components follows the same procedure as for capacitive unbalance. The series sequence inductive impedance matrix takes the form:

$$\begin{bmatrix} V_0 \\ V_1 \\ V_2 \end{bmatrix} = j\omega \begin{bmatrix} L_{00} & L_{01} & L_{02} \\ L_{10} & L_{11} & L_{12} \\ L_{20} & L_{21} & L_{22} \end{bmatrix} \begin{bmatrix} I_0 \\ I_1 \\ I_2 \end{bmatrix} = \begin{bmatrix} Z_{00} & Z_{01} & Z_{02} \\ Z_{10} & Z_{11} & Z_{12} \\ Z_{20} & Z_{21} & Z_{22} \end{bmatrix} \begin{bmatrix} I_0 \\ I_1 \\ I_2 \end{bmatrix} \quad \text{2.5-34}$$

The series impedance matrix is diagonal for a perfectly symmetrical or perfectly transposed transmission line. For the transposed case, a current of one sequence results in a voltage drop of only that sequence. For an untransposed line, a current of one sequence generally results in voltage drops in all three sequences. As was the case with capacitive unbalance, inductive unbalance can be studied by injecting a current of a single sequence and comparing the voltage drops in the three sequences. Two helpful ratios for looking at inductive unbalance are the zero sequence unbalance ratio, M_0; and the negative sequence unbalance ratio, M_2. The unbalance factors M are defined in percentages as:

$$M_0 = \left| \frac{Z_{01}}{Z_0} \right| \times 100 \quad \text{2.5-35}$$

$$M_2 = \left| \frac{Z_{21}}{Z_1} \right| \times 100 \quad \text{2.5-36}$$

The X_0/X_1 ratio is very useful for assessing fundamental frequency overvoltages on unfaulted phases for single or double line to ground fault conditions (Peterson 1966). A frequently used measure of whether a system is effectively grounded is $X_0/X_1 \leq 3.0$ and $R_0/X_1 \leq 1.0$. For the case of zero resistance and $X_0/X_1 = 3$, a single phase to ground fault on phase A will result in 1.25 per unit phase to ground voltage on phase c. If $X_0/X_1 = \infty$, the phase to ground voltage will rise to phase to phase voltage (1.73 per unit of phase to ground voltage). No system is truly ungrounded, as there is always capacitance to ground resulting in a negative zero sequence reactance. In such a case, the phase to ground voltage can rise above phase to phase voltage. For further details, see Peterson 1966.

Shield wires affect the zero sequence impedance of a transmission line, but have little impact on the positive or negative sequence impedances. This is apparent because zero sequence current flows in a grounded continuous shield wire, but positive and negative currents sum to zero and thus have no contribution to shield wire current. Compared to a line with no shield wires, the presence of a shield wire reduces the zero sequence reactance and increases the zero sequence impedance. The physical explanation for the reduction in reactance is the reduction in flux loop caused by the presence of a return current path in the shield wire that is closer to the phase conductors than the equivalent return current path in the earth. The apparently odd phenomena of the increase in zero sequence resistance is due to the reactance distribution forcing current into the closer, higher-resistance, shield wire path, thus increasing the zero sequence resistance.

2.5.3 Unbalance in Parallel Double-Circuit Untransposed Lines

Unbalance in parallel, double-circuit untransposed lines can be analyzed on a phase impedance matrix basis using one of the available computer programs such as the electromagnetic transients program EMTP. Double-circuit line unbalance can also be analyzed on a symmetrical component basis. A current of a pure single sequence in a single–circuit, untransposed transmission line results in voltage drops in all three sequences. In the case of a double–circuit, untransposed transmission line, a single sequence current in one circuit in general results in voltage drops in all three sequences in *both* lines. As part of the overall system, this voltage drop results in currents of all three sequences in both circuits.

A double circuit line has a 6 x 6 phase impedance matrix consisting of self-impedances of all six conductors and mutual impedances between all combinations of pairs of conductors. In symmetrical components, each circuit has a 3 x 3 sequence impedance matrix for each circuit (Equation 2.5-34), and in addition, there is a mutual sequence impedance matrix relating the two circuits, illustrated by Equation 2.5-37. Notation in Equation 2.5-37 is as follows: $V_{1\text{-}0}$ means zero sequence voltage drop in circuit 1. $I_{2\text{-}0}$ means zero sequence current in circuit 2. For example, a positive sequence current in circuit 2 results in voltage drops in all three sequences in circuit 1. It is important to keep in mind the distinction between the mutual impedances within a circuit and the mutual impedances between circuits, where a sequence current results in voltages of different sequences in both circuits. The zero sequence coupling between circuits is especially important to relay engineers.

$$\begin{bmatrix} V_{1-0} \\ V_{1-1} \\ V_{1-2} \end{bmatrix} = \begin{bmatrix} Z_{00} & Z_{01} & Z_{02} \\ Z_{10} & Z_{11} & Z_{12} \\ Z_{20} & Z_{21} & Z_{22} \end{bmatrix} \begin{bmatrix} I_{2-0} \\ I_{2-1} \\ I_{2-2} \end{bmatrix} \quad \text{2.5-37}$$

The self and mutual phase and sequence impedance matrices can be calculated using available transmission line constants programs. Calculations with a pocket calculator can

be used to estimate the relative degree of unbalance, or appropriate ratios of terms can be used as unbalance factors.

The mutual impedance in the positive sequence has the effect of changing the effective impedance of the individual circuits. For the phasing:

a	a
b	b
c	c

the mutual positive sequence impedances add, slightly increasing the line impedance. This relative phasing is called "superbundle" because conductors at the same electrical phase angle are adjacent.

For the phasing:

a	c
b	b
c	a

the mutual positive sequence impedance subtracts, slightly reducing the line impedance. This relative phasing is called "low reactance" because of this effect.

This discussion has focused only on unbalance as it relates to the transmission circuit itself. Any circuit is part of the overall power system, and thus actual unbalance voltages and currents will be determined by analysis of the whole system. However, investigation of the sequence impedance matrices is a useful exercise in comparing circuits of different designs, and in determining whether transposition is necessary.

2.6 INDUCED VOLTAGES ON PARALLEL CONDUCTORS

A number of situations arise where electric and magnetic field induction into conductors parallel to an energized transmission line is an important consideration. This includes the case of induction to a de-energized conductor of the same circuit. For example, single-pole switching is sometimes used to increase the stability limits of a transmission system. The success of single-pole switching depends on sufficiently small induction (called secondary arc current) to the switched conductor so that the fault arc extinguishes by itself. An excessive secondary arc current may result in continued arc burning and failure of the fault to clear (Lambert et al. 1978). Parallel transmission lines with shunt reactors may exhibit resonance phenomena with one circuit energized and the other de-energized (Chaston 1969; LaForest 1972).

Another example of induction within a circuit is induced circulating current in shield wires. Reduction of shield wire current is sometimes considered as part of reducing circuit power losses. The induction of concern may be to a conductor of a parallel circuit that is de-energized and undergoing some maintenance operation, or the induction may be to some parallel conductor different from the power system, such as telephone circuits, railroad signals, fences or pipelines. These effects fall under environmental effects of transmission lines.

Induction to parallel power transmission lines is an important safety consideration for protection of workers during construction and maintenance operations. Adequate grounding must be provided to protect workers on de-energized lines paralleling operating lines during normal line operation as well as during power system faults. Details of grounding protection are given in IEEE Standards on power line grounding (IEEE 1993a; IEEE 2003).

Induction to parallel conductors is both capacitive (electric field) and inductive (magnetic field). Electric and magnetic field induction and environmental effects on objects near the earth's surface are addressed in Section 7, starting from the physics of electromagnetic fields. In the case of long parallel conductors, it is also possible to calculate induced voltages and currents starting from the point of view of circuit theory. Induction is calculated from series inductive reactance and shunt capacitive admittance matrices. The matrix formulation is given in Sections 2-4 and 2-5. This section extends that development to the parallel conductor induction issue.

The same geometrical and electrical parameters affect the amount of induction as enter an impedance calculation. Among these are phase spacing, circuit spacing, conductor height, and transposition scheme (if any). Circuit loading is a factor, whether the condition is normal operation or fault current. As impedance matrix methods are based on sinusoidal steady-state phasor analysis, steady currents and voltages are assumed for either condition. In each case a matrix is developed relating voltages and currents, and the resulting system of equations is solved to determine the induction.

2.6.1 Electric Field Induction on the De-Energized Circuit

Electric field induction for a double circuit line is calculated from the shunt capacitive admittance Equation 2.5-14 recast in admittance form in Equation 2.6-1 (IEEE 1972; IEEE 1993a). Rows and columns 1,2, and 3 represent the energized circuit; rows and columns 4, 5, and 6 represent the de-energized circuit. Additional rows and columns could be added to represent shield wires. By specifying the line voltages V_1, V_2, and V_3 and setting currents I_4, I_5, and I_6 to zero, solving the resulting set of equations calculates

the induced voltages V_4, V_5, and V_6. The mathematics to do this is programmed into Applet CC-7. If voltages V_4, V_5, and V_6 are set to zero instead of the three currents, short circuit to ground induced on the de-energized conductors can be calculated. The short circuit current gives the secondary arc current for single-pole switching analysis.

$$\begin{bmatrix} I_1 \\ I_2 \\ I_3 \\ I_4 \\ I_5 \\ I_6 \end{bmatrix} = \begin{bmatrix} Y_{11} & Y_{12} & Y_{13} & Y_{14} & Y_{15} & Y_{16} \\ Y_{21} & Y_{22} & Y_{23} & Y_{24} & Y_{25} & Y_{26} \\ Y_{31} & Y_{32} & Y_{33} & Y_{34} & Y_{35} & Y_{36} \\ Y_{41} & Y_{42} & Y_{43} & Y_{44} & Y_{45} & Y_{46} \\ Y_{51} & Y_{52} & Y_{53} & Y_{54} & Y_{55} & Y_{56} \\ Y_{61} & Y_{62} & Y_{63} & Y_{64} & Y_{65} & Y_{66} \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \\ V_3 \\ V_4 \\ V_5 \\ V_6 \end{bmatrix} \quad \text{2.6-1}$$

As an example of this calculation, consider the base case 345-kV double circuit line. One circuit is energized at a nominal 345 kV, and the other is floating. The three phases of the de-energized circuit rise to 24, 18, and 32 kV.

The induced voltage calculation can be visualized as a capacitive voltage divider consisting of all the self and mutual capacitances relating the six phases. Because all the capacitances are proportional to line length, the induced voltage is independent of the length of the line.

The short circuit to ground calculation can be visualized as a voltage source and a capacitive source impedance to the grounded conductor. Because the source impedance is proportional to line length, the resulting current is also proportional to length. In this example case, the three phases each have induced current of approximately 2 mA per mile.

2.6.2 Magnetic Field Induction on the De-Energized Circuit

Magnetic field induction for a double circuit line is calculated from the series impedance matrix in Equation 2.6-2 (IEEE 1974; IEEE 1993a). As in Equation 2.6-1, rows and columns 1, 2, and 3 represent the energized circuit; rows and columns 4, 5, and 6 represent the de-energized circuit. Additional rows and columns could be added to represent shield wires. By specifying the line currents I_1, I_2, and I_3 and setting currents I_4, I_5, and I_6 to zero, solving the resulting set of equations calculates the induced voltages V_4, V_5, and V_6. The mathematics to do this is programmed into Applet CC-7.

$$\begin{bmatrix} V_1 \\ V_2 \\ V_3 \\ V_4 \\ V_5 \\ V_6 \end{bmatrix} = \begin{bmatrix} Z_{11} & Z_{12} & Z_{13} & Z_{14} & Z_{15} & Z_{16} \\ Z_{21} & Z_{22} & Z_{23} & Z_{24} & Z_{25} & Z_{26} \\ Z_{31} & Z_{32} & Z_{33} & Z_{34} & Z_{35} & Z_{36} \\ Z_{41} & Z_{42} & Z_{43} & Z_{44} & Z_{45} & Z_{46} \\ Z_{51} & Z_{52} & Z_{53} & Z_{54} & Z_{55} & Z_{56} \\ Z_{61} & Z_{62} & Z_{63} & Z_{64} & Z_{65} & Z_{66} \end{bmatrix} \begin{bmatrix} I_1 \\ I_2 \\ I_3 \\ I_4 \\ I_5 \\ I_6 \end{bmatrix} \quad \text{2.6-2}$$

The self and mutual terms in the impedance matrix in Equation 2.6-2 are dimensioned in ohms per unit length. Thus the voltage calculated by Equation 2.6-2 is the longitudinal voltage along the parallel conductor. This voltage is frequently called "longitudinal electromotive force" (LEF), formerly called "longitudinal electric field." If the conductor were grounded at one end, the voltage represents the voltage along the conductor as one moves away from the ground.

As an example of this calculation, consider the same base case 345-kV double circuit line used for the capacitance calculation. One circuit has a specified balanced 1000 ampere current, and the other circuit's phase conductors are floating. Voltages induced in the three phases of the de-energized circuit are approximately 1, 5, and 10 volts per mile. Setting the three currents I_4, I_5, and I_6 to zero instead of the voltages gives the induced currents.

A similar calculation for a 10,000-ampere fault current in phase 1 of the energized circuit gives induced voltages in the three phases of the de-energized circuit of approximately 5 kV per mile. This illustrates the significance of considering fault currents in magnetic field induction problems.

It is possible to combine the electric and magnetic field calculations by developing the ABCD matrix of the six-conductor array and manipulating the resulting equations. More elaborate calculations, including the effects of resistance in the ground connection, can be made using the ABCD matrix approach.

Magnetic field induction causes circulating current in continuous grounded shield wires and can be calculated in the same manner as induced current in parallel circuits. See Chapter 6 and Applet EMF-8 for a fuller description. One consideration in the sizing of shield wires is the ability to carry the portion of fault current that flows in the shield wires (Lambert et al.1978). Some utilities use segmented shield wires and similar approaches as a method of reducing power losses connected with circulating shield wire current (Fakheri et al.1984). System relay engineers generally desire a continuous shield wire path for zero sequence current return.

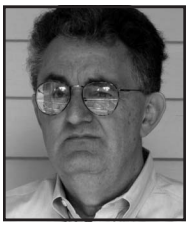
CHAPTER 3



Insulation Design

Nicholas C. Abi-Samra
Ian Grant

This chapter describes insulation coordination, or how overvoltage and line insulation performance are balanced in a transmission-line design. Guidance is provided for determining overvoltages (stresses), insulation levels (strengths), and the balance between them to achieve acceptable line performance.

Nicholas (Nick) C. Abi-Samra is a leading expert and practitioner in transmission line and station insulation coordination. He has conducted numerous lightning and switching surge analysis studies for utilities in the U.S. and other countries. He was instrumental in designing a high-voltage test facility for the study of insulation strength, as well as a facility to collect and analyze contamination on line insulators. Abi-Samra taught Insulation Coordination in graduate-level courses at Carnegie-Mellon, Penn State Universities, and the Westinghouse Advanced School in Power Engineering. He has co-authored more than 50 technical papers for IEEE, IEE, and CIGRE, as well as a number of articles for trade magazines. Presently, as Senior Technical Director of EPRIsolutions, he has the responsibility for a wide range of power system technical issues in transmission and distribution engineering. He is a Registered Professional Engineer in several states in the U.S., and the recipient of more than 10 engineering awards.

Ian Grant has worked in all aspects of transmission-line design for more than 40 years, initially with the Electricity Commission of NSW, Australia, later with GE's HV Laboratories in Pittsfield and Lenox, Mass, Power Technologies, Inc., and most recently as Manager of Special Studies at the Tennessee Valley Authority. He is a co-author of the *EPRI Compact Line Design Book* (the Light Blue Book) and over 40 IEEE, CIGRE, and EPRI publications on transmission-line design, insulation, lightning, and switching surge research. He also developed a number of early computer programs for transmission studies. Ian pioneered use of polymer insulators in compact lines, and helped design and build the first experimental high-phase-order 6 and 12 phase lines. He has chaired and contributed to numerous IEEE and CIGRE committees and working groups. Ian is a Fellow of IEEE and a Distinguished Member of CIGRE.

3.1 INTRODUCTION

The apparent simplicity of a transmission line is, in reality, the result of a sophisticated design process. Tradeoffs are made between performance, which requires withstanding all overvoltages, and the cost of controlling them and providing sufficiently strong insulation. This chapter describes insulation coordination, or how overvoltage and line insulation performance are balanced in a transmission-line design. Insulation coordination addresses critical tower dimensions and insulation, and is based on a mass of experimental data, modeling and calculation techniques, operating and design experience, and economics. Guidance is provided here for determining overvoltages (stresses), insulation levels (strengths), and the balance between them to achieve acceptable line performance. Properly coordinated transmission-line insulation achieves reliability goals at least cost.

3.1.1 Definition

In his seminal book on the subject, Hileman (Hileman 1999) provides a range of definitions of insulation coordination. His simplest definition is perhaps also the most sophisticated: "Insulation coordination is the selection of the insulation strength."

In selecting insulation strength for transmission lines, we consider all the following:

- A transmission line is subject to power frequency voltage and to transient voltages resulting from switching and lightning. These voltages can differ substantially from event to event.
- The strength of air gap clearances and insulation varies with weather and voltage stress characteristics.
- Voltage stress can be controlled by shielding, grounding, and by devices such as surge arresters and breaker resistors.
- The goal of the designer is the optimum combination of insulation, clearances, and voltage control to achieve a reliability target at least cost. As will be pointed out in this chapter, perfect performance is impossible or too costly to achieve.
- Since insulation breakdown is inevitable, provision should be made to ensure that any insulation breakdown is self-restoring.

Good transmission-line insulation coordination is not only important to achieve high reliability of transmission lines, but is also a key element to obtain acceptable mean time between failures (MTBF) for substations. Well-coordinated designs in both lines and substations are crucial to attaining a reliable transmission system at an affordable cost.

3.1.2 Design Factors for Transmission Lines

Transmission-line design requires the following specifications:

- The type of structure—single or multiple circuit, wood or metal, phase geometry
- Airgap clearances, including phase-to-tower, phase-to-phase, and phase-to-ground at midspan
- The amount, type, and configuration of insulators
- Grounding, including paths to ground and grounding resistance
- The number and location of overhead shield wires
- The need for, rating, and location of voltage-limiting devices, such as line surge arresters and breaker insertion resistors
- Possible use of wood in the lightning flashover paths for arc quenching

3.1.3 Critical Factors versus Stress Type

The flashover strength of air gaps and insulators differs depending on whether the voltage stress is power frequency, switching surge, or lightning, and the factors affecting flashover performance differ for each stress type. If the line strength is overdesigned for any one of these factors, the cost is nonoptimal. The insulation for power frequency (or switching surge, or lightning) is overdesigned when the cost of having provided better power frequency (or switching surge or lightning insulation) is greater than the cost of the avoided insulation failures. So the concept of overdesign resides within each type of stress, not in the comparison between stress types. Table 3.1-1 illustrates which design variables are critical for each of the stresses.

3.1.4 Design Optimization

A typical insulation coordination process is shown in Figure 3.1-1.

Switching Surge						
Lightning						

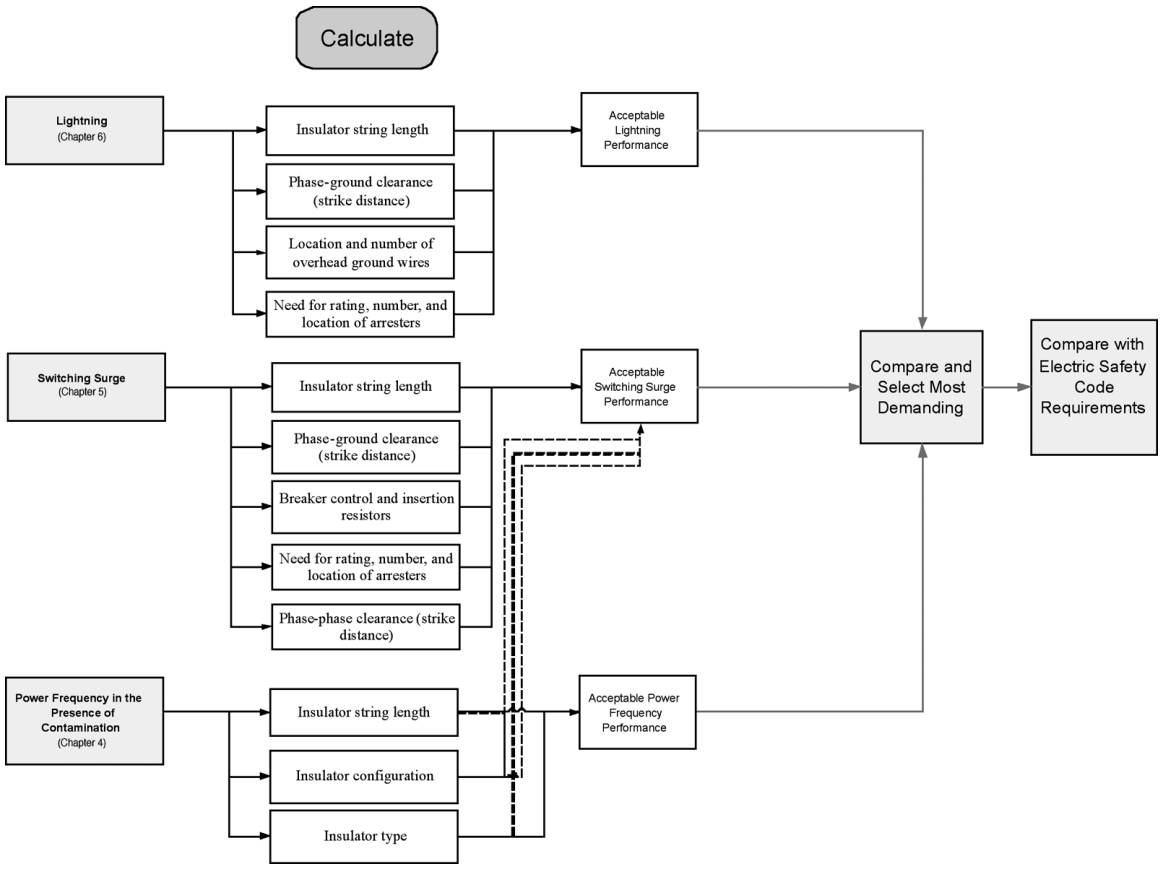

Figure 3.1-1 Insulation coordination process.

3.1.5 Calculation Methodology

This chapter provides designers with details on how to calculate voltage stress, and refers to Chapters 4-6 as appropriate for additional details on the calculation of strength. The process of insulation coordination is illustrated in Figure 3.1-2, showing how the range of stress is related to strength, to arrive at a practical low level of failure.

Two principal methods for coordination are described, deterministic and probabilistic, and reference is given to useful computer tools to help designers. In the simpler deterministic process, the stress and strength curves of Figure 3.1-2 would not overlap but would be separated by a safety margin. The more sophisticated probabilistic process provides a more realistic representation of the overlap of the curves in cost-effective designs. The probabilistic method is used in Applet IC-1 to calculate the risk of line flashover caused by switching surges. The calculation requires knowledge of the probability of overvoltage amplitudes, the strength of all the insulation elements of the line, and the value of the parameters affecting the strength.

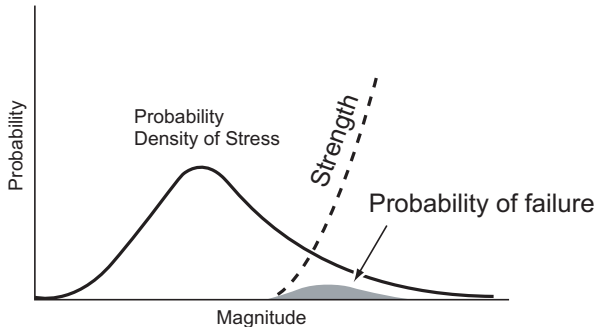

Figure 3.1-2 The balance of stress and strength in insulation coordination.

3.1.6 Typical Performance Criteria and Design Clearances

Today, in the absence of contamination, there is normally no performance criterion for power frequency voltages, such as there is for switching surges and lightning. Power frequency failures may be related to events causing insula-

tor damage, such as gunshots or aging, but, since these events are difficult to assess, it is not possible to derive a performance indicator. If contamination is an issue, a criterion may be set, but more typically the designer attempts to eliminate the problem. For switching surges, performance is specified in terms of flashovers per 100 switching operations, and for lightning, the performance criterion is normally specified as the number of flashovers per 100 km-years. Another criterion for lightning is denoted as the storm outage rate (SOR), which is the number of unsuccessful reclosures per year, obtained by multiplying the lightning flashovers per year by the switching surge flashovers per switching operation. For example, assuming the lightning flashover rate to be two per year, and the switching surge flashover rate to be one per 100 switching operations, the storm outage rate is two per 100 years. Both the storm outage rate and the lightning flashover rate may be important to customer power quality. Figure 3.1-3, derived from (Hileman 1999), illustrates relationships between typical performance criteria and designed strike distance as a function of system voltage.

Applet IC-2 calculates the strike distances required by the different stress types for system voltages from 200 to 1200 kV. Strike distances are calculated with various assumptions regarding acceptable performance criteria.

Although lines are typically designed for switching surge flashover rates between 1 and 10 flashovers per 100 switching operations, switching surge flashovers are extremely rare due to conservative assumptions in the design process. Lightning flashover rates on transmission lines vary with system voltage, and may range from 0.5 for systems exceeding 345 kV to 20 per 100 km-year for lower-voltage systems. Acceptable levels of lightning flashovers for a line are most often determined by soil resistivity and the cost of implementing countermeasures, such as supplemental grounding.

3.1.7 Applets

Two applets are provided with this chapter:

- IC-1: "Insulation Coordination—Comparative Evaluation of Insulation Distance Requirements." The applet compares the strike distances resulting from design specifications regarding power frequency (insulator contamination), switching surges, lightning, and the U.S. National Electrical Safety Code. The user may set the design specifications: contamination level, ceramic or nonceramic insulators, switching surge level, number of towers, admissible switching surge flashover rate, lightning flash density, footing resistance, and admissible lightning flashover rate. The applet shows graphically, for maximum system voltages from 200 to 1200 kV, the

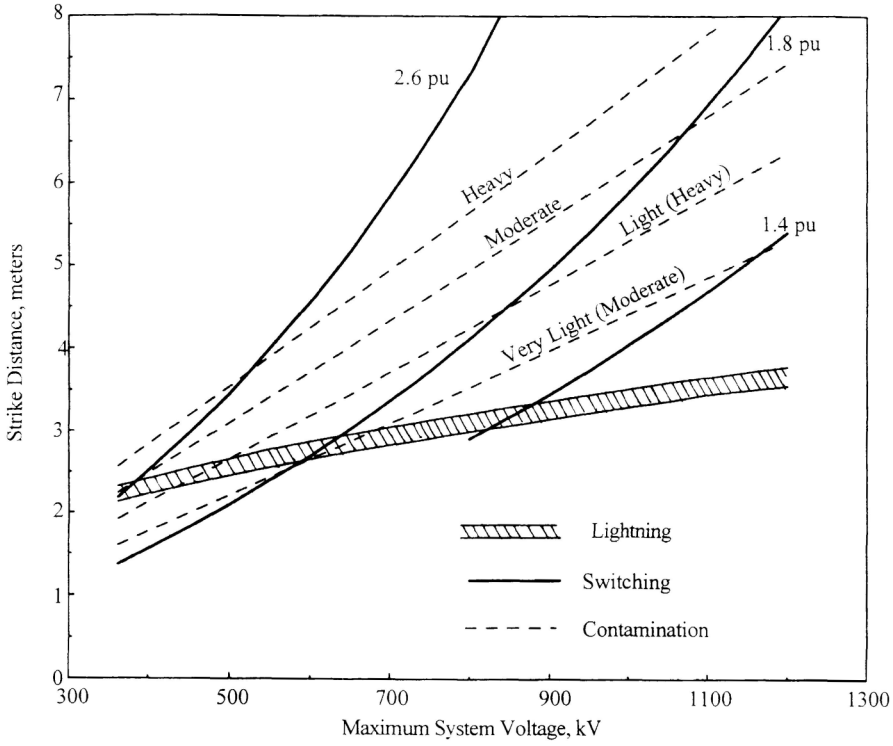

Figure 3.1-3 Comparison of requirements for power frequency, switching, and lightning.

strike distances conductor-to-tower that are required to meet the various specifications.

- IC-2: "Risk of Failure Calculations for Transmission Line Switching Surges." This applet calculates the risk of failure of a transmission line due to switching surges. The risk of failure is defined as the probability of an unwanted flashover of any insulation element of the transmission line when a switching operation is made. The risk of failure may be expressed as expected flashovers per million operations (e.g., 2.64 flashovers every million switching operations) or expected number of operations that result in one flashover (e.g., one flashover every 380,000 switching operations). Only three-phase lines and phase-to-ground flashovers are considered. It is implicitly assumed that the risk of phase-to-phase flashover is much lower. The user must input all the parameters that affect the risk of failure, such as the statistical distribution of the surge amplitudes, the statistical distribution of the surge waveshape, the statistical distribution of the weather conditions, the strength of each insulation element type, and the number of insulation elements for each type. The applet calculates the risk of flashover for the entire line and for each phase and each line section individually. The user may assess the effect of surge waveshape by comparing the results with those obtained if all the surges had critical waveshape.

3.1.8 Summary

The absolute protection of transmission lines against overvoltages is practically impossible. The task of this chapter is to help designers develop transmission lines that combine low risk with economy. No matter what the dictating stress may be, large economic incentives exist to reduce insulator string length and other tower dimensions. In the remainder of the chapter, we review the sources and nature of voltage stress; describe how to design for insulation strength with cross-references to the more detailed chapters on power frequency, switching surge, and lightning insulation design; and provide guidance and examples for optimization.

This chapter demonstrates that, with the use of measures like preinsertion resistors and controlled switching, switching surges do not dominate the design for transmission lines except at 1200 kV. It also shows that a number of measures can be employed to keep lightning flashovers under control, ranging from improving the grounding to employing transmission-line arresters. Finally, with the use of nonceramic (polymer) insulators, and special insulators, flashovers due to contamination can be minimized.

The ultimate goal of line design is that some day the line insulation will be dictated only by the normal power frequency voltage. We are still years away from this, but it can be stated with certainty that major accomplishments in countermeasures over the last 40 years have been achieved.

3.1.9 Layout of this Chapter

Section 3.2 describes the voltage stresses to which a transmission line is subjected and the key parameters that are significant to designers. Section 3.3 defines transmission-line insulation strength. Section 3.4 discusses the countermeasures available to line designers to control for lightning, switching surge, and power frequency under contamination. Section 3.5 illustrates how the requirements of local safety codes can influence transmission-line design (using the U.S. National Electric Safety Code as an example). Section 3.6 reviews the line insulation requirements and explains how they are coordinated. Section 3.7 discusses some of the economic decisions that designers may face during and after the technical tasks are completed.

Appendix 3.1 describes analytical tools available to line designers for use with insulation coordination. Appendix 3.2 identifies different types of surge arresters and their applications for controlling lighting and switching overvoltages. Appendix 3.3 reviews two types of approaches to insulation coordination—a probabilistic and a deterministic method. Appendix 3.4 presents IEC's approach to line insulation coordination.

3.2 VOLTAGE AND ENVIRONMENTAL STRESSES ON TRANSMISSION LINES

3.2.1 Introduction

This section describes the nature of the voltage *stresses* that a transmission line is subjected to, and hence, for which the insulation *strength* (as described in Section 3.3) should be designed. These stresses are caused by power frequency voltage (also known as "service voltage"), and temporary, switching, and lightning overvoltages.

Lightning strokes to transmission structures, phase conductors, or shield wires can cause flashovers that force the line to trip. Switching surges result from energizing and de-energizing of lines, capacitors, reactors, and transformers. Temporary overvoltages, also known as power frequency overvoltages, are caused by faults or are due to the Ferranti Effect (the phenomenon caused by capacitive charging of lines, and by which the steady voltage at the open end of an uncompensated unloaded transmission line is always higher than the voltage at the sending end). Environmental stresses to lines—due to pollution, rain, snow, ice, and temperature affecting the line insulation—are also important, and are covered briefly in this chapter and in detail in Chapter 4 for power frequency voltage and in Chapter 5 for switching overvoltages.

This section provides an overview of voltage stress and the key parameters that are significant to the designer. It covers the voltage stresses in the following order:

- Lightning overvoltages
- Switching surge overvoltages
- Temporary overvoltages
- Environmental stresses

For greater detail, the designer is referred to the chapters on power frequency (Chapter 4), switching surge, (Chapter 5), and lightning (Chapter 6).

3.2.2 Lightning

A detailed discussion of lightning is provided in Chapter 6. The following provides an overview of key issues for the designer. Design applications are discussed in Section 3.3.

Lightning is usually the principal factor in setting transmission insulation levels. Lightning strokes to transmission structures, phase conductors, or shield wires can cause flashovers that force the line to trip. Lightning can damage insulators, shatter wood poles or crossarms, and sever conductor strands, although these are rare occurrences on properly designed lines.

During the 1960s and 1970s, a number of new line designs were developed, including those for higher system voltages. These designs required detailed studies of lightning performance to ensure that appropriate performance was achieved, and years of operation to confirm the design expectations. Today most line construction uses designs or derivative designs for which the lightning performance is understood, so greater confidence can be placed in the study of the effects of design modifications. Typical practice is to refer to standards or expectations for each line type, with the primary parameter for adjustment being the footing resistance. On some lines having high exposure to lightning or where soil resistivity is high, it may also be necessary to address "hot spots" with special measures such as special grounding schemes, line arresters, or underbuilt shield wires. Use of the arc-quenching properties of wood (Darveniza 1980) has been successful on lower voltage lines, but may be difficult to incorporate as a retrofit. Adding insulators may seem a simple way to deal with hot spots, but it is usually impractical since it requires redimensioning and special structures to accommodate the longer insulator strings. Nonceramic insulators can offer an improved performance over glass and porcelain for the same connecting length. Their relatively light weight is also an advantage, and they can, frequently, be used to address "hot spot" problems.

Transmission-line lightning performance is, in the end, simply a matter of economics. At one extreme, a lightly insulated line with no shield wires and no grounding augmentation will have lighter and less costly structures, but will trip out more often during lightning (higher tripout rate). As each ameliorating measure is added—first one shield wire, then another, longer insulator strings and greater phase-ground clearance, basic grounding augmentation, then grounding measurements and special measures, line arresters, and other schemes—there is a tradeoff of cost versus tripout rate. Selection of tripout rates based on cost is, of course, complex, since the cost of an outage is difficult to quantify, and varies widely with time of day and the type of load served; also tripout rates can vary widely from year to year.

Lightning Characteristics

A lightning stroke can be considered as a high-impedance source of current. A stroke to a line structure or shield wire places the line in series with a discharge path between the cloud and ground, and the current passing through the structure raises its potential with respect to ground. The structure potential may increase to the point that a flashover occurs from the (higher-potential) structure to one or more of the (lower-potential) phase conductors. Because of the unusual circumstance of the structure being at a potential higher than the phase conductor, this type of flashover is called "backflashover." If a stroke connects to a phase conductor, then the reverse process may occur: a higher potential is created on the phase conductor than on the structure, and a flashover may occur if the difference in potential is sufficiently high. This type of flashover results from a "shielding failure," which is the failure of the shielding wires to intercept the lightning.

Most lightning strokes terminate on the shield wires at, or close to, the structure, which is the highest point at the end of a span, or on the structure itself. Strokes to the midspan of the conductor or shield wire appear to be less of a factor in line flashover rates than strokes near the support structures.

The strength of line insulation elements, such as insulators and air gaps, is often defined by the lightning impulse 50% flashover voltage, which is the crest voltage of a double-exponential impulse with a standardized waveshape (1.2 μs front time and 50 μs tail time) traditionally used to simulate lightning stress. For the calculation of lightning performance of transmission lines, however, Chapter 6 shows that the waveshape of the stroke current is defined in various ways to reproduce the most important features of the variety of waveshapes seen for actual strokes. Stroke characteristics and the number of strokes per year in a given area can vary widely with location and season as well as from year to year.

Table 3.2-1 Lightning Overvoltages

Source of Lightning Overvoltages	Comments
Flashes to the phase conductors (shielding failure).	Due to lack of shield wires or to inadequate shielding.
Flashes to the grounded line structure (or shield wires), which raises its potential so that it may flash over to a phase conductor (backflashover).	Voltage surges from backflash are usually more severe than those caused by shielding failures.
Flashes to ground in proximity to the line, which induce overvoltages in the phase conductors.	Voltages induced from nearby flashes are generally below 400 kV and pose no threat for lines of 200 kV and above.

Effect of Lightning on a Line

Overvoltage resulting from a lightning stroke develops in three ways, as shown in Table 3.2-1.

The lightning performance of transmission lines over 200 kV is then the sum of the following:

- The Shielding Failure Flashover Rate (SFFOR), and
- The Backflashover Rate (BFR).

Both these flashover rates are directly proportional to the number of lightning flashes to the line. In lightning performance calculations, this is assumed to be proportional to the lightning flash density, typically stated as flashes per square km per year. Statistically, however, it is possible to have high lightning activity, yet low tripout rates, if the lightning does not terminate in the immediate vicinity of the line. This might result from natural shielding, such as where a line is sheltered by trees or higher terrain. Conversely hot spots can occur where a portion of a line is particularly exposed.

Chapter 6 provides details of flash density that can be used by the designer and describes systems that provide real-time information on lightning occurrence. These systems can be useful in identifying "hot spots" where line improvements may be needed.

Effect of Power Frequency Voltage

As the current from a lightning stroke passes through the impedance of a structure, it raises the structure potential relative to ground. Since the phase conductors are insulated from the lightning current and are otherwise oscillating about true ground potential at power frequency, the potential difference across each phase insulator string is affected by the instantaneous value of power frequency voltage at the instant of the stroke, so this affects which phase flashes over first. For example, if the instantaneous value of power frequency voltage on a phase is opposite in polarity to the structure voltage caused by the lightning current, then the potential difference across the insulators is higher, and a backflashover may be more likely to occur on that phase. For shielding failures, the probability of flashover is slightly increased if the instantaneous value of power frequency voltage has the same polarity as the lightning-caused voltage.

While power frequency voltage may determine which phase flashes over first, it may be secondary to other considerations. For example, a design where one phase is higher on the structure than another will result in different instantaneous voltages at each location. These differences may be much greater than differences caused by power frequency voltage.

For shielding failures, the probability of a lightning stroke hitting a phase is theoretically increased slightly when the instantaneous value of the power frequency voltage is of opposite polarity to that of the lightning stroke, because in this case upward streamer generation is facilitated. Section 6.2 shows, however, that the leader potentials are in the range of 20-100 MV so the effect is small. Once a phase is hit, however, the overvoltage is greater if the instantaneous value of the power frequency voltage is of the same polarity and would, therefore, add to the voltage caused by the lightning. The two factors may balance each other and can be ignored. Generally, the effect of power frequency is not considered in the calculations of shielding failure rate.

Finally, some lighting-caused flashovers are self-extinguishing because they occur when the power frequency voltage is near zero and, therefore, may not be sufficient to sustain the arc. For lines with voltages greater than 200 kV, this effect is considered negligible and is not taken into account in the calculations of lightning flashover rates.

Shielding

If a stroke reaches a phase conductor, it creates an overvoltage whose amplitude depends on the stroke current and the surge impedance of the phase. If the stroke current is sufficiently high, the overvoltage exceeds the level that can be withstood by line insulation. In most regions, the frequency of flashovers caused by flashes to phase conductor would be intolerably high, if shield wires were not installed above the phase conductors to intercept lightning strokes. Thus overhead shield wires are customarily used to shield the phase conductors of a transmission line from lightning strokes.

As described in Chapter 6, a lightning leader develops as a series of steps between the cloud and ground. Whether or not a lightning stroke hits a phase conductor is governed by the length of the upward leader from the conductor to the downward leader. Lightning strokes with smaller currents have smaller charges and, therefore, induce shorter upward leaders from the shield wires. With shorter upward leaders, the protection provided by the shield wires is less.

A lightning stroke to a phase conductor injects a current pulse, creating traveling waves of current and voltage emanating from the strike point. The phase-ground voltage stress caused by a stroke to a phase conductor is as shown in Equation 3.2-1.

$$V_c = I_c \times Z_p / 2 \quad \text{3.2-1}$$

Where:

I_c is the stroke current.

Z_p is the surge impedance of the phase conductors, typically between 350 and 600 Ω. With corona, Z_p is typically between 250 and 350 Ω.

If the shielding angle (see Figure 3.4-3) is designed so that lightning strokes with currents greater than the critical current cannot terminate on the phase conductor, the SFFOR should be low but some subsequent strokes will still cause flashovers.

Note that, at midspan, the sag of the phase conductor is usually greater than the sag of the shield wire. Thus the shielding angle will be better at midspan than at the tower.

On some lines, the shield wire is insulated from the tower for communications purposes or to reduce losses from induced currents. These insulators are small and designed to flash over at very low voltages, so for the purposes of lightning protection and insulation design, it can be assumed that the shield wire is connected to the tower.

Design of line shielding is usually considered independently from design for backflash.

Backflash

A lightning stroke terminating at a tower top initially sees the surge impedance of the tower, paralleled by the surge impedances of the shield wires on both sides. Thus the initial (up to 3μs) surge impedance is:

$$Z = Z_{Tower} \,//\, Z_{OHGW} / 2 \quad \text{3.2-2}$$

Where:

Z_{Tower} is the traveling-wave surge impedance of the tower, 100-150 Ω

Z_{OHGW} is the self- and mutual surge impedance of the overhead groundwire in corona, 250-350 Ω.

The initial surge impedance rings down quickly to the footing resistance of the tower, Z_{ground}, in a process described in Section 6.4 and Applet L-5. For the time of main interest in the insulation coordination process, while the tower stands without help from adjacent structures (between 0.2 and 3 μs), the equivalent circuit become:

$$Z = Z_{Ground} \,//\, Z_{OHGW} / 2 \quad \text{3.2-2A}$$

The initial impedance to the stroke is then approximately Z = 75 ohms, falling to about 22 Ω for the case where Z_{Ground} = 25 Ω If a lightning stroke were considered as a current step with a very steep front relative to the tower travel time, a 100-kA stroke would raise the tower voltage to approximately 7.5 MV for about 200 ns (on a 60-m tower), and 2.2 MV thereafter. The phase conductors, connected to a remote source, may be considered at ground potential. Therefore, potentially, all the 2.2 MV would be across the insulation between phase conductors and tower.

However, the voltage across the insulator string is not the full 2.2 MV of the tower. There is strong coupling between the traveling waves on the shield wires and the phase conductors. There are reflections from the footing impedance at the bottom of the tower. There are traveling waves also on the shield wires and reflections and refractions at adjacent towers. In reality, the wavefront of the current is not a step wave, so the voltage does not immediately rise or fall to the 7.5 or 2.2-MV values. Also there is significant loss from the traveling waves due to corona, and as noted above, the instantaneous value of the power frequency voltage adds or subtracts from the total. The insulator strings are located partway down the tower, so the voltage across them is affected by the travel time of the waves up and down the structure. The grounding and soil characteristics provide a dynamic impedance varying as a function of current and time, which affects the reflections of traveling waves from the tower base. As a result, the actual voltage seen across the insulator strings has a peak magnitude considerably less than the theoretical maximum, and a waveshape based on all the above factors. An excellent description of the development of voltages due to traveling waves that serves as the basis of many calculation methods is given in (Bewley 1951), and this work is described in detail in Chapter 6.

Ground flash density establishes the occurrence frequency of voltage stresses but does not affect the magnitude distribution. The factors that affect the lightning overvoltages, leading to backflashovers are in order of sensitivity: insulator length and tower striking distances; the presence of Transmission Line Surge Arresters (TLSAs); tower footing resistance; and the conductor geometry and its effect on coupling between the shield wire and phase conductors. A discussion of insulation strength is provided in Section 3.3, and a discussion of the effects of varying line design parameters to improve lightning performance is given in Section 3.4. A detailed description of how the expected frequency of occurrence of backflashovers is affected by line design parameters and how it can be calculated is included in Chapter 6.

Induced Voltages

The electric and magnetic fields from a lightning stroke to ground close to a line can induce currents and voltages in the various line components. As described in Chapter 6, induced voltages across the insulators are typically less than 400 kV. Induced voltages can be a significant source of tripouts at distribution voltages, but not for transmission voltages covered by this reference book.

Conductor Damage

Although uncommon, conductor damage from lightning on both steel shield wires and aluminum conductors is known to occur. Typically the damage consists of two to three severed strands. As verification that this damage is solely due to the lightning and not to power frequency fault currents, it has been observed on new lines that are not yet energized.

An exception to this phenomenon occurs for covered conductors (or tree wires), where the phase conductor has a layer of insulation intended to protect it against momentary contacts to grounded objects such as trees. Covered conductor has been widely used, but primarily at distribution voltages. Faults caused by lightning can result in power frequency arcs being channeled to a particular point on the conductor through a puncture in the covering, and severing the conductor. Special measures, such as additional hardware, have been proposed to eliminate this problem, but transmission designers are unlikely to use this type of conductor.

Calculation of Lightning Voltage Stress

Lightning voltage stress is calculated using a transmission-line model, typically based on surge impedance, and a probabilistic approach to describe the variable characteristics of lightning. A number of computer programs are designed to calculate lightning-caused voltage stress, as part of the process to determine line lightning performance. A more detailed discussion is provided in Appendix 3.1 in this chapter, and in Chapter 6.

3.2.3 Switching Surges

Switching surges in a power system result from the energizing and de-energizing of lines, capacitors, reactors, and transformers. Energy is stored in the system's electric and magnetic fields, with magnetic energy stored in the inductance of the system and electric energy stored in the capacitance. Energy transfer between a transmission line and the system during a switching operation causes voltage surges.

Switching surges are not normally a determining factor for line voltages below 345 kV. Prior to the advent of 500-kV transmission in the early 1960s, line insulation was solely determined by lightning and power frequency voltage. Switching surges were recognized as important with the advent of 500 kV and higher voltages, and many studies were then made to predict and measure surges and insulation strength.

An idealized representation of a phase-ground switching surge is shown in Figure 3.2-1. Switching surges can have a wide range of waveforms, corresponding to the range of initiating influences. A "typical" waveform could be considered as a 250 x 2500 μs double-exponential, as illustrated in the figure. Switching surges are customarily expressed in per unit of the phase-ground peak steady-state voltage.

The switching operations of greatest concern in lines over 345 kV are:

- Line energization
- Line re-energization with trapped charge on the line
- Load rejection with a circuit breaker opening at the far end of a line, possibly followed by disconnection at the near end
- Transformer switching at no load or with a secondary load of shunt reactors
- Reactor switching

A detailed discussion of switching surge strength is provided in Chapter 5. The following provides an overview of key issues for the designer in considering switching stress on a line.

The Effect of Trapped Charge

If the breaker at the energizing end of an open-circuited line is opened at line charging-current-zero, the line voltage will be at peak and charge will be trapped on the phase conductors. The only path for discharge is leakage over the insulators, which usually have a very high resistance, so discharge can take several minutes. If the line is re-energized while trapped charge remains, it is possible for this to occur with opposite polarities between the supply and line sides of the breaker. A 2 p.u. traveling wave can be doubled at the open-circuit far end of the line, resulting in a 4 p.u. line-to-ground voltage. If the line is long enough to have an appreciable Ferranti effect (see Section 3.2-4), the initial wave may be greater than 2 p.u.

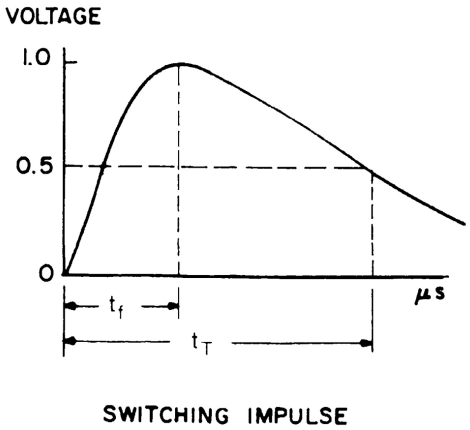

Figure 3.2-1 Idealized surge waveform.

Overvoltages from a Circuit Opening

Switching surges from de-energizing a transmission line are usually of less concern, since the line is in the process of being de-energized anyway. Circuit breakers are controlled to open their contacts at zero instantaneous phase current, but if a nonzero current is interrupted, this will cause a transient that is usually small. The greatest concern for circuit opening is a restrike across the opening contacts, which can initiate a traveling wave to the far end of the line. If the far circuit breaker has already opened, then a voltage doubling can occur as the traveling wave is reflected, with the possibility of further arcing across the breaker contacts. In reality, these voltage surges would be limited, for example by arresters, and the primary concern in this circumstance would be the failure of the breaker.

Circuit Opening with a Fault

A fault on an overhead line is most commonly phase to ground, but other types of fault may occur. Faults can result in high currents and depressed voltages. When the breaker operates to de-energize the line and clear the fault, there may be significant voltage swings—in particular on unfaulted phases. However, since the line is being de-energized, any resulting voltage surges are of little consequence to the line insulation, except when single-phase switching is used.

Variation of Switching Surge Amplitude along a Transmission Line

Unlike lightning, where the most severe voltages occur at a few structures close to the stroke, a switching surge voltage is considered as appearing on all the structures of the line.

The magnitude of the surge varies along the line. This variation is described by the *surge profile*, which gives the relation between the surge magnitude at a point of the line and the surge magnitude at the receiving end—i.e., the end of the line opposite to the location where switching operation takes place. At an unterminated receiving end, a surge propagating along the line reaches its highest value. The switching surge amplitude distribution for a transmission line refers to the receiving end. The surge profile is usually simplified by considering a linear variation of amplitude versus distance. In this case, the surge profile is characterized by the ratio, α, between the surge amplitudes at the sending end, S_S, and at the receiving end, S_R:

$$\alpha = \frac{S_S}{S_R} \qquad 3.2\text{-}3$$

Values of α range between 0.6 and 1.0.

Distribution of Switching Surge Waveshapes

The shape of the switching surges is usually not considered as a variable in line design: all surges are assumed to have the same shape with an equivalent time-to-crest corresponding to the critical wave—i.e., the shape that corresponds to the lowest strength (see Section 5.2.3). This simplification leads to some conservatism in estimates of the risk of failure. It is known that most surges have equivalent times-to-crest much longer than the critical, but quantitative data are scarce. Four distributions of times-to-crest have been reported for 345-kV transmission systems (McElroy and Charkow 1967). The reported times-to-crest were converted into equivalent times-to-crest of double-exponential impulses (see Section 5.2.3). The 50% values and the standard deviations were estimated, and the curves were approximated by Gaussians and plotted as shown in Figure 3.2-2. For these examples, practically all surges have equivalent times-to-crest far greater than those that are critical for the insulation systems of 345-kV transmission lines, which are in the range of 50 to 150 μs.

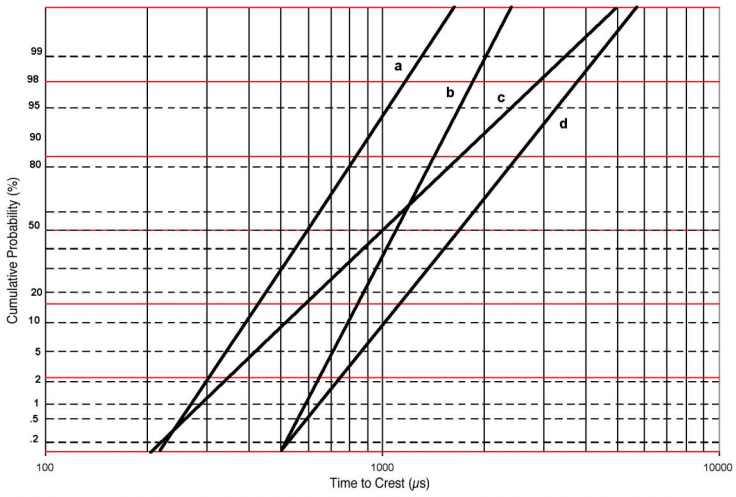

Figure 3.2-2 Distribution of switching surge equivalent times-to-crest recorded on various unterminated configurations of well-developed 345-kV transmission systems (McElroy and Charkow 1967). (a) Receiving end of 100-km line. Source with transformers and two other lines. (b) Receiving end of 100-km line. Source with transformers only and no other lines connected. (c) Receiving end, composite of configurations with line lengths between 100 and 250 km. (d) At 345-kV buses, composite for all configurations.

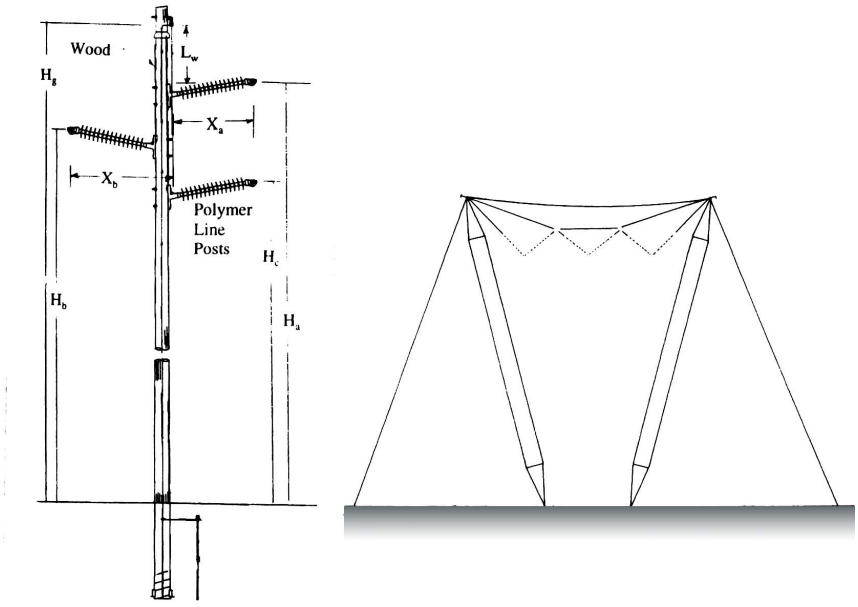

Figure 3.2-3 Examples with phase-to-phase clearances with no grounded member between phases. Left side: vertical configuration with insulator posts. Right side: Chainette.

Phase-to-Phase Switching Surges

Until recently, overhead transmission-line designs were built using structures where the phases were separated by grounded tower members—for example, in a typical H-frame structure. As a result, phase-to-phase spacing was determined as a byproduct of two phase-to-ground clearances. However, in some modern designs, such as the Chainette or where insulator posts are used, as shown in Figure 3.2-3, there may be no grounded member between phases, and the phase-to-phase clearance must be considered.

Phase-to-phase switching surges can be characterized as shown in the idealized waveform in Figure 3.2-4. The phase-to-phase voltage results from the difference between the phase-to-ground voltages. Factors include relative polarity, relative magnitude, and the time difference between crest values (Grant and Paulson 1980).

Distributions of phase-to-phase switching surges can be calculated in just the same way as for phase-to-ground using EMTP or similar programs, although most programs are configured solely for phase-to-ground voltages, and obtaining phase-to-phase values may require extra work. The wider range of variables involved in the waveform makes it more difficult to characterize the surge in a way that can be compared with insulator flashover strength information.

While the peak value of the phase-to-ground surges are often known with a sufficient degree of confidence, there have been only a few data on phase-to-phase switching surges. These data suggest an approximate relation between phase-to-ground and phase-to-phase magnitude (EPRI 1978; CIGRE 1979). This relation may be used to estimate the phase-to-phase surge amplitude distribution. If the 2% or the 50% values of the phase-to-ground surge magnitudes are known, the corresponding 2% or 50% values of the phase-to-phase surge magnitudes may be estimated using the curves of Figure 3.2-5. The figure shows that, although the theoretical maximum of the phase-to-phase surge is twice the maximum of the phase-to-ground surge, this is far from the practical case. The ratio between phase-to-phase and phase-to-ground surges goes from $\sqrt{3}$

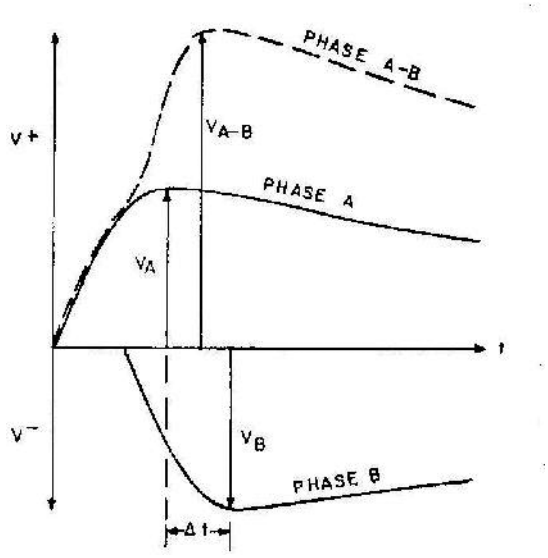

Figure 3.2-4 Idealized phase-to-phase waveform.

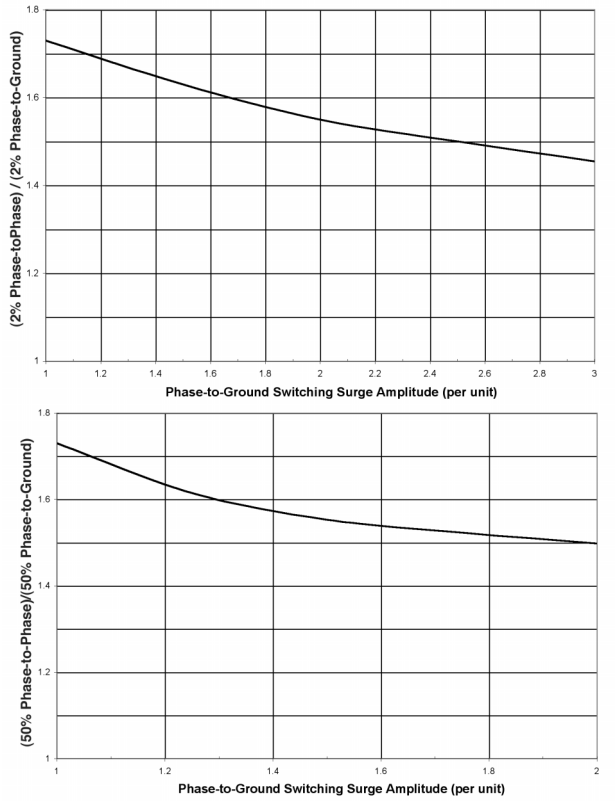

Figure 3.2-5 Approximate relation between phase-to-phase and phase-to-ground switching surge distribution values.

in the steady state (set of three phase-to-ground voltages at power frequency) to less than 1.5 for high-surge values; i.e., when one phase-to-ground surge is high, there is a low probability that another simultaneous phase-to-ground surge is also high and of opposite polarity.

The standard deviation, σ_S, of the phase-to-phase surge amplitude distribution may be estimated from Figure 3.2-6, which represents the average results obtained in a large number of Transient Network Analyzer (TNA) tests (CIGRE 1979). The standard deviation of the switching surge amplitude distribution is important for the design of phase-to-phase distances. It should be noted that, for this purpose, the most important surges are those with the largest amplitudes. The surge amplitude distribution is far from Gaussian in the region of highest surges (see example in Figure 3.2-8) and it would be preferable to consider the equivalent standard deviation obtained interpolating with a Gaussian only the highest surges. The equivalent standard deviation so obtained is much smaller than that reported in Figure 3.2-6.

A much more difficult parameter to obtain from switching surge studies is the value of the ratio, α, between the voltage applied to the negative phase and the phase-to-phase

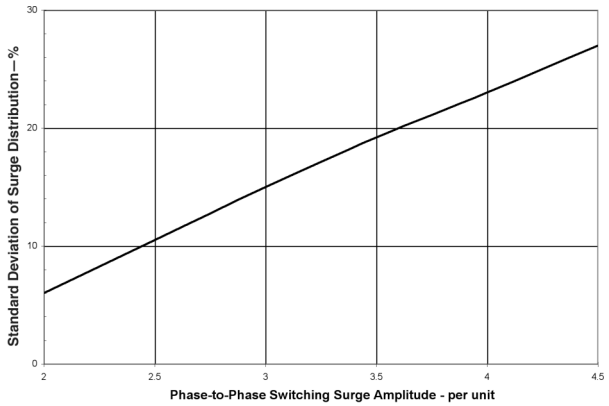

Figure 3.2-6 Standard deviation of the distribution of phase-to-phase switching surge amplitudes versus the 2% phase-to-phase surge amplitude.

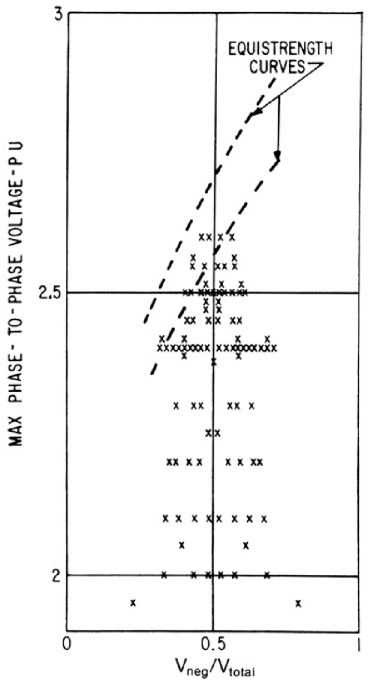

Figure 3.2-7 Example of phase-to-phase crest voltages and corresponding values of $\alpha = V_{neg}/V_{tot}$. One per-unit equals the crest value of line-to-ground voltage.

amplitude at the instant of maximum phase-to-phase surge ($\alpha = V_{neg}/V_{tot}$). An example is shown in Figure 3.2-7, which is representative of cases in which surges are minimized by using breakers with pre-insertion resistors (EPRI 1982). In this example, the maximum phase-to-phase overvoltages are concentrated around $\alpha = 0.5$. Another example that confirms this conclusion can be found in (Cortina et al. 1976).

Because the strength is a function of α, each point of Figure 3.2-7 may be shifted along equi-strength lines having the slope equal to that of the curves showing V_{50} versus α

(see Section 5.8). In such a manner, all the points can be transported on the line for $\alpha = 0.5$. Each surge is now assumed to consist of the combination of equal positive and negative phase-to-ground surges ($\alpha = 0.5$). The statistical distribution of the values so obtained is drawn in Figure 3.2-8 in a log-normal graph. It represents the same stress as the real distribution. An equivalent Gaussian distribution may be obtained by interpolating with a straight line the upper part of the curve, which is the most important for insulation design. This procedure yields the 2% and 50% phase-to-phase surge values and the standard deviation of the surge amplitude distribution that should be used for phase-to-phase distance design. The values applicable to the example of Figure 3.2-7 are:

V_{tot}, 2% = 2.6 per unit.
V_{tot}, 50% = 2.47 per unit.
σ_S = 2.4%.

Calculation of Switching Surge Magnitudes

Switching surge magnitudes were once determined from TNA studies, but today are obtained from digital programs such as EMTP (see Appendix 3.1). Magnitudes can be modeled as a statistical distribution. Early models considered magnitudes as histograms, but today they are typically modeled as continuous functions.

Several examples of switching surge voltage distributions can be found in the literature (CIGRE 1979; Truax et al. 1978; Clerici 1972; CIGRE 1972; CIGRE 1973-2; CIGRE 1974). The region of interest consists in the upper third of the distribution, because only the high-surge values have an impact on the risk of failure. Unfortunately, the upper portion of the distribution is the most difficult to define. Although a majority of switching surge results are reasonably fit by a Gaussian distribution, others have shown better fit to an extreme value or to a bimodal distribution. A reasonable approximation consists of a Gaussian curve that interpolates only the upper third of the switching surge distribution up to a point at which the curve can be truncated. An example of a surge distribution determined with a large number of digital switching simulations and of the truncated Gaussian approximation is shown in Figure 3.2-9. The truncation point depends on the type of distribution, and varies between 2 and 3 standard deviations above the 50% value.

The surge value, S_2, corresponding to 2% probability is considered a good measure of the level of surges in the low probability region, and is defined as the statistical maximum surge. For a Gaussian curve, 2% probability corresponds approximately to the 2.05 standard deviations above the 50% value, $S_2 \approx S_{50}\,(1+2.05 \cdot \sigma_s)$. The statistical maximum surge, S_2, the standard deviation, σ_s, and the value of the probability at the truncation point are needed to characterize the surge distribution. In the example of Figure 3.2-9 S_{50} = 1.47 per unit, S_2 = 1.82 per unit, $\sigma_s = \dfrac{(1.82 - 1.47)/2.05}{1.47} \cdot 100 = 11.6\%$, and the truncation point is set at about 2.1 standard deviations above the 50% value.

There are several data on the statistical maximum switching surges on transmission lines. As transmission-line voltages are increased, and switching surges play a more limiting role in line design, there are more economic incentives to reduce their maximum values using sophisticated surge control techniques. For this reason, the statistical maximum values usually considered in the design of transmission lines decreases with system voltage, as indicated in Table 3.2-2.

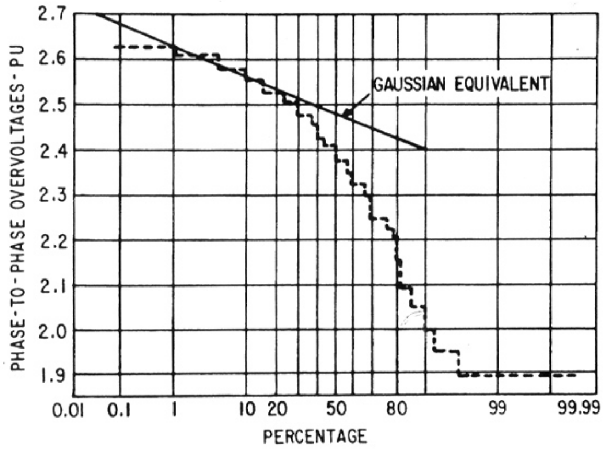

Figure 3.2-8 Distribution of phase-to-phase equivalent (α = 0.5) surge amplitudes for the example of Figure 3.2-7.

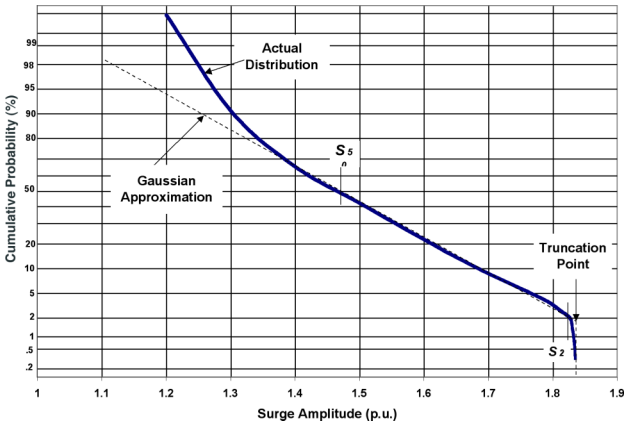

Figure 3.2-9 Example of switching surge amplitude distribution and its approximation with a truncated Gaussian curve.

Table 3.2-2 Practical Values of Statistical Maximum Phase-to-Ground Switching Surge Amplitudes versus System Voltage

Maximum System Voltage (kV)	230	362	550	800	1200
Statistical Maximum (2%) (p.u.)	2.5 2.25 2.0	2.25 2.0 1.75	2.0 1.75	2.0 1.75	2.0 1.75 1.5

The standard deviation of the Gaussian equivalent of the upper portion of the surge distribution varies with the system parameters and configurations, and with the method of interpolation of the actual distribution, especially if the truncation point is not well defined. Most likely values of σ_s are between 10 and 20%.

3.2.4 Temporary Overvoltages

Transmission lines operate continuously at their design voltage (230 kV, 345 kV, etc.), and their voltage is controlled within very narrow bounds, typically no more than ±5%, although ±10% is sometimes used. Line insulation is not normally governed by power frequency, unless the insulation is damaged or degraded, or environmental stresses are significant. Environmental stresses include contamination, ice, snow, fires, bird droppings, and rain, and like the temporary overvoltages, have the effect of reducing the resistance of the insulation to flashover. Allowance for these stresses is described in the later design sections of this Chapter.

Two sources of elevated voltage are considered in the same time domain as power frequency: the Ferranti effect, and the effects of faults.

Ferranti Effect

The steady voltage at the open end of an uncompensated transmission line is always higher than the voltage at the sending end (see Figure 3.2-10). This phenomenon is known as the "Ferranti effect." It occurs because the capacitive charging current flows through the series inductance of the line. The voltage at the sending end, although lower than that at the remote end, is still higher than the one that prevailed when the line was loaded. Overvoltages due to the Ferranti effect are sinusoidal in nature.

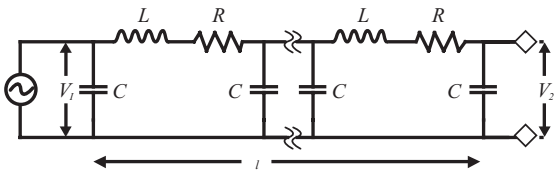

Figure 3.2-10 Typical uncompensated long transmission line.

As shown in Equation 3.2-4, for a typical uncompensated line, the voltage at the open end of the line is approximately (Naidu and Kamaraju 1995):

$$V_2 = \frac{V_1}{l.\cos\beta} \qquad 3.2\text{-}4$$

Where:

V_1 = sending-end voltage.
V_2 = receiving-end voltage, open circuit.
β = phase constant of the line.

$$\approx \left[\frac{(R + j\omega L)(G + j\omega C)}{LC}\right]^{1/2}$$

≈ about 7.2° per 100-km line (4.5° per 100-mile line) at 60 Hz and 6° per 100-km line (3.75° per 100-mile line) at 50 Hz.

Where:

ω = angular frequency.
l = line length.
R = resistance per unit length.
C = capacitance per unit length.
L = inductance per unit length.
G = leakage conductance per unit length.

An approximate solution can be derived simplifying the circuit of Figure 3.2-10 as in Figure 3.2-11. The capacitance is concentrated in the middle of the line. The charging current, I_C, is:

$$I_C \approx j\omega C V_1 = \frac{V_1}{X_C} \qquad 3.2\text{-}5$$

And the voltage

$$V_2 \approx V_1\left[1 - \frac{X_L}{2X_C}\right] \qquad 3.2\text{-}6$$

Where:

X_L = line inductive reactance.
X_C = line capacitive reactance.

This approximate solution is shown in Figure 3.2-11.

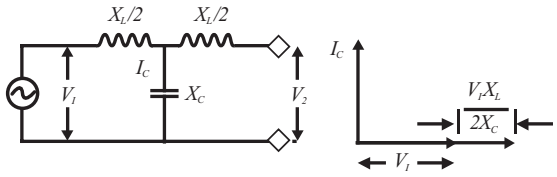

Figure 3.2-11 Transmission-line approximation for Ferranti Effect calculations.

Overvoltage due to the Ferranti effect is more pronounced the longer the line, the higher the line voltage, and the lighter the load at the receiving end. It is one of the most common overvoltages on lines exceeding 345 kV, and unless corrected, may be a concern for the insulation level of relevant components and the selection of the surge arresters. In some cases, the overvoltage due to the Ferranti effect may be higher than the maximum continuous operating voltage of the arresters at the transmission terminals (Petcharaka et al. 1999). In 345-kV systems and above, after a full-load rejection, the phase-to-ground overvoltages may reach 1.5 p.u., or even more when Ferranti or resonance effects occur. Overvoltage durations may be in the order of seconds. Figure 3.2-12 illustrates the receiving-end voltage rise due to Ferranti effects with different voltage level and load conditions.

Design for Ferranti Effect

Because Ferranti effect overvoltages are controlled by line compensation, they are typically considered separately from the main insulation coordination process. Compensation can be achieved with either shunt (inductive, more common) or series (capacitive, sometimes used—e.g., Hydro-Quebec, see below) compensation. Figure 3.2-12, from Diesendorf (Diesendorf 1974), shows the results of shunt and series compensation. Some shunt reactor compensation may be controlled in order to dampen all significant voltage surges and to improve power stability limits. In 500-kV transmission systems, the optimal ratio of controllable to noncontrollable shunt reactors is about 1:3.

In the Hydro-Québec 735-kV transmission system, the length of the two major transmission branches running from Churchill Falls to Québec City and from James Bay generating stations to Montreal is approximately 1000 km

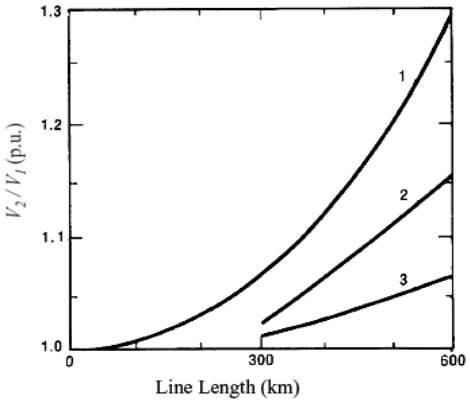

Figure 3.2-12 Effects of line compensation on Ferranti Effect (Diesendorf 1974)
1) No compensation;
2) 50% series capacitor compensation; and
3) 50% series capacitor and 70% shunt reactor compensation

(Bui-Van and Rousseau 2001). Shunt reactors, synchronous condensers, and static VAR compensators were installed on this transmission system. However, after a system separation occurred as a result of a system fault, severe temporary overvoltages due to the Ferranti effect appeared on long unloaded lines connected to generators. In order to control the magnitude and duration of such temporary overvoltages, several measures were also applied including implementation of series-capacitor banks, instantaneous 1.2 p.u. overvoltage protection, and various automatic switching schemes.

Fault-Related Overvoltages

The occurrence of a fault on a transmission system causes both a switching overvoltage and a temporary overvoltage. Temporary overvoltages initiated from faults may persist and stress the insulation until the voltage is removed by switching.

Line fault conditions include single line-to-ground (SLG), double line-to-ground (DLG), three-phase grounded (3ϕG), and three-phase ungrounded (3ϕU) (Colclaser et al. 1970). The most common fault is single line-to-ground, especially on high-voltage lines (Kimbark and Legate 1968). Three-phase faults are very rare, and their likelihood decreases as the system voltage increases. The waveform of fault-initiated overvoltages is generally sinusoidal, and may be described in terms of an rms or a peak value. If the voltage is high enough, there may be saturation effects in transformers, leading to the generation of harmonics and waveform distortion. Under any conditions in which the waveshape is distorted, a description of the voltage in terms of an rms value would be misleading if one were considering insulation. The peak voltage is a better measure of the effects of the voltage on the insulation, but even this may not be very appropriate.

Whenever a fault occurs, a current is suddenly injected into the system from the fault point, and a voltage with equal and opposite polarity to that existing is also suddenly applied to the same point. This will result in traveling waves along both the faulted lines and the electrically adjacent unfaulted lines. The resultant transient voltages are normally damped out within half a cycle similar to switching overvoltages. This initial transient is followed by longer-term voltage changes on the faulted and unfaulted phases until the fault is cleared. The magnitudes of such voltages are influenced by the length of the line, the losses in the conductors, and the ground path.

Switching overvoltage related to faults depends on many factors such as:

- The “stiffness” of the system
- The grounding of the system

- The length of the transmission lines
- The location and parameters of the transformers
- The degree of compensation, and
- The nature of the fault

Overvoltages on Unfaulted Phases

Single line-to-ground faults can cause a significant increase in voltage of the other two phases due to the asymmetry of a system if its neutral is not solidly grounded. Theoretically the magnitude of an overvoltage can reach 2.73 p.u. when the peak of the overvoltage occurs simultaneously with the peak of the power frequency voltage. In practice, it is suppressed by charge reversal of capacitances and lines, and is generally well below 2.7 p.u. It is higher only in exceptional cases in radial lines or widely spread-out systems with floating neutrals or ground fault compensation. Reported values range from 1.45 p.u. for an UHV system (Colclaser et al. 1970) to as high as 2.1 p.u. for 345-kV and above systems. The worst location of a single line-to-ground fault is at the midpoint of a line. The worst termination is zero impedance, which is approximately the situation for a bus having several other lines (Kimbark and Legate 1968; Boonyubol et al. 1970). As the line length increases, the maximum transient overvoltage due to a single line-to-ground fault increases (with a decreasing rate). For example, simulation shows that this overvoltage can range from about 1.9 p.u. for a 50-mile line to about 2.1 p.u. for a 1000-mile line (Boonyubol et al. 1970).

If a healthy phase cannot withstand the overvoltage during a single line-to-ground fault, a double line-to-ground fault will occur. The magnitude of a double line-to-ground fault-initiated transient overvoltage can reach 2.2 p.u., and the resulting transient recovery voltage (TRV) can be as high as 3.8 p.u. for a series-compensated line (Thanassoulis et al. 1975).

Overvoltages on Compensated Lines

Because of transmission-line reactive characteristics, the fault-clearing operation of a breaker can be equivalent to the opening of a capacitive circuit. The resulting overvoltage magnitude can easily reach 1.7 p.u. for a single line-to-ground fault (Colclaser et al. 1970; Thanassoulis et al. 1975) and as high as 2.2 p.u. for a double line-to-ground fault (Kimbark and Legate 1968). If the line is equipped with series or shunt compensation, the fault-clearing phenomena are usually more complex and the overvoltages higher. A series-compensated system can experience high-magnitude overvoltages on unfaulted lines following the fault initiation and subsequent bypassing of series capacitors. Series capacitors can suppress power frequency temporary overvoltages, such as those due to the Ferranti effect, but when there is a fault on a line, the voltage increase across the series capacitors will cause a bypassing operation to protect them. The decay of capacitor-stored energy can produce transients with very high frequency oscillations and high peaks that can reach about 2.0 p.u. The case is particularly serious for long and highly compensated lines. The magnitude of these voltage transients depends on the parameters of the line, the values of system impedance, and the characteristics of series capacitor protective bypass devices. These transients can be minimized by careful selection of the bypass devices.

Effect of System Grounding on Overvoltages

An isolated-neutral system can give rise to dangerous arcing fault overvoltages if the capacitive arc current exceeds 5 to 10 A. An arc initiated by a fault can persist if its current is maintained through the capacitive coupling of the other two healthy phases. When the arc experiences continual extinguishing and restriking, there is a high risk of a very high voltage because of the capacitive nature of the arc current (Bickford and Heaton 1986). These conditions rarely exist in 345-kV and above systems, since most are effectively grounded, but under certain conditions, the grounding of a system may change—for example, if a transformer with a grounded neutral is removed from the system. It is important for insulation design that overvoltages be calculated under the worst possible conditions to identify the highest values that are likely to occur. With the loss of effective grounding, the temporary overvoltages might be high enough to operate surge arresters. The resulting waveforms will be nonsinusoidal, and calculations of insulation performance must allow for this.

Overvoltages from "Short Line" Faults

When a ground fault occurs within a short distance along the transmission line, a triangular wave voltage appears on the line side terminal of the circuit breaker when the fault is cleared (Greenwood 1991). This phenomenon is named as a short line fault or a kilometric fault. The triangular waveform appears also as a component in the transient recovery voltage (TRV) across the circuit breaker. The frequency of the triangular component of voltage is inversely proportional to the travel time along the length of line between the fault and the circuit breaker. The amplitude of this component is directly proportional to the length of the line between the circuit breaker and the location of the fault itself. For faults up to a few kilometers from the circuit breaker, high initial rates of rise of TRV are obtained. These are onerous for the circuit breaker.

Design for Fault-Initiated Overvoltages

Since system insulation must be able to withstand overvoltages caused by faults, it would be prudent to design or use breakers that limit switching overvoltages to less than these values. When breakers operate to clear fault current, a switching overvoltage may occur. This overvoltage magnitude may exceed 1.7 per unit. If the line is equipped with

series or shunt compensation, the resultant transients may be more complex and the overvoltages may be higher. For example, when an unloaded transmission line is exposed to a single or two-phase fault, the circuit breaker at its sending end may open the contacts to interrupt the current. The interruption of current on the unfaulted phases is a case of capacitive switching. Circuit unbalances introduced by the fault also affect the voltage on the unfaulted phases prior to current interruption, causing in most cases a voltage rise on the unfaulted phases. The magnitudes of overvoltages appearing on unfaulted phases depend on fault location, system X_0/X_1 ratio, and fault current magnitude. The overvoltage on the unfaulted phases will be less than 1.4 per unit on effectively grounded systems and 1.73 per unit or greater on ungrounded systems. According to IEEE Standard C62.11 (IEEE 1999), a system is defined as effectively grounded when the highest rms line-to-ground voltage on a sound phase is 80% or less of the normal line-to-line voltage at the fault location. An ungrounded load supplied from the delta winding of a transformer is an example of an ungrounded system. Under certain conditions, the grounding of a system may change—for example, if a transformer with a grounded neutral is removed from the system. It is important for insulation design that the overvoltages be calculated under the worst possible conditions to identify the highest values that are likely to occur. With the loss of effective grounding, temporary overvoltages might be high enough to operate surge arresters. Arresters on a well-grounded system are normally exposed to only low-magnitude temporary overvoltages during a single-line-to-ground fault.

As for Ferranti effects, overvoltages due to faults are typically considered separately from the main insulation coordination process. Accommodation of these overvoltages is achieved through selection of appropriate grounding, breakers, and station arresters.

3.2.5 Environmental Stress

Environmental stresses to lines—due to pollution, rain, snow, ice, and temperature affecting the line insulation—are important. Like temporary overvoltages, they have the effect of reducing the resistance of the insulation to flashover. A brief overview is provided here, and more detailed information in Chapter 4 for power frequency voltage and in Chapter 5 for switching overvoltages.

Sources of Contamination on Line Insulation

Contamination and humidity falling on the insulators produce a conductive film on the surface that causes a surface leakage current that can increase and eventually result in flashover. Many types of contamination may be present along the route of the transmission line, depending upon their source. Table 3.2-3, which is from IEEE Standard 957 (IEEE 1995), details the most common types of contamination. Basically, the types of contamination can be classified into two categories: sea contamination and industrial contamination. Different laboratory tests are used to determine the strength of insulators against these two types of contamination. The severity of sea contamination may be defined by the salinity (amount of salt per unit of water volume) or electrical conductivity of the water used to spray the insulators under tests. Industrial contamination is sometimes expressed by the equivalent salt deposit density (ESDD), which is defined as the equivalent amount of NaCl that, when wet, would yield the same conductivity as the actual contaminant.

The general site severity and its definition from the IEC 60815 Guide (IEC, 1986) are shown in Table 3.3-3 in terms of the ESDD. The amount of salt deposit density that leads to flashovers at line voltage depends mainly on the voltage stress across the insulators and the insulator material. The pollution deposit on the top surfaces of insulators builds up rapidly, but is also effectively cleaned by relatively small amounts of rain.

Icing

Under conditions of moderate icing, it is common for icicles to form on insulator strings. These icicles tend to grow in length, bridging the air gaps between insulator caps or

Table 3.2-3 Typical Sources of Contamination on Line Insulators

Type of Contaminant	Typical Source of Contamination
Sea	
Salt	Coastal areas Salt industries/farms
Industrial	
Cement	Cement plants Construction sites Rock quarries
Dust	
Earth	Plowed fields Earth moving on construction projects
Fertilizers	Fertilizer plants Frequent use of fertilizers in cultivated fields
Metallic	Mining handling processes Mineral-handling processes
Coal	Coal mining Coal-handling plants/thermal plants Coal burning/brick kilns areas
Feedlot	Provender dust and earth dust stirred by animals in large feedlots
Defecation	Roosts in bird areas
Chemical	Wide variety of chemical / process industries, oil refineries, etc.
Smog	Automobile emissions at highway crossings Diesel engine emissions at railway crossings / yards
Smoke	Wild fires Industrial burning Agricultural burning

sheds and shorting out the leakage distance. The combination of pollution accumulation—for example, from road salting—followed by ice or freezing fog accretion, has proved to be particularly severe conditions for insulators in power systems to withstand.

Most troubles have occurred on transmission lines and stations that are located near sources of salt, such as the ocean or urban expressways. With typical road salting levels of 16 tons per lane mile in the winter season for most provinces and states that perform winter maintenance, a location near an expressway is equivalent to a location 1 km from the sea coast.

Rain

Rain may substantially reduce the ac strength of insulators, depending on the rate of rainfall, conductivity of the rainwater and the insulator configuration considered. Typical flashover stress levels on glass and porcelain cap-and-pin insulators lie between 250 and 300 kV per meter of section length during standard wet tests with a low conductivity artificial rain. Figure 3.2-13 shows the wet ac flashover strength of a selection of typical disc insulators.

Birds

Birds resting on or taking off from transmission lines may produce a stream of defecation that contaminates an insulator or even creates a conductive path between a phase and grounded structure component. Other bird-caused problems include nests on transmission structures that include sticks or material that can bridge an insulator.

Bird contamination may cause either direct flashovers or subsequent flashovers in the presence of dew or rain. The problem tends to be regional, depending on the preferred habitat and sources of food of the birds.

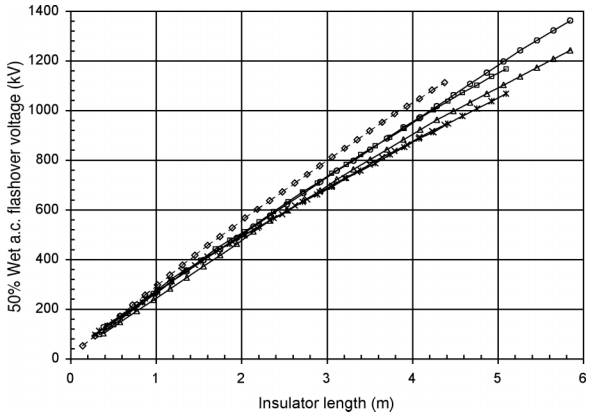

Figure 3.2-13 Wet ac flashover voltage of various shapes of cap-and-pin insulator strings.

3.2.6 Summary

This section described the nature of the voltage stresses that a transmission line is subjected to, and hence, for which the insulation strength should be designed.

Lightning Overvoltages

Lightning strokes to transmission structures, phase conductors, or shield wires can cause flashovers that force the line to trip. On transmission lines covered by this reference book, lightning-related outages are of two kinds: shielding failures or backflashovers. For the calculation of lightning performance of transmission lines, the waveshape of the stroke current is defined in various ways that either try to reproduce the variety of waveshapes of actual strokes or are convenient for carrying out calculations (see Chapter 6). While power frequency voltage may determine which phase flashes over first, it may also be secondary to other considerations.

Design for lightning includes setting the insulation level, line geometry and clearances, shielding, grounding, pole-top arresters, and other self-extinguishing discharge mechanisms, and rearrangements of line phases.

Switching Surge Overvoltages

Switching surges in a power system result from energizing and de-energizing of lines, capacitors, reactors, and transformers. Switching surges from de-energizing a transmission line are usually of less concern from those associated with the energization of lines or the equipment. The greatest concern for circuit opening is a restrike across the opening contacts, which can initiate a traveling wave to the far end of the line.

Distributions of phase-to-phase switching surges can be calculated in just the same way as for phase-to-ground using a transients program, although most programs are configured solely for phase-to-ground voltages, and obtaining phase-to-phase values may require extra work. While the peak value of the phase-to-ground surges is often known with a sufficient degree of confidence, little data is available on phase-to-phase switching surges.

As transmission-line voltages are increased, and switching surges play a more limiting role in line design, there are more economic incentives to reduce their maximum values using more sophisticated surge control techniques. For this reason, the statistical maximum values usually considered in the design of transmission lines decrease with system voltage.

Temporary Overvoltages

Transmission lines operate continuously at their design voltage (230 kV, 345 kV, etc.), and their voltage is controlled within very narrow bounds, typically no more than

+5%, although +10% is sometimes used. Line insulation is not normally governed by power frequency, unless the insulation is damaged or degraded, or contamination is present. However, there are two sources of elevated power frequency voltages. These are the Ferranti effect, and the effects of faults. Overvoltages due to the Ferranti effect are more pronounced the longer the line, the higher the line voltage, and the lighter the load at the receiving end.

Unless corrected, these temporary overvoltages may be a concern for the insulation level of relevant components and the selection of the surge arresters. It is important for insulation design that the temporary overvoltages be calculated under the worst possible conditions to identify the highest values that are likely to occur.

Environmental Stresses

Environmental stresses to lines—due to pollution, rain, snow, ice, and temperature—have the effect of weakening the line insulation, and are considered at the appropriate level together with the worst-case temporary overvoltages, as described above.

Given the voltage stresses, the insulation for the transmission line is specified and coordinated, as discussed in Section 3.3.

3.3 INSULATION STRENGTH

3.3.1 Introduction

This section provides an overview of transmission-line insulation strength and the key parameters that are significant to the line designer. For greater detail, the designer is referred to the chapters on power frequency (Chapter 4), switching surge (Chapter 5), and lightning (Chapter 6).

The line insulation must have enough strength to meet the stresses produced by the overvoltages discussed in Section 3.2. In all cases (lightning, switching, and power frequency), the insulation strength is expressed in terms of a withstand voltage. This voltage is the highest voltage that the insulation can withstand without failure or disruptive discharge, and is a quantity determined by tests conducted under specified conditions with a specified waveshape of the applied voltage. The parameters generally used to characterize the waveshape of a lightning or a switching impulse are polarity; “front time” (variously defined), or time from zero to crest; and “tail time” (variously defined), or time from zero to half value after crest. In particular, this chapter and Chapters 4, 5, and 6 relate the strength of the insulations in terms of a statistical term, V_{50}. V_{50} is the crest value of the impulse wave that, under specified conditions, causes flashover through the surrounding medium on 50% of the applications. It is also known as the *critical flashover voltage* (CFO). The term V_{50} will be used throughout this book.

Since overvoltages may have a wide range of waveshapes, rather than attempting to determine the withstand strength for each of the naturally occurring stresses by test, it is common practice to assign a specific testing waveshape and duration of its application to each category of overvoltage.

The purpose of the lightning impulse test is to evaluate the performance of insulation when exposed to short-duration voltages, principally those produced by lightning. It is performed with a test voltage having a shape of 1.2/50 μs.

The purpose of the switching impulse test is to evaluate the insulation under stresses such as those produced by switching operations. Since switching surges may occur with a variety of waveshapes, it is of particular importance to test the insulation with the waveshape that corresponds to the lowest flashover voltage. The critical waveshape is of positive polarity, and the critical time-to-crest varies from 50 to 500 μs, depending on the length of the gap between the energized electrode and the grounded part of the insulation. The performance of insulation subjected to switching impulses is discussed in Chapter 5. Since the lowest values of V_{50} flashover voltage occur for a positive polarity impulse applied to a rod protruding toward a plane, the strength of this gap geometry is given particular attention.

The purpose of the long-duration, low-frequency test is to determine if the insulation can operate permanently at the maximum system voltage. For internal insulation, the test is concerned with a demonstration of aging, and for external insulation, with the effect of the usual types of contamination. The testing waveshape is 60- or 50-Hz voltage, and the duration of its application may extend from minutes to hours, depending on the test's specific purpose. Tests to determine the effects of contamination, in particular, require the test voltage be maintained for long periods of time. Even though contamination itself may hardly be classified as voltage stress, it certainly is a factor determining insulator withstand. Behavior of insulation under this test is discussed in Chapter 4.

3.3.2 Lightning Impulse Strength

This section briefly summarizes the lightning impulse strength (more detail is available in Section 6.5). It describes the insulation dielectric strength when subjected to the standard lightning waveshape, and explains how to calculate the strength for nonstandard lightning waveshapes.

The lightning impulse strength is proportional to the gap spacing (strike distance in the case of insulators) and depends on polarity. The lowest strength, about 520-560 kV/m, occurs

when the conductor is positive with respect to the tower, such as when a negative stroke hits the tower (backflash). When the conductor is negative with respect to the tower, such as when a negative stroke hits a conductor (shielding failure), the strength is about 600-610 kV/m.

The insulation strength for lightning impulses is normally only available through testing for the standard lightning impulse voltage wave, specified by its rise time and time to half value as 1.2/50 μs. However, this waveshape seldom occurs on the utility system; as noted in Section 6.2, there is no "one" lightning waveshape. Instead a statistical approach is needed to define the stress correctly. Therefore, either some approximations or a mathematical model of the breakdown process are frequently necessary to evaluate the strength of the insulation for nonstandard waveshapes. This is of primary importance in evaluating the insulation strength for surges resulting from a backflash, since the waveshape is nothing like the standard lightning waveshape. In contrast to the switching impulse, the tail or time-to-half-crest value of the lightning impulse usually has a significant influence on the V_{50}. Steep-rising overvoltages with duration that is limited by the distance to adjacent structures can cause less flashovers than indicated by test results obtained with a standard 1.2 x 50 μs voltage wave. From experience, the authors found that on a 345 kV line the calculated lightning outage rate is decreased by a factor between 2 and 3 by using the short-time impulse strength (2 μs).

Strength to Standard Lightning Waveshape: Volt-Time Curve Penetration Algorithm

In the second edition of the Red Book (EPRI 1982), a simple empirical expression was used to describe the flashover process (modeling the dielectric strength for positive polarity as a function of time to flashover) for a standard lightning impulse voltage wave, which is repeated here in Equation 3.3-1.

$$V_{50\%} = L(400 + 710 / t^{0.75}) \qquad 3.3\text{-}1$$

Where:

$V_{50\%}$ is the flashover voltage in kV (the actual voltage at flashover for flashovers occurring before crest and the crest voltage for flashovers occurring after crest).

t is the time to flashover in μs.

L is the insulator length in m.

For wet tower insulation in center or outside phases, approximations of insulation tower requirements for lightning have been recommended by Hileman (Hileman 1999). Hileman recommends a positive-polarity gradient for the $V_{50\%}$ of 560 kV/m for positive polarity and 605 kV/m for negative polarity for air-porcelain insulation. These apply for the porcelain insulator string length as well as strike distance.

Strength for Nonstandard Waveshape

The strength for nonstandard lightning waveshape has been approximated by a number of techniques. Two such techniques are presented here. This strength to nonstandard waveshapes is of primary importance in evaluating the insulation strength for surges resulting from a backflash since the waveshape is very different from the standard lightning waveshape.

The Disruptive Effect (DE) Algorithm, Typically for Faster-Front Flashover/Puncture

A widely used algorithm in digital programs to determine insulator strength to nonstandard lightning waveshape is the Disruptive Effect (DE) Algorithm. This method assumes that a critical voltage, V_0, could be withstood by the insulation even if applied continuously. If the voltage exceeds the critical voltage it acquires a Disruptive Effect which may lead to flashover depending on the magnitude of the voltage and the time above the critical voltage. The DE of a waveshape is evaluated as shown in Equation 3.3-2. As long as the voltage remains above the critical value, the disruptive effect keeps increasing until flashover when DE reaches a fixed critical value, DE_{crit}, which depends on gap configuration and voltage polarity. Different waveshapes may reach the critical DE at different voltages, as shown in Figure 3.3-1.

$$DE = \int_{T_0}^{T_d} (V(t) - V_0)^n dt \qquad 3.3\text{-}2$$

The IEEE Task Force (IEEE 2001) noted that the use of $n = 2.5$, $DE = 10^{10}$, and $V_0 = 300$ kV offers the best match to the volt-time characteristics of porcelain insulators in Equation 3.3-1.

The Leader Progression Model

Another model used to depict lighting insulation strength for nonstandard waveshapes is the leader progression model. CIGRE recommendations for leader propagation modelling, along with the reference volt-time characteris-

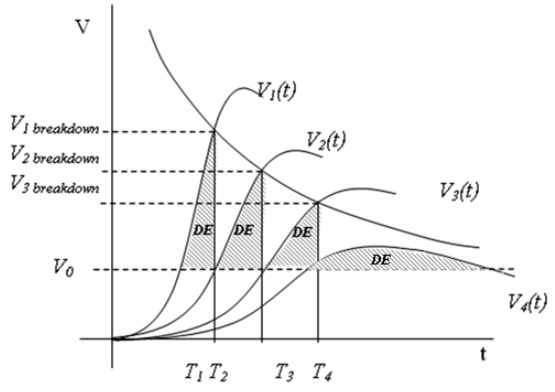

Figure 3.3-1 Disruptive effect for three nonstandard voltage waves.

tic for standard lightning impulse voltage on insulator strings, are shown in Figure 3.3-2. In examining this figure, there are two times of interest in the high-voltage flashover process: t_s, the time to develop streamers across the gap from both electrodes, and t_l, the time for a leader to propagate across the gap.

3.3.3 Switching Impulse Strength

A switching surge on a phase of a transmission line stresses all the insulation elements present on that phase. Insulation elements to be considered are the conductor-to-tower air gaps and insulator strings that are present on that phase. Calculation of the risk of switching surge flashover requires consideration of the parameters that define the surge (stress) and those that define the strength of the insulating elements (see Applet IC-2).

The parameters that define the stress are discussed in Section 3.2. They are:

- The statistical distribution of surge amplitudes at the receiving end. For application to Applet IC-2, this distribution is assumed to be a Gaussian distribution truncated at the upper end, and is defined by the value of:
  - The statistical maximum amplitude, S_2, which is the amplitude exceeded by 2% of all possible surges. This parameter is expressed in per unit of the crest value of the maximum phase-to-ground power frequency voltage.
  - The standard deviation of the surge amplitudes, σ_S. This parameter is expressed as a percentage of the amplitude exceeded 50% of the time, S_{50}.
  - The truncation value, which is the highest possible amplitude. This parameter is expressed by the number, T, of standard deviations above the 50% value.

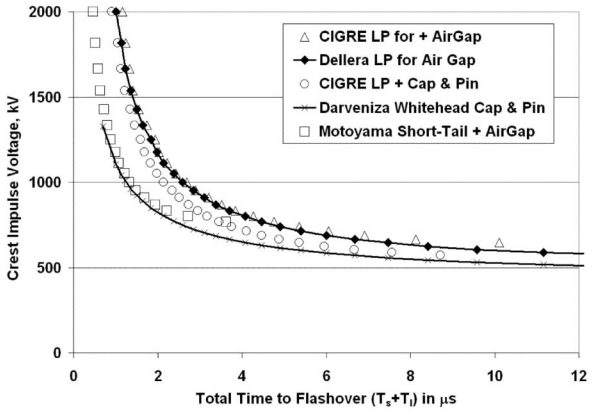

Figure 3.3-2 Comparison of predicted crest flashover voltage for leader progression (LP) models and observed volt-time characteristic of Equation 3.3-1.

- The function describing how the surge amplitude varies from sending to receiving end. Generally, this function is assumed linear. It is then defined by a parameter, α, which is equal to the ratio between sending-end and receiving-end amplitudes.
- The statistical distribution of the equivalent times-to-crest of the surges. The equivalent time-to-crest of a surge is defined in Chapter 5, Section 5.2.3. It is assumed that the distribution of equivalent times-to-crest is independent of the distribution of amplitudes. The distribution of times-to-crest is assumed to be Gaussian, and is defined by the 50% time-to-crest value, T_{50}, and by the standard deviation, σ_T.
- The polarity of the surges. It is assumed that surges may be either positive or negative with equal probability. For practical line insulation elements, the strength with negative polarity surges is significantly greater than that with positive polarity surges, so much so that negative polarity surges may be neglected entirely. The calculated risk of line flashover is divided by two.

The parameters that define the strength are:

- The switching surge strength of each insulating element of the line, defined by:
  - The 50% flashover voltage, V_{50}, corresponding to the critical time-to-crest. This parameter also is expressed in per unit of the crest value of the maximum phase-to-ground power frequency voltage. The value of V_{50} versus gap length is provided in Chapter 5 for a large variety of geometry. For a geometry that is not considered in Chapter 5, V_{50} may be calculated with Applet S1, "Switching Surge Flashover Model."
  - The standard deviation of the flashover probability function, σ_V. This parameter is expressed as a percentage of V_{50}. It is assumed that σ_V is independent of gap geometry and weather conditions. A large number of switching impulse flashover tests performed in several laboratories on transmission-line insulation elements indicates that the best estimate of the standard deviation is $\sigma_V = 4.5\%$. A conservative value of 5% is recommended for risk of flashover calculations.
  - All the parameters that may affect V_{50}. V_{50} depends on altitude above sea level (see Chapter 5, Section 5.11). V_{50} depends on the time-to–crest, and the dependence is a function of gap length (see Chapter 5, Section 5.10). V_{50} is also affected by wet weather, and the dependence is a function of gap length and of insulator strike distance (see Chapter 5, Section 5.12.1). Therefore, altitude, gap length, and insulator strike distance must also be provided (in addition to V_{50} or σ_V) to fully describe the switching surge strength of an insulating element.

Calculation of the risk of flashover of a transmission line due to a switching operation is based on comparing stress to strength. The line design is often uniform along the line. In some cases, however, various considerations may result in different insulation elements for different line sections. For instance, a certain type of tower may be preferable for aesthetic reasons in a populated area, all V-strings may be used in sections with high winds, more massive stronger towers may be used in sections with high icing incidence, different types of insulators may be used in sections with a high level of contamination and humidity, etc. Finally, even when the towers are the same, the insulation elements of each phase vary along the line if the line is transposed. It is, therefore, convenient to divide the line into sections in which there are different sets of insulating elements with all the elements of a set having the same strength and being subjected to the same stress.

Within each section, each phase is considered separately, since the insulating elements of the different phases are different (the phase-to-tower geometry, the height of the phase above ground, or the type of insulators may be different). Line sections must be chosen so that there is no transposition within the section, and the types of towers and the phase arrangements do not vary within the section. In addition, the surge amplitude, the altitude above sea level, and the atmospheric conditions applicable to each insulation element should not be too variable within the section so that they could be reasonably described by the average surge amplitude, the average altitude, and the average atmospheric conditions of the section.

While certain parameters (S_2, σ_S, T, T_{50}, and σ_T) are clearly attributes of the stress, and certain others (V_{50}, σ_V, gap length, insulator strike distance) are clearly attributes of the strength, other parameters that affect the risk of flashover may be considered as attributes of either the stress or the strength. Take, for instance, the effect of atmospheric conditions: temperature, humidity, and air pressure. As they vary, so does V_{50} (see Chapter 5, Section 5.11). The effect of atmospheric conditions would, therefore, appear to be an attribute of the strength. However, since temperature, humidity, and air pressure may be assumed to vary in a similar way for all the insulation elements of a line section, it is more convenient to incorporate their effect into the stress by introducing the *Relative Insulation Stress (RIS*). RIS is defined as the ratio between the flashover voltage in standard atmospheric conditions (760 mm Hg, 20˚C, 11 g/m^3) and that in actual atmospheric conditions. A statistical distribution of RIS may be defined for a specific section or for the entire line.

The calculation of risk of line flashover is made by dividing the stress into a number of "stress situations," and the insulation elements of each section and phase into "sets" in which the elements have the same strength. The probability of flashover is then calculated for each combination of stress situation and insulation set (see Applet IC-2).

Rod-Plane Strength

The lowest values of V_{50} flashover voltage occur for a positive polarity impulse applied to a rod protruding toward a plane.

The 50% flashover voltage of rod-plane gaps is a function of the time-to-crest of the impulse, with the lowest value appearing at the critical time-to-crest (see Figure 5.5-2). Three equations describing this switching surge strength versus the spacing of the rod-plane gap are given in Table 3.3-1. These are plotted in Figure 3.3-3, which is taken from Section 5.5. Note the saturation characteristic of the strength with respect to gap spacing. This is a very important behavior compared to the strength required for lightning, and explains the importance of keeping switching surge overvoltages under check for higher voltages; otherwise, the insulator string length, and hence the tower dimensions, become excessively demanding and expensive. Figure 3.3-4 shows an approximate comparison of the switching impulse (SI) and lightning impulse (LI) strengths (both positive and negative polarity).

Parameters Affecting the Switching Surge Strength

The effect of selected other parameters on the critical flashover voltage, $V_{50\%}$, is presented in Table 3.3-2. These, and other factors, are covered in detail in Section 5.6.

3.3.4 Power Frequency Strength

Line insulators must withstand the maximum system voltage over long periods of time. In addition, they must either withstand or be protected against temporary overvoltages

Table 3.3-1 Common Equations Governing the Switching Surge Strength of the Rod-Plane Gap

Electricité de France (EdF) (Gallet et al. 1975)	CRIEPI (Kishizima et al. 1984)	Rizk 1989 (Rizk 1989)
$V_{50,Rod-Plane} = \dfrac{3400}{1+\dfrac{8}{L}}$ 3.3-3	$V_{50,Rod-Plane} = 1080 \cdot \ln(0.46 \cdot L + 1)$ 3.3-4	$V_{50,Rod-Plane} = \dfrac{1830 + 59 \cdot L}{1+\dfrac{3.89}{L}} + 92$ 3.3-5
$V_{50\%}$ is expressed in kV, and the gap length or strike distance, L, in m. The equations are valid for standard atmospheric conditions of relative air density, δ, and absolute humidity, h: = 1 and h = 11 g/m^3.

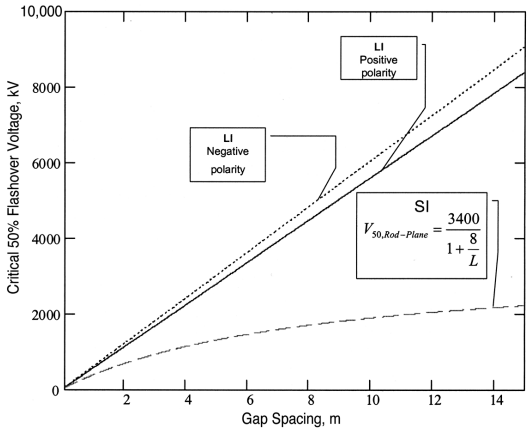

Figure 3.3-4 Comparison of rod-plane for switching impulse (SI) vs. lightning impulse (LI) strengths.

Table 3.3-2 Effect of Different Parameters on Switching Surge Impulse Strength

Parameter	Effect on $V_{50\%}$
Effect of Length of V-Insulators	The 50% flashover voltage is reduced when the gap spacing across the insulators becomes less than the gap spacing conductor-to-tower. The insulator length is generally considerably greater than the gap spacing, and therefore, the presence of V-insulators does not affect the switching impulse strength.
Effect of Atmospheric Conditions	Rain does not affect the switching impulse strength of tower windows, except when the insulator length becomes comparable or less than the gap length. These variables are normally correlated with each other— i.e., high humidity corresponds to low air density. Calculations may be simplified, assuming that they vary randomly within a given range, maintaining a certain correlation with each other. However, they have the same values along the line, with the exception of a systematic variation of relative air density due to altitude, if the altitude varies along the line.
Effect of Window Shape	Whenever the geometry departs significantly from a simple known configuration, reliable strength data can be obtained only by performing switching impulse tests on full-scale models in an outdoor high-voltage laboratory.
Conductor Size	Varying the size of the phase conductors, from single conductors to four-conductor bundles with a bundle diameter of 65 cm, does not affect significantly the flashover strength if the same gap spacing clearance is maintained between conductor and tower.
Outside Phase	In general, the switching impulse strength of outside phase tower gaps with V-insulators is stronger than that of tower windows with the same gap length. The increase in strength depends on the geometry, particularly the dimensions of the tower arm and of the tower body and the horizontal distance to the tower body. If the outside phase conductor has the same distance to the tower arm and to the tower body, and if the tower arm and body have the same width of those of a square window, the outside phase strength is about 6% greater than that of the tower windows for gap spacing less than 5 m. For gap spacing of 7 m or longer, the outside phase strength is only slightly (2~3%) greater of that of the tower window.
Insulator Strings	For positive polarity, the strength in fair weather is the same as the strength of the gap without insulators, provided the insulators are not placed directly along the possible flashover path. V-insulators in a tower window, where flashovers occur from conductor to upper truss, do not affect the tower window strength. The positive dry switching impulse strength is reduced by up to 5% when the insulators are placed along the shortest gap distance, such as vertical insulators in a tower window or in an outside phase, or horizontal insulators in a dead-end structure. For negative polarity, the strength in fair weather is usually much higher than the positive-polarity strength. The negative polarity strength is generally significantly reduced by foul weather. For very light or light contamination, a 10-20% reduction is suggested. In these cases, and if the switching impulse strength becomes a limiting factor in line design, the use of antifog or other special types of insulators is recommended.
Conductor-to-Grounded Objects at Midspan	Minimum clearances of transmission-line conductors to ground are recommended by national standards, such as the National Electrical Safety Code (NESC 2002) in the U.S., which are based, among other factors, on the requirement that the gap between conductor and grounded objects should withstand switching surges with a high degree of reliability.

having a magnitude equal to the short-duration, power frequency overvoltages. Temporary overvoltages are described in Section 3.2.4, and will not be discussed any further here.

Key points of significance to insulator strength under power frequency conditions include:

- Consideration of contaminated performance (if applicable) versus clean conditions.
- Contaminated performance is dependent on the insulator design, including type, profile, material, and dimensions.
- Flashover values are influenced by the type and level of both soluble and nonsoluble contaminants.
- When designing for contaminated conditions, a worst-case assumption is usually made that the contaminant is evenly distributed with critical wetting.

Figures 3.3-5 and 3.3-6 illustrate the withstand contamination performance for both ceramic and polymer insulator types.

Power Frequency Strength Under Clean Conditions

In the absence of contamination, power frequency voltages will not drive the insulation requirements (strike distance) of transmission lines. Flashover from ice bridging will only occur if the ice is contaminated, and hence it will not be covered any further here.

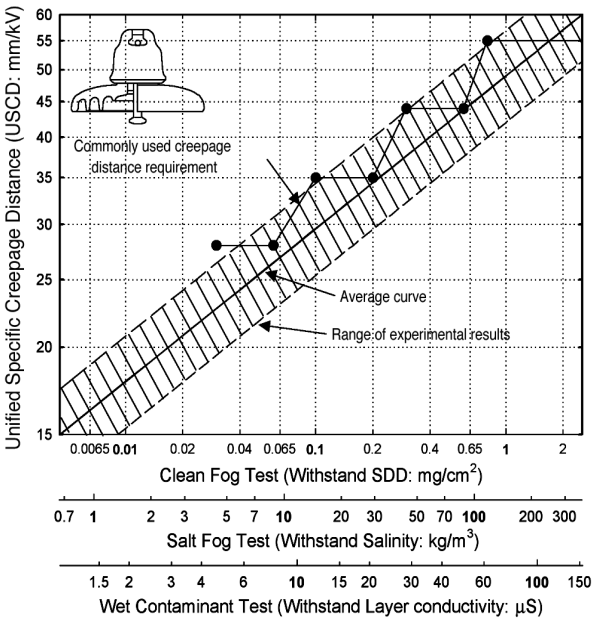

Figure 3.3-5 The withstand ac contamination performance of standard types of disc insulator based on the results from Salt-Fog and the Solid-Layer tests.

The flashover of clean insulators in wet conditions is very similar to that of dry insulators, so no allowance for this is normally made.

Power frequency flashovers at normal operating voltage can occur to ground if there is a fire under the line. This is a common operating consideration in countries where bush fires travel across lines. Flashovers of this type can also occur for gas or oil pipe line accidents.

For tower configurations for which the gap factor, "K", is known (see Section 5.2.4); the ac 50% flashover strength can be estimated from (IEC 1993):

$$V_{a.c.50} = 750(1.35K - 0.35K^2)Ln(1 + 0.55L^{1.2})$$

This equation is valid for gap spacings greater or equal to 2 m. A standard deviation of 2% may be assumed for the ac flashover strengths of air gaps. If the withstand voltage is assumed to be at the 3-σ level, it voltage would be 94% of the 50% flashover voltage (CFO).

Power Frequency Strength Under Contaminated Conditions

When contamination is present, coordination of flashover strength with power frequency voltage stress becomes important, and may even dictate the design of the transmission-line insulation (Table 3.3-3).

Insulation strength in the presence of contamination is dependent on the following factors:

- leakage distance and length,
- profile (sheds, etc.),

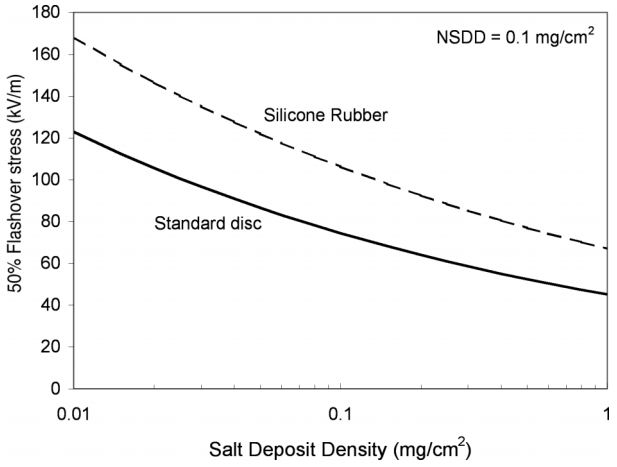

Figure 3.3-6 Comparison of the flashover stress of a hydrophobic silicone rubber insulator to that of a standard shape disc insulator.

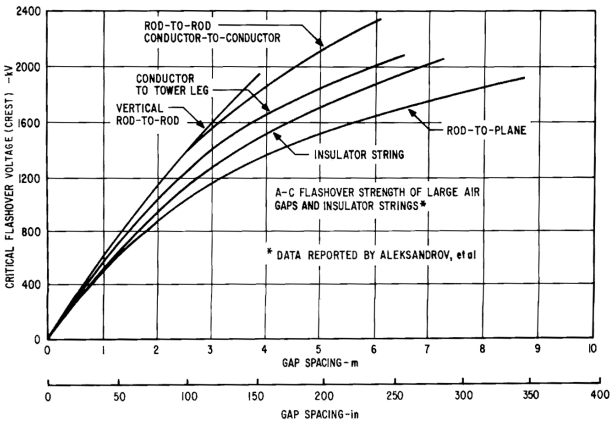

Figure 3.3-7 AC Flashover strength of large air gaps as reported by Aleksandrov (Aleksandrov et al. 1962).

Table 3.3-3 Contamination Site Severity

Site Severity	ESDD, mg/cm²	
	CIGRE	IEEE
None	0.0075—0.015	
Very light	0.015—0.03	0—0.03

- type and level of contaminant, and
- type and amount of wetting (dew, light or heavy rain, etc.).

3.3.5 Effect of Weather Conditions

The vulnerability of exposed insulation to surges and, in the case of lightning, the number of surges themselves, depend greatly on weather conditions. Therefore, weather data must be considered in design procedures.

In general, in the absence of contamination, occurrences of rain, drizzle, fog, snow, and any other type of precipitation do not affect the strength of air gaps, and without some form of precipitation, the presence of contamination alone does not affect the air-gap strength either. However, the combination has low electrical strength. The occurrence of extended periods with high wind or without rain, followed by light precipitation, is an important consideration for line insulation coordination in many areas.

Flashover voltages for air gaps depend on the moisture content and density of the air. Generally, insulation strength increases with absolute humidity, but test results become erratic above 85% relative humidity. Insulation strength decreases with decreasing air density, which is a concern for lines at high elevations. A detailed description of the effects of air density and absolute humidity is given in IEC 60-1 (IEC 1989) for different types of voltage stresses. Therefore, the estimation of the strength can usually be based on the average ambient conditions at the location. For insulators, the possible reduction in the withstand voltage due to snow and ice (0°C, 100% RH), or dew and fog (10-20°C, 100% RH) should be taken into account. Corrections applicable for humidity and ambient temperature variations may cancel each other. The effects of relative air density and absolute humidity are discussed in Section 5.13.

Rain does not affect the switching impulse strength of tower windows, except when the insulator length becomes comparable or less than the gap length. In this case, rain and other wet weather conditions, such as fog, drizzle, wet snow, and high humidity, may, depending on the type of insulators, further reduce the switching impulse strength (see Section 5.12).

The positive polarity switching impulse for most transmission-line insulation systems is not affected by wet weather because flashover paths are in the air, away from insulators. Vertical insulator strings supporting a transmission-line conductor from a tower crossarm may be an exception, especially if the crossarm is slender.

In this case the positive polarity switching impulse strength may be reduced by a few percentages, with a 5% reduction being a reasonably conservative value. The negative polarity strength of insulation systems with insulator strings is significantly affected by wet weather, yet the reduction in negative polarity strength is of little concern regarding line performance, because negative polarity strength in dry conditions is generally much higher than the positive polarity strength.

Conventional insulators designed to sufficient dry arc distance to withstand the power frequency voltage when covered with ice or snow will also generally withstand switching impulses with crest values of at least 2.5 per unit.

Generally, for the transient voltage case and, to some extent, for the 60-Hz case, it is most economical to consider flashovers as noncatastrophic, and to consider a certain number of flashovers of line insulation as tolerable. Likewise, it is more economical to consider a temporary insulator contamination situation as endurable, or a nonzero value of lightning tripout-rate-per-year as allowable. Given that insulation analysis is statistical in nature and that some flashovers may be permitted, it is most appropriate to consider the effects of weather on insulation in a statistical manner.

Figure 3.3-8 describes the effect of weather on the performance of line insulation.

High wind speeds off the ocean increase the contamination level rapidly (something like the third power of wind speed), so annual extreme wind will have an effect on contamination too.

Lightning occurrence increases rapidly as dew point temperature rises above 25°C. This could be a lower limit for the absolute humidity value to be used in RAD corrections.

RAD/RH corrections for impulse may be less important than characterizing the change in standard deviation of flashover strength when RH rises above 85%.

3.3.6 Summary

This section provided an overview of insulation strength and the key parameters that are significant to the designer. As a principle, the line insulation must have enough strength to meet the stresses produced by the overvoltages discussed in Section 3.2.

Insulation strength is expressed in terms of withstand voltage, a quantity determined by tests conducted under specified conditions with specified waveforms, and depends greatly on the waveshape of the applied voltage. The parameters generally used to characterize the waveshape of a lightning or a switching impulse are polarity, "front time" (variously defined) or time from zero to crest, and "tail time" (variously defined) or time from zero to half value after crest.

Transmission-line insulation, being air, is a self-restoring insulation, and hence can be mathematically represented by cumulative Gaussian distribution with a mean ($V_{50\%}$), and a standard deviation σ.

Of the three withstands needed to specify the insulation coordination of a transmission line (lightning, switching, and power frequency), the lightning withstand is characterized by having greater linearity than for the other stress types. The withstand to lightning is dependent on the polarity of the lightning, as well as atmospheric conditions (wet vs. dry)—positive polarity withstand being inferior to that of negative. For quick calculations, recommended gradi-

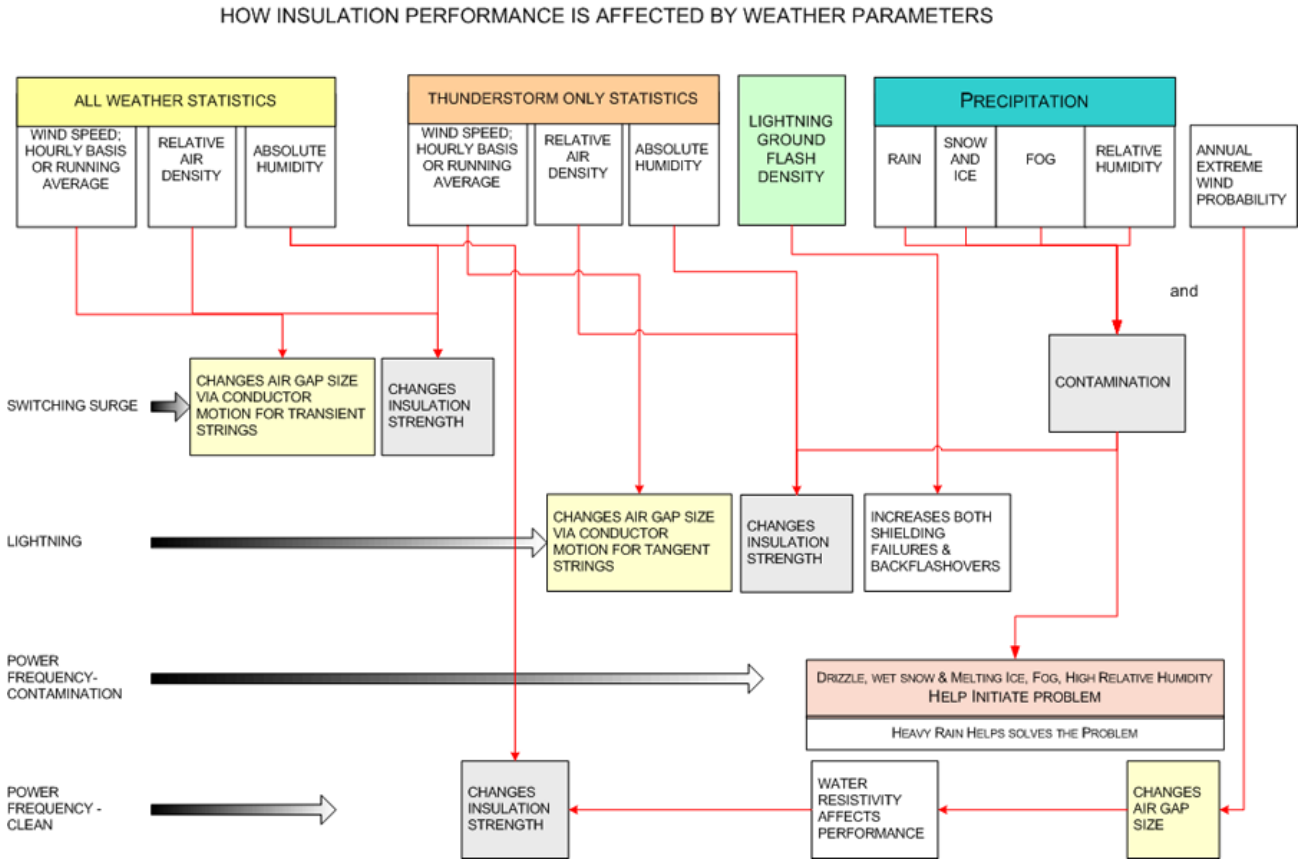

Figure 3.3-8 Effect of weather parameters on insulation performance.

ents are 560 kV/m for the positive polarity Critical Flashover Voltage (+V50%) and 605 kV/m for negative polarity (-V50%). For laboratory tests, the relative standard deviation of lighting impulse strength is about 3%.

The switching surge strength is dependent on many variables, including altitude above sea level, wet weather, gap length, and insulator strike distance.

For switching surges, the calculation of risk of line flashover is made by dividing the stress into a number of "stress situations," and the insulation elements of each section and phase into "sets" in which the elements have the same strength. The probability of flashover is then calculated for each combination of stress situation and insulation set. The lowest values of V_{50} flashover voltage occur for a positive polarity impulse applied to a rod protruding toward a plane. Switching surge strength exhibits a saturation effect with the strike distance. This is a very important behavior compared to the strength required for lightning, and explains the importance of keeping switching surge overvoltages under check for higher voltages; otherwise, the insulator string length, and hence the tower dimensions, become excessively demanding and expensive. Negative polarity switching impulse is sufficiently higher than the positive polarity strength, which is not considered in the insulation coordination. For laboratory tests, the relative standard deviation of switching impulse strength is about 6%.

In the absence of contamination, power frequency voltages do not drive the insulation requirements (strike distance) of transmission lines. When contamination is present on insulator surfaces or in ice layers, protecting for power frequency voltages becomes more important, and may even dictate the design of the transmission-line insulation. For laboratory tests, the relative standard deviation of contamination flashover strength varies from 3 to 10%.

3.4 OVERVOLTAGE CONTROL

3.4.1 Introduction

While the previous sections described the stress on line insulation (overvoltages) and insulation withstand characteristics (the strength), this section describes the ameliorating measures for reducing flashovers from lightning, switching, and power frequency under contamination.

Design for lightning flashovers (associated with shielding failures and backflashovers) includes setting the insulation level, line geometry/clearances, shielding, grounding, and the application of surge arresters. Design for switching surge (typically associated with reclosing on transmission lines) can be achieved through a number of measures, such as strategically placed surge arresters, use of closing resistors, or controlled switching. Designs to withstand the effect of insulator contamination include use of nonstandard ceramic insulators (insulators with longer creepage) or fog-type insulators), use of nonceramic insulators such as polymer insulators, or the use of special insulator surface coatings.

This section describes these countermeasures and others in some detail to provide line designers with an arsenal of solutions to choose from in overall line insulation coordination specification. The objective is to match the stresses with strength, and thereby achieve acceptable reliability of the line at an affordable cost.

3.4.2 Control of Lightning Overvoltages

Design for lightning includes setting the insulation level, line geometry and clearances, shielding, grounding, and transmission line arresters. Typical practice is to set standards for design and construction of each line type, and then address "hot spots" with special measures. Extra effort may be required for lines having high exposure to lightning or where soil resistivity is high.

Chapter 6 provides a detailed discussion on the occurrence and characteristics of lightning. For convenience, the key information is summarized here, to give a context for discussion of insulation coordination design for lightning and other stresses.

Table 3.4-1 and Figure 3.4-1 summarize the lightning overvoltage design options typically considered by utilities for transmission lines.

Figure 3.4-2 summarizes the steps needed for evaluating the lightning performance of existing transmission lines, and finding appropriate measures to support line performance within acceptable standards.

Design for Lightning Protection

One of the most successful ways to estimate the lightning performance of a new transmission circuit is to perform multiple linear regression of the observed performance of nearby lines against the most sensitive parameters. This is especially helpful when comparing lines with similar conductor geometry, tower style, and span length. If such information is not available, the designer must consider the following design variables.

Design Variables and Protection Techniques

The principal parameters available to a line designer to improve lightning performance are structure type, line routing, insulation level, number and placement of shield wires, grounding, and transmission-line surge arresters.

Table 3.4-1 Lightning Overvoltage Design Options

	Shielding Failures	Backflashover Failures	Induced Failures
Root Cause	Small first strokes that terminate on the phase conductor rather than the shield wire.	Large first stroke currents, in combination with high footing resistance and/or high tower surge impedance on tall towers.	Fast-rising (high dI/dt) current in proximity to phase conductors.
Insulation	Does not affect shielding failure flashover rate much, since subsequent strokes follow same path.	Strong effect on backflashover rate.	Transmission lines have >450 kV BIL and are generally immune to induced voltage flashovers.
Add or Move Overhead Groundwires	Moving the shield wires outward will increase their effectiveness. On EHV lines, some shield wires are outside of the phases (negative shielding angle).	Adding more shield wires, above or below the phases, improves electromagnetic coupling and reduces backflashover rate.	Adding more grounded shield wires will reduce the induced voltage.
Improve Grounding	No effect, except on multiple-circuit flashover rates.	Strong effect on backflashover rate.	Induced voltages higher in areas where grounding is difficult.
Install Transmission Line Surge Arresters (TLSA)	Reduces number of shielding failures by limiting voltage across insulator of stricken phase.	Reduces number of backflashovers by limiting voltage on protected phases and improving coupling on unprotected phases.	Clips induced voltage to less that peak flashover level of insulator.

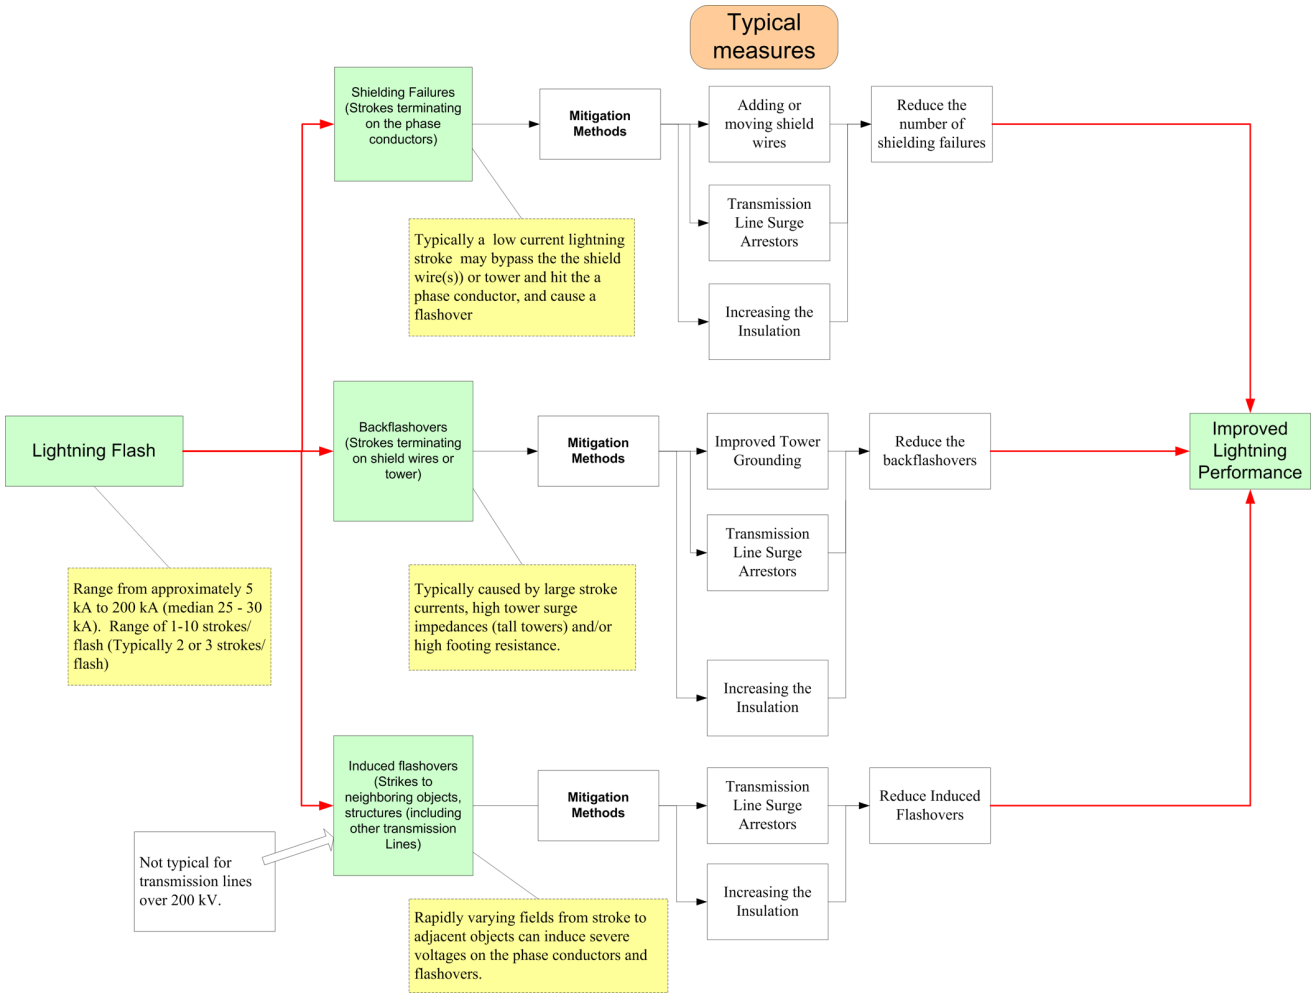

Figure 3.4-1 Lightning overvoltage design options

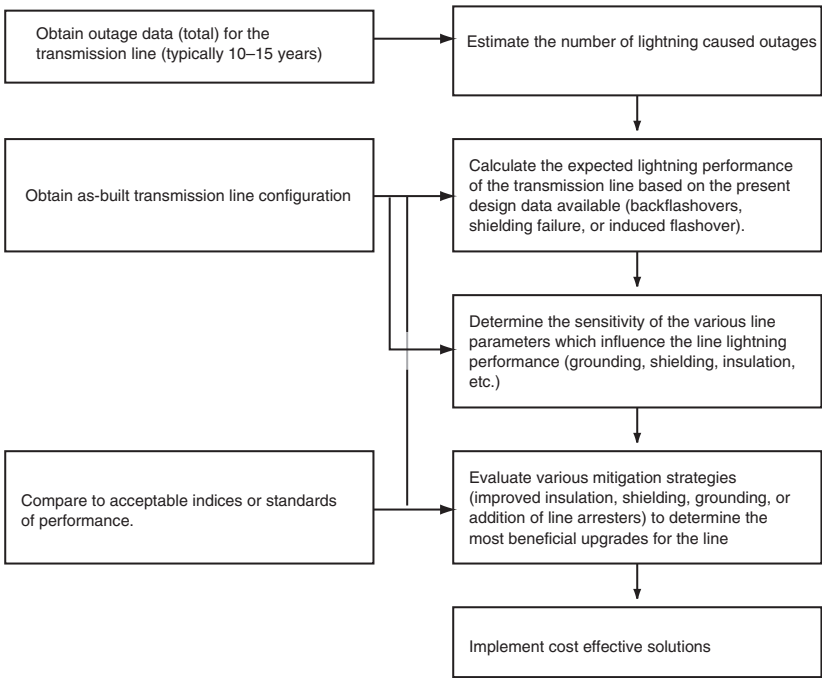

Figure 3.4-2 Lightning performance analysis for existing lines.

Structure Type

It is unlikely that the choice of structure type would be determined exclusively by lightning performance, but some lines have indeed been designed in this way. Key issues in choosing the structure type when considering lightning performance are:

- Steel lattice structures have lower surge impedance than steel poles (or wood poles with grounding downleads).
- Guyed structures have lower surge impedance than free-standing towers.
- Lattice and guyed structures have larger foundation footprints and hence lower footing resistance.
- The strength of steel allows flexibility for placement of shield wires.
- Although rarely used for transmission lines above 200 kV, wood structures offer an ability to use the arc-quenching capabilities of wood members. Unbonded wood crossarms can be used on steel structures to the same end. The wires connecting the shield wires and, in the case of wood crossarms, the ground-end insulator hardware to the tower footing must be kept away from the wood structure.

Line Routing

It is unlikely that a line designer will be able to choose the line route based only on lightning performance or ease of grounding. However, there are benefits from:

- Routes through forested areas, which provide some degree of natural shielding.
- Routes that avoid exposed structures, such as on top of ridges. Fortunately the routing of lines along the side of hills is also consistent with environmental desires to reduce the visual impact. On the other hand, location of structures on hilltops, rather than in valleys, allows longer conductor spans that meet ground clearance requirements, and so reduces the number of structures and the line cost.
- Routes that take some advantage of the tower-to-tower variation in resistivity, by selecting those locations where earth resistivity is lower.

Insulation Level

The length of insulator strings and of air gaps may be increased in order to increase the insulation strength and reduce the flashover rate.

Number and Placement of Shield Wires

Shielding failure is an uncommon cause of transmission-line lightning flashovers, with shield wire effectiveness reaching more than 95% for most new designs. Shield wires are quite successful in intercepting lightning flashes, using design methods that have been extensively studied and developed for more than 50 years. A shielding failure occurs when a flash appears in such a location that it gets by the shield wire protection and strikes a phase conductor. Shielding failures (i.e., lightning hitting a phase conductor rather than a shield wire) are more likely to occur for low-current strokes. For stroke currents above a certain value, I_S, the upward leader starting from the shield wire is always able to intercept the downward leader of a vertical stroke

channel. Even if the stroke current is sufficiently low that its voltage stress on the phase conductor does not exceed the insulation strength, one of the subsequent strokes that follows the same path will likely be large enough to cause a phase-to-tower flashover.

Shielding failure calculations usually assume that stroke leaders advance vertically. This is the least conservative assumption. Leaders approaching the transmission line at an angle from the vertical may cause shielding failures with higher stroke currents. Adding or moving shield wires is one method of improving the lightning performance of a transmission line. A poorly placed shield wire can allow an excessive number of lightning strokes to attach directly to the phase conductors and cause flashovers. Improved shielding reduces the number of shielding failures, and resulting flashovers, on a transmission line. The type and size of the shield wire are not important for lightning performance calculations. Shield wire parameters should be based on the expected mechanical loads for a specific installation.

The principle of so-called "perfect shielding design" is to locate the shield wires so that the value of I_S, the maximum stroke current that can cause a shielding failure, is greater than the value of I_C, the maximum stroke current that, if applied to a phase conductor, can cause a flashover of the line insulation. In practice, lines should usually be designed with a small (0.05 per 100 km per year) shielding failure rate (Hileman 1999) to acknowledge and minimize some of the uncertainties in the calculation process. Figure 3.4-3 defines the shielding angle of transmission lines. For lines above 200 kV, it is common practice for transmission lines to have two shield wires, with shield angles in the range of +30 to -12 degrees. However, to save costs, lines may be built with one shield wire, or even with no shield wires, where weather conditions allow or require it (for example, infrequent lightning or unusually severe icing).

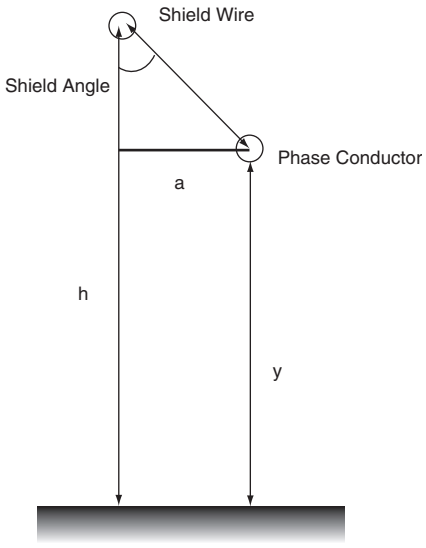

Figure 3.4-3 Definition of the shielding angle.

One of the limitations of the use of "perfect" shielding is that, on average, subsequent strokes tend to follow the same ionized path as the first stroke. For instance, 500-kV line insulators and air gaps may withstand lightning impulses with crest voltages up to 1800 kV or higher. A stroke hitting a phase of a 500-kV line, whose surge impedance in corona is, for example, 300 Ω, may cause a flashover only if any of the stroke currents is greater than I_C =1800/(300 Ω/2) = 12 kA. A shielding failure with first-stroke current $I_S<I_C$ stroke may not cause a flashover but one of the subsequent strokes, each having a 12-kA median, may still cause a flashover. Section 6.6.4 gives more details on this issue. Perfect shielding must also be violated by flashes approaching a line at an angle rather than vertical. One photograph exists of a flash coming in almost horizontal and hitting a phase.

In addition to the number of shield wires, the midspan clearance between shield and phase conductors should be considered. The midspan clearance between a shield wire and a conductor must also withstand the overvoltages caused by lightning. In most cases, the possibility of a flashover from a shield wire to a phase conductor may be ignored because of several mitigating factors:

1. The voltage wave created by a stroke injected in the shield wire at midspan travels toward the two ends of the span, and is reflected at the structures. A significant fraction of it comes back with the opposite polarity, and reduces the voltage at midspan after a time equal to the travel time along the span.
2. The shield wire-to-phase conductor clearance is usually much larger at midspan than at the tower because the shield wire sag is significantly smaller than the phase conductor sag.
3. The voltage wave on the shield wire induces a wave of the same polarity on the phase conductor, which causes a reduction of the voltage between shield wire and conductor. This effect is more significant the closer the phase conductor is to the shield wire.
4. Lightning hits at midspan are less frequent than those at or near the structures because of the lower height at midspan.
5. Predischarge effects (Wagner and Hileman 1963) may reduce the shield wire voltage significantly.

Grounding

Grounding is one of the most effective and cost-effective methods of controlling backflashover performance. Reducing the ground impedance of a tower reduces the voltage developed on the structure when a lightning stroke hits the structure or shield wire. A lower crossarm voltage reduces

the insulation stress during a lightning event and reduces the number of backflashovers for the line. The voltage over the insulator strings is significantly reduced when the first reflected traveling wave returns from the bottom of a well-grounded structure.

There is a large body of publications (see Chapter 6) on measuring soil resistivity and footing impedance. Section 6.10 provides many details and some simplified models for the relationship between soil resistivity, foundation shape and as-built impedance. Some cost-effective methods of reducing footing impedance by addition of combinations of ground rods, counterpoise, and soil treatment are also described. Designers should also consider the effects of high-impulse current from lightning on the soil impedance. At high currents, ionization and breakdowns may occur, effectively reducing the soil resistivity.

High footing impedance, such as in rocky terrains, often coincides with higher exposure to lightning. Even one or two poorly grounded and exposed structures can be the source of very significant increases in tripout rates above design expectations. Detection and remedial measures can include visual inspection of the line, local soil resistivity measurements, footing resistance measurements by disconnecting the ground wires at the tower top, or footing impedance measurements using a portable impulse source. Lightning location network data can also be compared with synchronized time tags of relay records to determine the likely location of a line "hot spot."

Many transmission-line structures have entirely satisfactory footing resistances from the standard foundation, with no augmentation. When additional grounding is required, a few grounding rods combined with horizontal counterpoise connections are often sufficient to reduce footing resistance to a desired level. The depth of the rods and the spread of the augmented grounding can be increased as needed. Although it is not normally a consideration, grounding beyond 60 m (200 ft) from the structure is subject to the law of diminishing returns; beneficial reflections from the grounding do not reach the structure in time to influence the backflashovers. On the other hand, continuous counterpoise reaching from one structure to the next is sometimes used. A "crows-foot" counterpoise or ring electrode is recommended in many areas.

There is a tradeoff between grounding improvement cost and effectiveness that is more difficult to manage than the tradeoffs in other approaches, such as fitting line surge arresters. After a certain level of grounding augmentation is reached, either an elevated probability of flashover is accepted, or other measures such as line-mounted arresters are used.

Changes in grounding have no effect on the shielding failure flashover rates and an indirect effect on induced overvoltages, as detailed in Chapter 6. However, the role of TLSA versus grounding improvements is an important evaluation in the modern insulation coordination process and is described next in detail.

Transmission Line Surge Arresters (TLSAs)

Transmission Line Surge Arresters have been used successfully on many transmission lines to control the lightning-caused overvoltages across insulator strings where high exposure and difficult grounding cause poor lightning performance. The superior life, ruggedness, and physical size of arresters with polymer housings provide a reasonably economic solution that can be retrofitted to lines that fail to meet expectations. Depending on the line voltage, specific problems, and desired performance, arresters may be applied at every structure or periodically at every second or third structure, and in any case, can be limited to the area of concern rather than the whole line. Appendix 3.2 provides details on applying transmission-line surge arresters.

Special Considerations

Multi-Circuit Lines, Unbalanced Insulation, Unsymmetrical Phase Arrangement. For double or multi-circuit structures, in addition to the single-circuit lightning tripout rate, the double-circuit tripout rate is of great concern. Losing one circuit—with the possibility of a single pole of conventional reclosing—may be acceptable, but loss of both circuits simultaneously could have serious consequences. Typically system planners need to know the probability of the loss of two circuits on the same structure or on the same right-of-way.

The double-circuit calculation requires that, after the first flashover has occurred, the calculation model must be modified to allow for the additional paths of currents on the flashed-over phase and the increased (and beneficial) coupling that will occur. Of course, on a perfectly symmetrical double-circuit design, with matching phases at the same heights on the structure, it is possible that simultaneous flashovers will occur on both circuits. If the two circuits have reverse phasing, such as ABC–CAB, one circuit will have a better chance of surviving after a flashover on the other.

Another practice that has been used is to deliberately build one circuit with slightly weaker insulation than the other circuit—the argument being that this circuit will flash over first, and by doing so, will improve the performance of the other circuit. In reality, this practice is more likely to result in significantly worse performance for one circuit and little, if any, improvement for the other circuit, so the practice is not recommended.

High-Phase Order. As discussed under multi-circuit lines, the flashover of one circuit results in a reduction of voltage over the unflashed insulators as a result of increased coupling from the flashed-over phase conductor. For the special case of high-phase order (6 or 12 phase) lines, this effect can provide an essentially lightning-proof design. After one or two phases have flashed over, the remaining phases will be protected, and the line is capable of operating with its remaining phases in an unbalanced mode until the faulted phases have been cleared. A short length of high-phase-order line has been operated on both the Niagara Mohawk and Tennessee Valley Authority (TVA) systems in the U.S.

Multiple Lines on a Right-of-Way. If two lines are on the same right-of-way and they are the same voltage, it is common practice to locate the structures immediately adjacent to each other for aesthetic reasons. This practice creates the possibility that a lightning flash to one line could affect the other. If the tower footings have augmented grounding, it is possible that the bases of the towers are connected below ground level.

Study of this case requires specially adapted software. As a general rule, it is preferable that the footings of adjacent lines not be interconnected, although attenuation, coupling, and other losses make it unlikely that a stroke to one can cause a flashover on both. If footing resistances are high due to poor soil resistivity, it may be practically impossible to keep them separate, in which case other measures such as arresters may be necessary.

3.4.3 Control of Switching Surges

The control of overvoltages due to switching surges is an important requirement for the economic design of transmission systems operating above 200 kV, and a necessity above 400 kV. Finding the most suitable and cost-effective solution depends on the initiating event. Switching overvoltage control strategy is largely dependent on the autoreclose operation requirements for the system.

To review, the switching operations of greatest concern in EHV are:

- Line energization
- Line re-energization with trapped charge on the line
- Load rejection, with a circuit breaker opening at the far end of a line, possibly followed by disconnection at the near end
- Transformer switching at no load or with a secondary load of shunt reactors
- Reactor switching

Energizing overvoltages are controlled by:

- One or multi-stage pre-insertion resistors
- Phased (voltage-controlled) closing of the breaker contacts
- Shunt reactors, or other drainage of the trapped charge before reclosing
- Use of suitably coordinated arresters

Various methods of control have been in use successfully for many years. These methods are described here, along with some new concepts.

Circuit Breakers

When a protective relay detects a fault or other system disturbance on the protected circuit or line, the circuit breaker operates to physically separate current-carrying contacts in each of the three phases by opening the circuit to prevent the continued flow of current. In addition, a circuit breaker is capable of load-current switching.

The major components of a circuit breaker include:

- The interrupters, which open and close one or more sets of current-carrying contacts housed therein
- Operating mechanism (provides the energy necessary to open or close the contacts)
- Arcing control mechanism and interrupting media
- One or more tanks for housing the interrupters
- Bushings
- Mechanical linkage connecting the interrupters and the operating mechanism.

Circuit breakers can differ in the overall configuration of the above components; however, the operation of most circuit breakers is substantially the same. A circuit breaker may include a single-tank assembly, which houses all the interrupters. Alternatively, a separate tank for each interrupter may be provided in a multiple-tank configuration. All circuit breaker switching operations generate closing or opening transients or switching overvoltages (SOVs) in the system as the system adjusts to the new set of operating conditions as a result of the switching operation. This section reviews some of the possible changes to the basic breaker configuration.

Pre-Insertion Closing and Tripping Resistors

Traditionally, the most common measure to reduce energizing transients is the use of pre-insertion resistors (PIRs) or closing resistors. Closing resistors are inserted in series with the line being switched for a short period of time, before closing the main contacts of the breaker, thereby damping the transient overvoltages. Optimum overvoltage control requires correct choice of the resistor value in rela-

tion to the source impedance level, the line length, and the line parameters. Luckily, the magnitude of the resulting overvoltages is not critically sensitive to any of these parameters (see Figure 3.4-4), making it an easier task for the design engineer. Nevertheless, detailed studies are necessary to quantify the value of the resistor (or resistors, if a dual-stage PIR is used), and this should be done under an overall line insulation coordination effort. Although a well-proven technology, breakers equipped with closing resistors inevitably involve relatively complex mechanical constructions. The complex mechanical linkages and an extra set(s) of contacts needed to equip the breaker with preinsertion resistors may present reliability and maintenance concerns. The use of PIRs for transmission-line energization has been a standard requirement on 550-kV systems, particularly on long lines (i.e., > 200 km).

If chosen properly, PIRs in the closing operation of the breakers can drastically reduce the SOVs. Figure 3.4-4 illustrates the reduction effect on SOVs in reclosing and energizing operations on a 500-kV transmission line. Note reclosing SOVs are more severe than those created from energizing the line, due to the residual trapped charge on the line in the case of reclosing.

A number of studies by the authors have shown that the use of PIRs was superior to other countermeasures in the control of SOVs. However, this was highly dependent on the system that was studied. In 500-kV studies performed in the 1980s, it was shown that the use of PIRs to control SOVs under specific system parameters and configurations resulted in the lowest voltage transient levels, compared to some other methods. Additionally, the overvoltage profiles of the lines where PIRs were used were much flatter, compared to those where other solutions were applied. For example, when arresters were used, they exhibited the major part of their control only close to their location, and hence resulted in less flat overvoltage profiles, unless many of them were used.

Today, with the advent of transmission-line arresters, new breaker technologies, and new concepts of applying system protection, other solutions (e.g., those involving strategically located surge arresters) may have equally good results compared to PIR-equipped breakers. For example, in the past decade, a large North American utility has been replacing older breakers equipped with PIRs with resistorless breakers and applying metal-oxide surge arresters (MOSAs) to the opposite end of a number of their 500-kV lines. The new breakers also incorporate staggered closing, where each phase closes about one cycle apart.

Another example can be found at another North American utility, where the desire to eliminate closing resistors led to the adoption of controlled high-speed auto-reclosing on its newest 500-kV lines. Malfunction or misoperation of the control device is mitigated by staggering the close signals to the control device, using special features in the control device itself, and by providing special low-protective-level metal-oxide surge arresters at the line terminals and in the middle of the line.

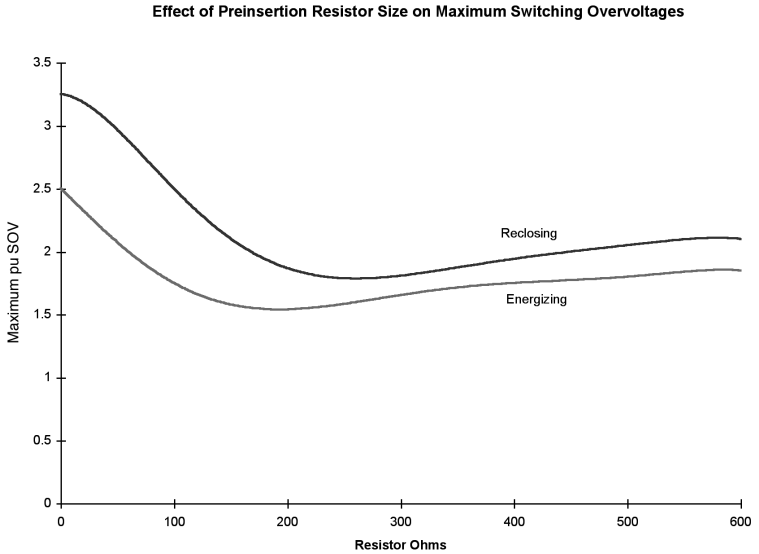

Figure 3.4-4 Effect of breaker preinsertion resistors on maximum switching surge overvoltages.

The preceding shows a trend in the industry that may be more acceptable and applicable at lower-voltage levels, especially with the use of transmission-line arresters.

Controlling Overvoltages from Circuit Opening

Switching surges from de-energizing a transmission line are usually of less concern for the line designer. Ideally, circuit breakers are controlled to open their contacts as the instantaneous phase current passes through zero, but if a nonzero current is interrupted, this interruption will cause a transient that is usually small. The greatest concern for circuit opening is a restrike across the opening contacts, which can initiate a traveling wave to the far end of the line. If the far circuit breaker has already opened, a voltage doubling can occur as the traveling wave is reflected, with the possibility of further arcing across the breaker contacts. In reality, these voltage surges would be limited (for example, by arresters), and the primary concern in this circumstance would be the failure of the breaker, rather than the possibility of a line insulation flashover.

Opening (or tripping) resistors are usually not the same as closing resistors. Insertion of these resistors during the opening of the breaker helps to drain the residual charge on a line and prevent trapped charge voltage. Opening resistors are typically not used on modern SF_6 circuit breakers. Surge arresters can be used across an interrupter to limit reactor-switching transient recovery voltage (IEEE 1993). Surge arresters can be used instead of opening resistors on circuit breakers to reduce trapped charge on shunt capacitors or transmission lines.

In past years, many U.S. utilities used bulk oil circuit breakers for most 230-kV applications. These circuit breakers sometimes had restrikes when switching capacitive current. Hence utilities equipped their breakers with opening resistors (with values > 3000 ohms) to control restrike transients while line dropping and capacitor switching. While the resistors were primarily intended for insertion on opening, some were inserted on both opening and closing, due to the mechanical complexities of the breaker mechanisms. Although such values would not help in reducing SOVs upon closing, their typical insertion of two to three cycles helped to discharge a large percentage of the trapped charge on the unfaulted phases, and hence the resultant SOVs during high-speed reclosing were lower with the use of the resistors. Today utilities are using SF_6 breakers for such applications, and some are applying controlled switching in place of the opening resistors.

Synchronous Switching

All circuit breaker switching operations generate closing or opening transients in the system as the system adjusts to the new set of operating conditions as a result of the switching operation. Synchronization of circuit breaker closing and opening to system voltage and current waveforms can drastically reduce these transients and, in addition, reduce interrupter wear. The most challenging application for synchronous switching is the switching of a de-energized shunt capacitor bank or high-speed reclosing of a long transmission line with trapped charge.

Synchronous switching of breakers in utility transmission systems can offer many benefits for reducing switching-related system problems. Application of synchronous switching in utility systems has been gaining interest and application. Synchronous switching can offer an economical alternative to conventional switching transient reduction methods such as pre-insertion resistors, current limiting reactors, and surge arresters by closing on the appropriate point of the voltage wave across the circuit breaker.

Several issues must be considered for the proper design of a synchronous-closing circuit breaker. These considerations include both system application requirements as well as circuit breaker performance requirements. Traditional circuit breaker technology has suffered from mechanical inaccuracies and lack of repeatability, which has prevented the widespread use of synchronous switching. Modern-day single-pressure SF_6 circuit breakers, when properly designed, can provide reliable and accurate synchronous switching performance for utility transmission systems. These design considerations include considerations for prestrike variations and control strategies for maintaining long-term consistent performance. The advent of single-pressure SF_6 interrupter technology has provided a significant boost to synchronous switching applications in utility transmission systems. Single-pressure SF_6 technology has eliminated the need for multiple-series interrupters, except at the highest transmission voltages. This change has reduced mechanical complexity, and made the application of synchronous switching easier. Among the common applications associated with synchronous switching is the zero-voltage-controlled closing of shunt capacitor banks to minimize the energization transients.

Design Considerations for Synchronous Switching

A simplistic view of synchronous switching would consider a circuit breaker coupled with the necessary control hardware to trigger the operation of the circuit breaker at the appropriate instant. From this simplified perspective, any circuit breaker containing a basic independent pole operation capability could be adapted with controls to provide synchronous switching capability. However, to provide a reliable, long-term solution in utility transmission systems, several special requirements must be considered in the original design of the circuit breaker and control algorithms. These requirements include accounting for the prestrike behavior of the interrupter and accounting for the

effect of operating variables such as temperature and control voltage.

While the concept of synchronous or controlled switching seems simple, cost-effective solutions are not always easy to achieve, primarily due to the high cost of providing the required timing accuracy in a mechanical system. One solution is to use three separate operating mechanisms and corresponding linkages to synchronously control the operation of each pole individually. This solution adds costs and increases the overall size and complexity of the circuit breaker. An advanced way to accomplish this goal is to provide a time shift between the instant of contact in the different phases. This approach requires a prior knowledge of the time required to close and open the interrupter contacts in each of the three phases. Any time differences can be accounted for by an appropriate design of the mechanical linkage. Circuit breakers applied in utility systems are expected to provide consistent performance for 20 or 30 years. Over the circuit breaker's operating life, the circuit breaker operating time can change as a result of mechanical wear.

Other ideas for the application of synchronous switching include: developing the means for continuous monitoring of current (or voltage) waveform on a switched circuit; and providing compensation for variations in operating mechanism stored energy, temperature, and controlled voltage. To account for these slowly changing operating time variations, it is important for the synchronous closing algorithm to allow some kind of feedback and apply correction to the operating parameters.

Surge Arresters

The application of surge arresters (either for lightning or switching surge overvoltage control) has yielded advantages, which have been documented in many technical papers.

Such advantages include:

- Increased reliability of existing lines
- Switching surge overvoltage (SOV) control
- Double-circuit outage reduction
- Compact line design
- Facilitating of line upgrading
- Compatibility between different voltage level lines
- Overvoltage control in the vicinity of HV and EHV substations
- Live working

Arresters can be used very effectively to reduce SOVs, and can be installed either at:

- Substations (the more traditional way to applying surge arresters)
- On the transmission line itself (transmission-line surge arresters, or TLSAs). The arresters can be installed directly on the towers.

Surge arresters dissipate switching surges by absorbing thermal energy. The amount of energy is related to:

- Prospective switching surge magnitude and waveshape (without the surge arresters)
- Circuit topology and impedance
- Arrester voltage-current characteristics
- Number of operations (single/multiple events).

The switching surge duty on metal-oxide arresters applied on overhead transmission lines increases for increased system voltage and increased length of switched line. Typically, transients occurring from high-speed reclosing impose greater duty than energizing. The selected arrester should have an energy capability greater than the energy associated with the expected switching surges on the system. The actual amount of energy discharged by a metal-oxide arrester during a switching surge can be determined through detailed system studies.

Transmission-Line Surge Arresters for SOV Control

A trend in recent years has been to try to find alternatives to the popular PIRs to control SOVs by more active use of arresters. Efficient limitation of the overvoltages along the lines by surge arresters is possible with the introduction of high-energy polymer-housed surge arresters that permit easy installation on the lines. Arresters can be installed directly on the towers. The energy requirements due to switching surges are considerably less for line arresters than for arresters located at the receiving end of the switched line. Hence, protection against switching typically requires one energy class lower for line arresters, than what is used for arresters installed at the substation. Unlike lightning-related applications, where arresters may be installed at consecutive structures, arresters to control switching surges may be needed only at the end of the line and maybe at one or two other points along the line. For switching overvoltage control, TLSAs are usually installed in all phases. The number of line arresters needed is dependent on the length of the line. For shorter lines, installation at the line ends may suffice to control SOVs. For longer lines, arresters may be needed at several locations. Compact lines, or those with upgraded voltage levels, may require line arresters on every tower for one or all phases. System studies show how many are needed, and in what locations. Appendix 3.2 goes into more detail on the application of TLSAs.

For delayed three-phase auto-reclose and high-speed single-phase auto-reclose, MOAs offer a good alternative to PIRs. However, for 550-kV systems, which require three-phase high-speed auto-reclose, the PIR has been the only economic solution, particularly for compact transmission tower designs. Alternatives, such as fitting surge arrester stations at line mid-points, have been proposed in place of PIRs, but could prove more costly. Controlling switching overvoltages by synchronizing the circuit breaker closing operation to a point at voltage zero has been researched for many years, but was inhibited by the available technology. However, with modern circuit breaker designs and electronic controls, the necessary equipment is available to achieve controlled switching.

Special Considerations

Capacitor Switching
Voltage and current transients generated during the energization of shunt capacitor banks have become an increasing concern for the electric utility industry. One concern relates to power quality for voltage-sensitive loads and excessive stresses on power system equipment on the utilization levels. Therefore, utilities have set objectives to reduce the occurrence of transients and to provide a stable power waveform.

Conventional solutions for reducing the transients resulting from shunt capacitor energization include circuit breaker preinsertion devices—for example, resistors or inductors, and fixed devices, such as current-limiting reactors. The maximum shunt capacitor bank energization transients are associated with closing the circuit breaker at the peak of the system voltage waveform, where the greatest difference exists between the bus voltage, which will be at its maximum, and the capacitor bank voltage, which will be at a zero level. Where the closings are not synchronized with respect to the system voltage, the probability of obtaining the maximum energization transients is high. One solution to this problem is to synchronously close the circuit breaker at the instant the system voltage is substantially zero. In this way, the voltages on both sides of the circuit breaker at the instant of closure would be nearly equal, allowing for an effectively "transient-free" energization.

Another major concern of capacitor switching is associated with addressing prestrike considerations of the breakers. During a closing operation, the circuit breaker interrupter contacts come together to close the circuit. The voltage withstand of the interrupter gap decreases from its peak voltage withstand capability (open position) to zero voltage withstand capability (closed position). A slower velocity results in a lower slope of the interrupter voltage withstand characteristic versus time, whereas a faster closing velocity results in a higher slope.

Reactor Compensated Line
Switching operations of shunt reactors are relatively frequent and primarily depend on power network loading. When a shunt-compensated line is switched off from the remote side, the line-side voltage may oscillate with a frequency determined by the line charging capacitance and the shunt reactor inductance with normally weak damping due to low losses in the line. Since the line voltages oscillate with a frequency that differs from the power frequency, the voltages across the open breaker poles show a low-frequency beat phenomena. Switching transients are inversely proportional to the shunt-reactor-rated power.

With regard to its inductive character, switching of shunt-reactor-rated-current-results can jeopardize insulation of the shunt reactor itself and other switchyard elements, and create mechanical stresses.

3.4.4 Control of Power Frequency Stress Caused by Insulator Contamination

The power frequency flashover voltage is considered to be the same for 60 Hz and for 50 Hz.

Contamination is a major criterion for design of transmission-line insulators. Control of power frequency strength of standard ceramic insulators under contamination depends on factors that include choice of insulator type, design, and leakage distance, depending on the type and severity of the contaminant, nature and frequency of the precipitation, and the degree of natural cleaning (see Figure 3.4-5). At this time, the following are the most common solutions adopted by utilities to successfully combat contamination:

- **Increasing the number of discs in the string.** Increasing the number of insulators in a string increases the creepage and dry arc distances, which, in turn, reduce the frequency of flashover due to contamination or ice bridging. However, a decision in this regard may be taken after examining whether adequate electrical clearances are available and ensuring that the angle of the V string would not be disturbed.
- **Using high-leakage insulators.** Insulators such as the fog-type units offer increased leakage distance per unit of insulator length. Leakage-distances-to-dry-arc distance ratios of 2.9 to 4.5 are available.
- **Using polymer insulators.** Over the last three decades, the use of polymer or non-ceramic insulators (NCIs) on transmission lines has become more prevalent. The flashover performance of NCIs in the presence of contamination is considerably superior to that of porcelain insulators. Nonceramic insulator qualities reduce the amount of leakage distance required, as described above. The improvement in terms of the withstand volt-

age per connected length is 40 to 100% (IEEE 1999a), falling to a margin of only 25% in freezing conditions. One concern regarding NCIs compared to porcelain insulators is that they cannot withstand as well the heat produced from leakage current. Chapter 4 of this book deals with NCIs in detail.

- **Silicone coating of the insulators.** Ceramic insulators and bushings may be coated with special electrical-grade silicone coatings or, less effectively, silicone or petroleum greases, to provide a smooth surface that is hydrophobic (beads water) and active (encapsulates surface contamination under a floating layer of low-viscosity oil). Grease coatings must be removed and reapplied periodically to maintain effectiveness. Greasing and silicone-rubber coatings can increase the interval between insulator maintenance activities such as washing. Greasing is not recommended for NCI insulators, but silicone coatings may be appropriate in some applications. The difficulty of application and cleaning/reapplication on transmission lines normally limits this technique to substations.
- **Washing/cleaning of the insulators.** Routine maintenance, such as live line or de-energized high-pressure water washing or dry cleaning, removes contamination and restores insulators to their original insulation strength, thereby preventing flashover. Care should be taken when washing these insulators, and methods developed for porcelain, which often include using high water pressures, may damage NCIs.
- **Insulators with semi-conducting glaze.** Coating the insulators with a thin layer of semiconductive glaze leads to a leakage current that can short out the dry banding activity that occurs under condensation and wetting. With no open arcing, the flashover strength of the contaminated surface is increased. By themselves in clean conditions, insulators with semiconductive glaze do not heat up very much, but they can run at 20 C° above ambient when heavily contaminated. Post-type insulators using semi-conducting glaze have superior contamination performance with in-service experience of more than 25 years. Early semiconducting glaze disc insulators encountered some problems with uneven current density—high at the insulator pins (causing glaze erosion) and low at the edges (reducing effectiveness)—but these problems have been addressed in more recent designs.

Consideration must also be given to the spacing of consecutive sheds/under-ribs, especially on polymer insulators. Other considerations that should be taken into account during the design of the insulator string for contamination include the ability to withstand the electrical stresses imposed and allowance of natural cleaning by rain and wind.

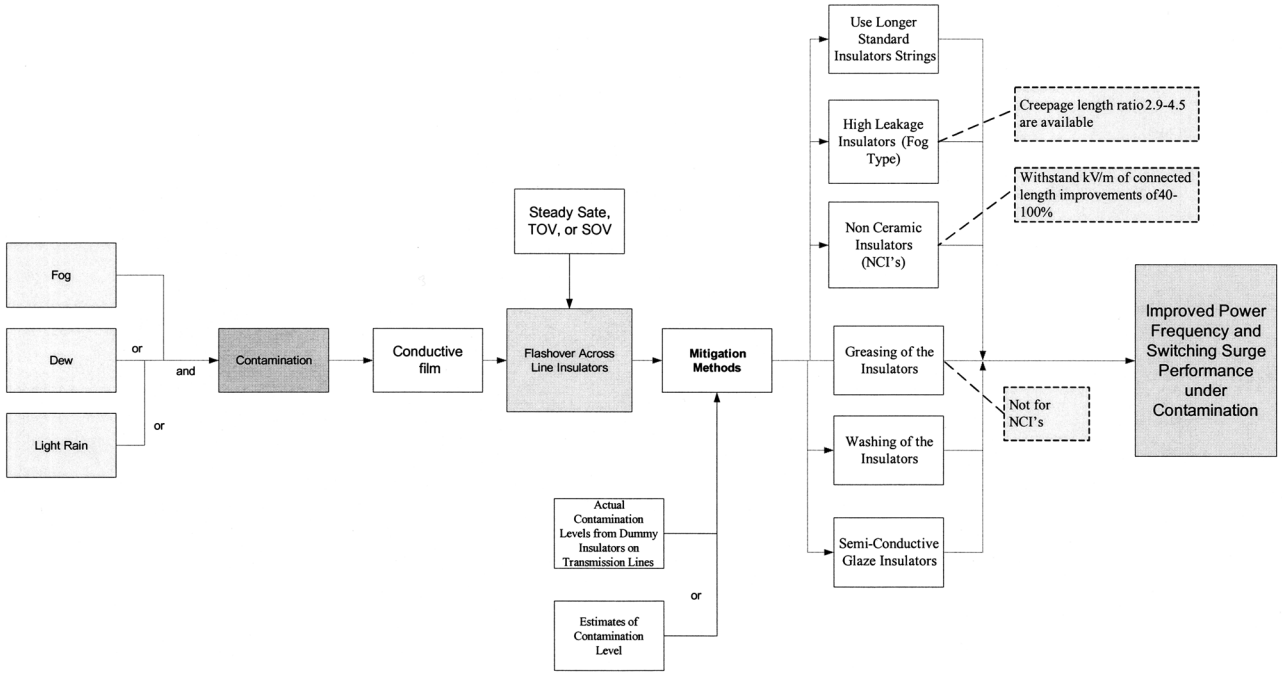

Figure 3.4-5 Power frequency performance under contamination.

3.4.5 Summary

This section provided an overview of some typical methods and design approaches needed to control the voltage stresses on the line insulation due to lightning, switching, and power frequency.

Design for lightning overvoltages includes setting the insulation level, line geometry and clearances, shielding, grounding, and arresters. Solutions for shielding failures and backflashovers are different in many respects, but some common solutions do apply. For example, improving the backflashover rate of an existing line can be accomplished by improving the ground resistance of the towers through supplemental grounding. If improved grounding is not an option, then enhanced lightning performance can be achieved by using transmission surge arresters. The use of surge arresters can also reduce the number of shielding failure flashovers. In many cases, a head start on the design of new lines for lightning overvoltages can be achieved by evaluating the lightning performance of existing transmission lines in the same geographical areas. This information can then be refined or supplemented by studies.

Design for switching overvoltages is an important requirement for the economic design of transmission systems operating above 200 kV, and a necessity above 400 kV. All circuit breaker switching operations generate closing or opening transients or SOVs in the system as the system adjusts to the new set of operating conditions, as a result of the switching operation. Various methods of control have been in use successfully for many years, and finding the most suitable and cost-effective solution for switching surge overvoltages depends on the initiating event. In contrast to lightning overvoltages design, examining the performance of existing lines in the same geographical areas would not be very beneficial in designing new lines, and detailed studies are necessary to quantify the switching overvoltages and the appropriate countermeasures.

The application of surge arresters (either for lightning or switching surge overvoltage control) have yielded advantages, which have been documented in many technical papers.

In the design of line insulation for reducing flashovers due to contamination, many methods can be used. For ceramic insulators, these methods include high-leakage insulator designs or washing/cleaning. Coating insulators with silicon or petroleum grease has been used on transmission lines but the difficulty of application and cleaning/recoating normally limits it to substations. Alternatively, polymer insulators offer improvement in terms of the withstand voltage per connected length of up to 100%.

With Sections 3.2 through 3.4 reviewing the stress, strength, and options available to the line designer for reducing flashovers, Section 3.5 will discuss the National Electric Safety Code (NESC 2002a) as an example of the local or government regulation to which the design has to adhere from the standpoint of public safety.

3.5 ELECTRIC SAFETY CODE REQUIREMENTS

3.5.1 Introduction

The previous sections discussed the voltage stress and the strength of the required line insulation, but nothing was mentioned about the safety of utility field personnel who maintain these lines, or the public who may go under these lines. The safety issue is as important as the technical requirements, and some may argue more important. As a result, designers have to factor safety into the final specification of the line insulation coordination.

In most countries, national electric safety code dictates line clearances; in some countries, even stricter local and state codes may apply. One such code is the National Electric Safety Code (NESC) (NESC 2002a), which is used in the U.S., and also (in full or in part) by other countries. The NESC is the subject of this section.

3.5.2 National Electric Safety Code (NESC 2002) Clearance Requirements

In the United States and certain other countries, the NESC prescribes minimum clearances for transmission lines. The 2002 NESC ANSI C2 has now succeeded the 1997 issue of the Code.

The NESC provides safety requirements for the installation, operation, and maintenance of outdoor communication and electric power facilities. It complements the National Electrical Code (NEC), which provides requirements for indoor facilities. The NESC is mainly concerned with the safety of employees and the public, and is not intended to be a design specification or instruction manual, although in some cases, it may dictate the tower strike distances as well as midspan clearances.

The minimum clearance requirements of the NESC are basically covered in Part 2. Part 2, (Sections 20–27), which deals with Safety Rules for the Installation and Maintenance of Overhead Electric Supply and Communication Lines, is divided into two subparts. Sections 20–23 (Overhead Lines—Clearances) define the organization and location of communication and supply conductors on the overhead facilities, clearances between conductors and structures, and the grounding and arrangement of circuits and associated overhead equipment and hardware. Sections

24–27 (Overhead Lines—Strength and Loading) define various grades of construction and the corresponding storm-loading and strength requirements for them.

In the 2002 edition, the Scope of Part 2 (Overhead Lines) was modified to include appropriate references and rules for personnel approach distances during various construction activities. Sag-related clearances addressing the separation between conductors carried on the same support structure were modified to ensure that adequate clearances are maintained under the worst-case combination of operating temperatures and ice loadings. A new rule was added to specify minimum clearances between supply line cables and communications antennas. Various other clarifications were included throughout Sections 21–23 regarding separations between conductors, equipment, objects, and surfaces. (As a point of reference, Sections 24–27 of Part 2 of the NESC were the subject of the most extensive changes from the earlier editions.)

For transmission lines, the NESC rules pertain to:

1. The midspan clearance to ground for the current-carrying conductors
2. Clearance to the tower: clearance from the current-carrying conductors to the tower body and its components (tower strike distances).

The NESC provides two approaches to calculate the above—a primary and an alternate approach.

Figures 3.5-1 and 3.5-2 describe the general process for calculating these according to the NESC 2002. Further details on the methods and their limitations can be found in this section.

Transmission-Line Midspan Clearance –(Primary Approach)

The lowest clearance of transmission lines from the ground between two towers (midspan clearance) is dictated by the 2002 NESC based on some "reference heights" and on the maximum operating voltage of the line. In some cases, especially for road crossing and voltages of 500 kV or higher, the electric field produced by the line near ground may dictate the ground clearances (see Section 7.8). In fact, the 2002 Code, as was the case in the earlier code, contains the following statement: "For voltages exceeding 98 kV ac to ground, either the clearances shall be increased or the electric field or the effects thereof shall be reduced by other means, as required, to limit the steady state current due to electrostatic effects to 5 mA, rms, if the largest anticipated truck, vehicle, or equipment under the line were short-circuited to ground. The size of the anticipated truck, vehicle, or equipment used to determine these clearances may be less than but need not be greater than that limited by federal, state, or local regulations governing the area under the line. For this determination, the conductors shall be at final unloaded sag at 120˚F (50˚C)."

Reference Heights

Reference heights are shown in Table 3.5-1 (which is extracted from NESC Table 232-1). These heights are divided into several categories, with categories 4 and 5 being the most applicable for the design of transmission lines clearances at midspan.

It must be noted that clearance values for this NESC 2002 edition cannot be directly compared with the 1987, 1990, 1993, or 1997 editions. Vertical clearance values ***appear*** smaller, because sag changes formerly included in these values are now addressed in the application rules.

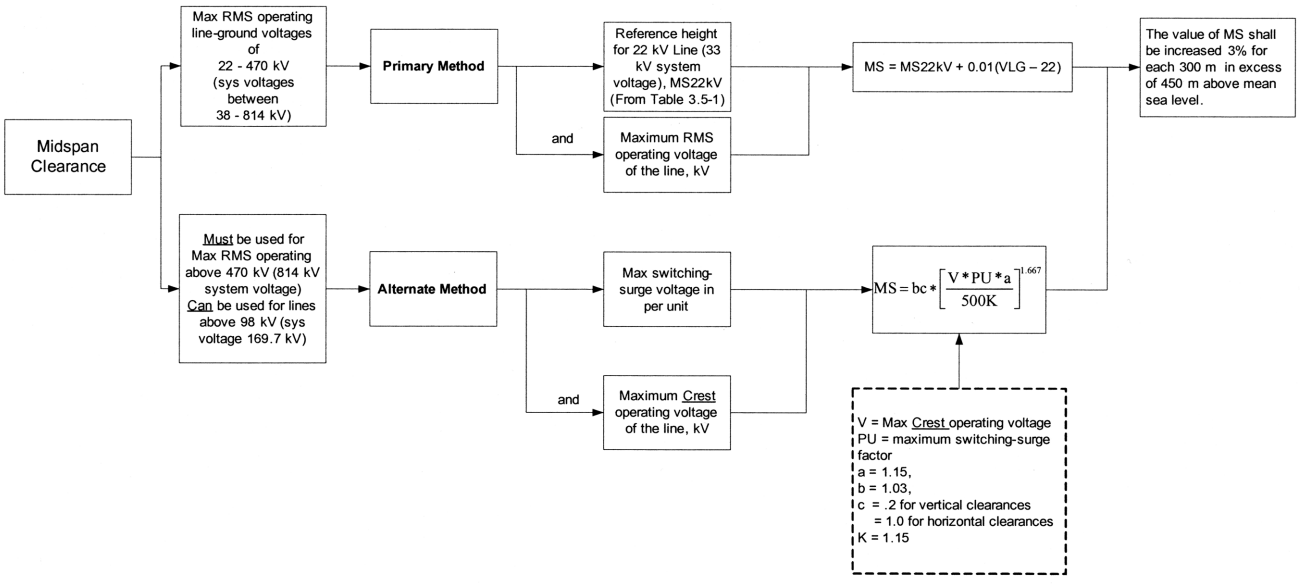

Figure 3.5-1 Determination of the midspan clearance according to NESC 2002.

Horizontal clearance values ***appear*** larger, because wind displacement is now applicable to energized conductors and certain supply cables only; clearances for all other wires, conductors, and cables are shown in the tables under at-rest conditions.

Maximum Operating Voltage

The minimum midspan clearance according to NESC for transmission lines with maximum phase-ground operating voltages between 22 kV and 470 kV (corresponding to maximum phase-phase system voltages between 38 kV and 814 kV) is given by:

$$MS = MS_{22kV} + 0.01\left(V_{LG} - 22\right) \qquad 3.5\text{-}1$$

Where:

MS_{22kV} is the midspan clearance for lines with maximum line-ground voltages greater than 750 V to 22 kV (38-kV system voltage) from Table 3.5-1, fifth column, in meters

V_{LG} is the maximum rms operating voltage of the line, kV.

Clearances must be increased by 3% for each 300 m in excess of 1000 m above sea level to allow for decreasing air density with altitude. The clearance is determined for conductor sags using 50°C or the maximum conductor temperature and 0°C temperature with radial ice and no wind displacement.

For category 4 (other land traversed by vehicles, such as cultivated, grazing, forest, orchard, etc.), the midspan clearance can be calculated as follows:

$$S = MS_{22kV} + 0.01(V_{LG} - 22)$$

For a maximum system voltage of 550 kV (maximum line-ground voltage of 317.5 kV), the midspan clearance is hence:

$$S\ (317.5) = 5.6 + 0.01\ (317.5\text{-}22) = 8.6\ m$$

Table 3.5-2 shows midspan clearances for other voltages for both categories 4 and 5.

Transmission Lines Midspan Clearances (Alternate Approach)

NESC allows an alternate method for determination of midspan clearances for lines with voltages exceeding 98 kV ac to ground or 139 kV dc to ground "with known maximum switching-surge factor." The alternate method usually yields clearances less than those required by the primary method described above. The alternate method must be used for voltages above 470 kV (814-kV system voltage). For voltages exceeding 50 kV, the additional clearance shall be increased 3% for each 300 m (1000 ft) in excess of 1000 m (3300 ft) above mean sea level.

Table 3.5-2 Midspan Clearances Derived by the Primary NESC Approach

Transmission Line Voltage (kV)		Midspan Clearance (m)	
Maximum L-G Voltage	Maximum System Voltage	Category 5	Category 4
140	242	5.6	6.8
209	362	6.3	7.5
318	550	7.4	8.6
461	800	8.8	10.0

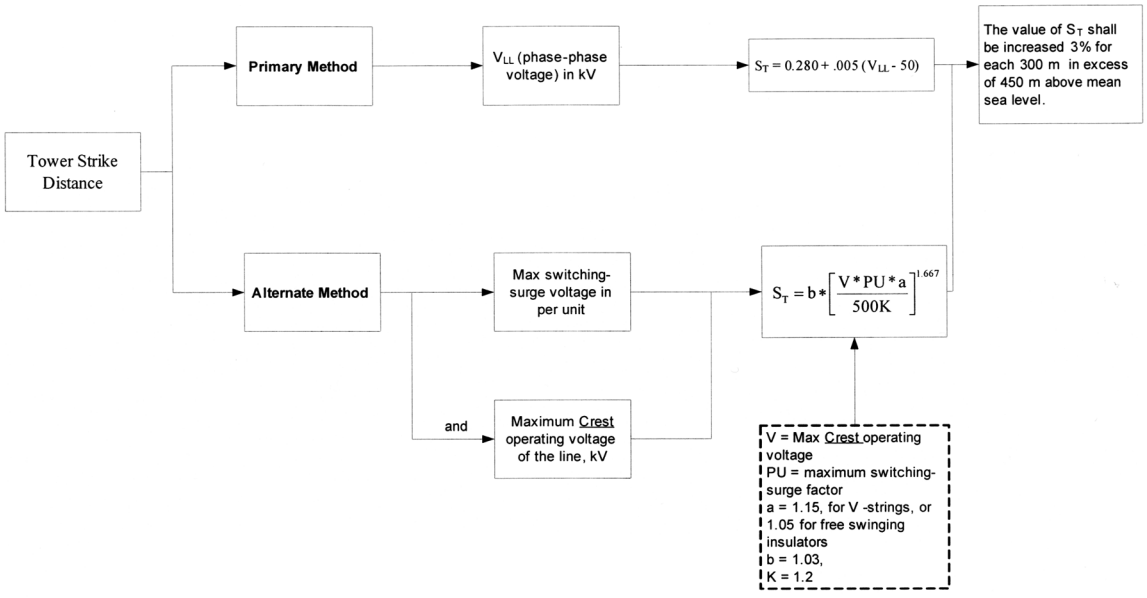

Figure 3.5-2 Determination of the tower strike distance according to NESC 2002.

Using the alternate method, the clearances specified may be reduced for circuits with known switching-surge factors, but shall be not less than the clearance computed by the primary method for a line with maximum line-to-ground voltage of 98 kV (169 kV system voltage).

Using the alternate method, the midspan clearance MS (in meters) shall be computed using Equation 3.5-2.

$$MS = bc * \left[\frac{V * PU * a}{500K} \right]^{1.667} \text{ m} \qquad 3.5\text{-}2$$

Where:

V = maximum ac crest (compared to the rms voltage used for the primary approach) operating voltage to ground or maximum dc operating voltage to ground in kilovolts.

PU = maximum switching-surge factor expressed in per-unit peak voltage to ground and defined as a switching-surge level for circuit breakers corresponding to 98% probability that the maximum switching surge generated per breaker operation does not exceed this surge level, or the maximum anticipated switching-surge level derived by other means, whichever is greater.

a = 1.15, the allowance for three standard deviations.

b = 1.03, the allowance for nonstandard atmospheric conditions.

c = the margin of safety:
1.2 for vertical clearances.
1.0 for horizontal clearances.

K = 1.15, the configuration factor for conductor-to-plane gap.

The value of MS shall be increased 3% for each 300 m (1000 ft) in excess of 450 m (1500 ft) above mean sea level.

Table 3.5-1 Vertical Clearances of Wires, Conductors, and Cables Above Ground, Roadway, Rail, or Water Surfaces (Extracted from Table 232-1 of the NESC 2002)

Nature of Surface Underneath Wires, Conductors, or Cables	Insulated Communication Conductors and Cable; Messengers; Surge-Protection Wires; Grounded Guys; Ungrounded Guys Exposed to 0 to 300 V Neutral Conductors Meeting Rule 230E1; Supply Cables Meeting Rule 230C1 (m)	Noninsulated Communication Conductors; Supply Cables of 0 to 750V Meeting Rules 230C2 or 230C3 (m)	Supply Cables Over 750V Meeting Rules 230C2 or 230C3; Open Supply conductors, 0 to 750V; Ungrounded Guys Exposed to over 300V to 750V (m)	Open supply Conductors, over 750V to 22kV; Ungrounded Guys Exposed to 750V to 22kV (m)	Trolley and Electrified Railroad Contact Conductors and Associated Span or Messenger Wires	
					0 to 750V to Ground (m)	Over 750V to 22kV to Ground (m)
Where wires, conductors, or cables cross over or overhang						
1. Track rails of railroads (except electrified railroads using overhead trolley conductors)	7.2	7.3	7.5	8.1	6.7	6.7
2. Roads, streets, and other areas subject to truck traffic	4.7	4.9	5.0	5.6	5.5	6.1
3. Driveways, parking lots, and alleys	4.7	4.9	5.0	5.6	5.5	6.1
4. Other land traversed by vehicles, such as cultivated, grazing, forest, orchard etc.	4.7	4.9	5.0	5.6	—	—
5. Spaces and ways subject to pedestrians or restricted traffic only	2.9	3.6	3.8	4.4	4.9	5.5

Limit:
The alternate clearance shall be not less than the clearance computed for 98 kV for the "primary" method.

Clearances in Any Direction From Line Conductors to Supports, and to Vertical or Lateral (Tower Strike Distance)
As for the midspan clearance, the NESC gives two ways to calculate the tower strike distance.

Transmission Lines Strike Distances (Primary Approach)
The primary method to calculate the strike distance at the tower can be calculated by Equation 3.5-3 for lines with voltages above 50 kV.

$$S_T = 0.280 + .005\ (V_{LL} - 50) \qquad 3.5\text{-}3$$

Where:
V_{LL} is the phase-phase voltage in kV.

Table 3.5-3 summarizes the strike distances calculated with the primary approach.

Transmission Lines Strike Distances, Fixed Insulators (Alternate Approach)
NESC allows an alternate method for determination strike distances for lines with voltages exceeding 98 kV ac to ground (maximum system voltage of 169.7) or 139 kV dc to ground "with known maximum switching-surge factor." The alternate method usually yields clearances less than those required by the primary method described above. The alternate method must be used for voltages above 470 kV (814-kV system voltage). For voltages exceeding 50 kV, the additional clearance shall be increased 3% for each 300 m (1000 ft) in excess of 1000 m (3300 ft) above mean sea level. With this method, the clearance at the tower (strike distance) is given by Equation 3.5-4:

$$S_T = b * \left[\frac{V * PU * a}{500K} \right]^{1.667} \text{ m} \qquad 3.5\text{-}4$$

Where:
V = maximum ac crest operating voltage to ground or maximum dc operating voltage to ground in kilovolts.
PU = maximum switching-surge factor expressed in per-unit peak voltage to ground and defined as a switching-surge level for circuit breakers corresponding to 98% probability that the maximum switching surge generated per breaker operation does not exceed this surge level, or the maximum anticipated switching-surge level generated by other means, whichever is greater.
a = 1.15, the allowance for three standard deviations with fixed insulator supports, or = 1.05, the allowance for one standard deviation with free-swinging manipulators.
b = 1.03, the allowance for nonstandard atmospheric conditions.
K = 1.2, the configuration factor for a conductor-to-tower window.

Table 3.5-3 Tower Strike Distances (Primary Approach)

Max. System Operating (kV)	Strike Distance (m)
169	0.9
242	1.2
362	1.8
550	2.8
800	4.0

The value of S_T shall be increased 3% for each 300 m (1000 ft) in excess of 450 m (1500 ft) above mean sea level.

The clearance derived from this alternate method (Rule 235E3b) shall not be less than the clearances obtained with the basic method computed for 169 kV ac.

This section does not detail the line working clearances. These clearances have to be factored in the ultimate design of the overall clearances. This topic is covered in Chapter 13.

3.5.3 Summary

This section summarizes some of the requirements and the working clearances of the U.S. National Electric Safety Code (2002) to the clearances at the tower and midspan. These are intended to uphold the safety of utility personnel as well as the general public. If the requirements by the NESC or other applicable codes are enforced, some of the strike distances that may be obtained by the probabilistic design of transmission lines may be exceeded, and hence may dictate the design.

3.6 COORDINATION OF DESIGN REQUIREMENTS

3.6.1 Introduction

This section offers an overview of line insulation coordination. It is where the line insulation is actually "coordinated." The intent here is to present the reader with a stand-alone section that reviews some of the concepts already discussed in this and other chapters, and presents a high-level picture of the challenges that line designers face.

The absolute protection of transmission lines against overvoltages (lightning, switching, and power frequency) is impossible, even with the use of the most conservative approaches. Hence the designer should strive to design transmission lines based on probabilistic methods (when sufficient probabilistic data exist) that combine low risk (not no risk) with economy of design.

Good line insulation coordination is not only important to achieve high reliability of transmission lines, but also is a focal element in station insulation coordination to obtain acceptable mean time between failures (MTBF). Well-coordinated designs in both lines and stations are crucial for attaining a reliable bulk transmission system, and because such designs are probability based, this goal is achieved at an affordable cost. This approach is becoming increasingly important under deregulation.

Line insulation coordination is the specification of all the dimensions or characteristics of the transmission line tower that affect its voltage withstand. These dimensions include:

1. Strike distance, or clearance between the phase conductor and the grounded tower sides and truss
2. Insulator string length (number and type of insulators)
3. Location and number of overhead ground (shield) wires
4. Specification of supplemental tower grounds
5. Phase-phase strike distances
6. Conductor clearances at midspan

The goal behind line insulation coordination is to specify the minimum line insulation for a specific degree of reliability at minimum cost. This specification is determined through:

1. Determining the electrical stress applied to the transmission line.
2. Comparing the stress to the insulation characteristics.
3. Applying ameliorating measures such as surge arresters, shield wires, breaker–closing resistors, etc., when the insulation strength requirements are excessive.
4. Balancing insulation strategy costs and—whenever possible—costs of failures.

3.6.2 Insulation Coordination Analysis Methods

The coordination efforts for lightning, switching overvoltages, and power frequency are essentially independent. Insulation coordination assumes that the magnitude of the overvoltages are known. Concurrently, the electrical insulation characteristics of the transmission lines are also assumed to be known. As a first step, and for a new line, experience on comparable systems and lines may be used in the rationalization of both the system overvoltages and line performance.

The insulation strength of lines for lightning and switching stresses should be chosen on the basis of predicted overvoltages. This determination is then combined with requirements from power frequency and temporary overvoltages. Either a statistical (probabilistic) or a conventional procedure may be used.

A statistical approach is particularly applicable when there is economic incentive for reduction of insulation strength, especially when switching overvoltages are a problem and primarily appropriate to the extra-high and ultra-high voltage. Appendix 3.3 describes in detail the principles of the deterministic and probabilistic approaches.

Statistical Procedure

The statistical procedure allows for some insulation failures to occur, and the procedure attempts to quantify the risk of its failure. A rigorous determination of the probability or risk of failure requires that both the overvoltage stresses and the line insulation strength be described in terms of their respective frequency distributions (see Figure 3.6-1). Simplifications of the rigorous approach are also made and have been applied. In such approximate methods, the statistical lightning or switching overvoltage is so defined that this voltage value, $E2$, has a 2% probability of being exceeded.

Lightning Impulse Strength (LI) and Switching Impulse Strength (SI)

For either Lightning Impulse Strength (LI) or Switching Impulse Strength (SI), tower insulation strengths are typically represented by cumulative Gaussian (normal) distributions. The mean of each distribution is called the Critical Flashover Voltage (CFO) or the $V_{50\%}$. The CFO is, therefore, the voltage where the probability of flashover of the insulation is 50% (the CFO is sometimes referred to as $V_{50\%}$).

Typically the standard deviation for the SI is about 5% of its CFO, and the standard deviation for LI is in the range of 1-2% of its corresponding CFO. For LI, the curve of the CFO as a function of the strike distance is linear, compared to the nonlinear relation for the CFO with strike distance for the SI, as can be seen in Figure 3.6-2. Table 3.6-1 compares the characteristics of lightning and switching impulse strengths. Note that the insulator strength characteristics are defined for standard conditions.

The phase-phase switching impulse insulation strength of transmission lines is a function of the components of the

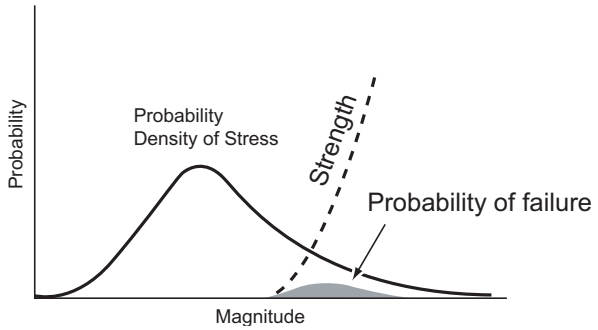

Figure 3.6-1 Statistical procedure for determining insulation failures.

phase-phase switching impulse. Because the switching impulse strength is dependent on the components of the phase-phase switching impulse, both the positive and negative switching overvoltages must be known.

Lightning Overvoltages (LOV)

The approximate distribution of peak magnitude of the lightning current distribution is shown in Figure 3.6-3, based on a relationship formulated by Anderson (EPRI 1982) and adopted by the IEEE/PES Working Group on Estimating the Lightning Performance of Transmission Lines (IEEE 1985). For transmission lines, two regions of the distribution can be viewed: the shielding region, where $I < 20$ kA; and the backflashover region, where $I > 20$ kA. These regions are identified in Figure 3.6-3.

$$P > 0 = \frac{1}{1 + \left(\frac{I_P}{31}\right)^{2.6}} \qquad 3.6\text{-}1$$

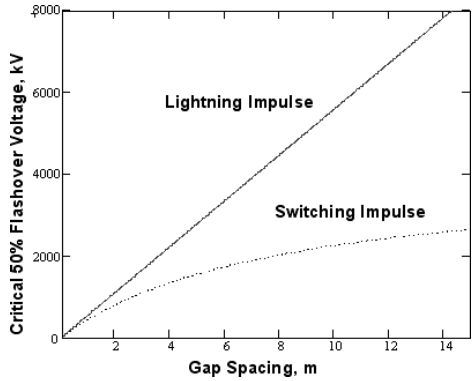

Figure 3.6-2 Comparison of lightning and switching impulse strength.

3.6.3 Lightning Performance of Transmission Lines

For EHV and UHV transmission lines, lightning can produce overvoltages by direct strokes to the shield wires or the phase conductors. Lightning strokes may hit the phase conductors directly, or they may strike the overhead ground (shield) wires.

The lightning performance of transmission lines is the sum of the following:

1. The shielding failure flashover rate (SFFOR), and
2. The backflash rate (BFR).

Both of these flashover rates are linearly dependent on the lightning ground flash density, measured in flashes per square km-year.

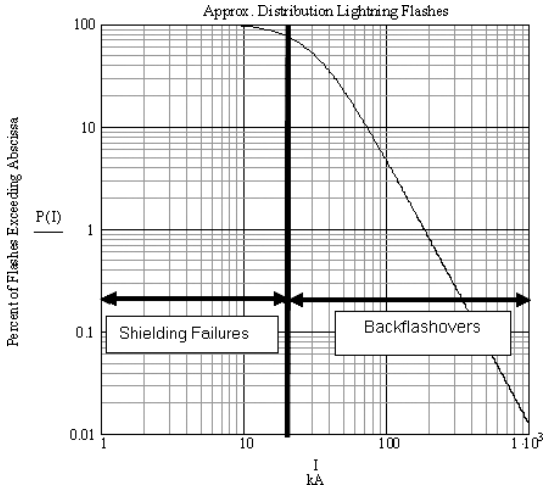

Figure 3.6-3 Cumulative distribution of first negative downward lightning flashes to objects < 60 m (Anderson and Eriksson 1980). (Note the extension of the curve beyond 100 kA is only a "mathematical" fit to the equation. Little actual data exists beyond 100 kA).

Table 3.6-1 Critical Flashover Voltage (CFO) for Lightning and Switching Impulse Strengths under Standard Conditions(1)

Switching Impulse Strength	Lightning Impulse Strength
$V_{50\%,Tower} = 1.2\,\frac{3400}{1 + \frac{8}{L}}$ L is strike distance in meters. Notes: Applies to center phase. @ Standard conditions, V strings. Both dry and wet conditions. Outside phase, increase CFO by 6%.	For positive polarity: 520-560 kV/m (160-170 kV/ft). For negative polarity: 605 kV/m (185 kV/ft). Wet conditions. Either center or outside phases.
1. Standard conditions are defined as follows: • Ambient temperature 20°C. • Air pressure: 760 mm of Hg. • Relative air density of 1. • Absolute humidity: 1.1 grams of water/m³ of air.	

Shielding of Transmission Lines

On a line with overhead shield wires, most of the lightning strokes that terminate on the line hit the shield wire. A shielding failure is defined as a lightning stroke that terminates on a phase conductor. The number of shielding failures calculated for a particular transmission-line model depends on a number of factors. These factors include the line's electromagnetic parameters, the stroke current distribution, and natural shielding from trees, terrain, or buildings. Not all shielding failures result in insulator flashover. A lightning stroke terminating on the phase conductor creates waves of current and charge. These waves develop into voltage waves that, with no surge protection, flash over the insulation in the majority of the cases (e.g., for a conductor with a surge impedance of 400 ohms, a 10 kA stroke can produce 10,000 x 400/2 = 2 MV). If the flashover occurs through the air or across the porcelain insulation, the power arc triggered by the flashover may cause damage, strip insulator sheds, etc. On the other hand, if the flashover occurs through solid insulation, such as a transformer or cable in a substation, permanent damage would result almost all the time. The critical current *Ic* is defined as the lightning stroke current that, when injected into the conductor, results in flashover. The critical current for a particular transmission line can be estimated by:

$$I_C = \frac{2.V_{50\%}}{Z} \qquad 3.6\text{-}2$$

Where:

$V_{50\%}$ = lightning impulse negative polarity critical flashover voltage.

Z = conductor surge impedance.

Shielding Failure Flashover Rate (SFFOR)

The primary aim in the selection of the number and the location of the ground wires is to provide a means of intercepting vertical lightning flashes before they hit the phase conductors—i.e., reducing the probability of shielding failure flashover rate (SFFOR). Hence one shield wire may be adequate in areas of low ground flash density, while two may be needed for areas with higher levels of lightning activity. A practical recommended value for the SFFOR is 0.05 flashovers per 100 km-year.

Even if the shielding angle is set so that lightning flashes with currents greater than the critical current do not terminate on the phase conductor, the SFFOR is not zero because subsequent strokes will follow the same path. The shielding angle is determined for the first stroke of the flash, because this current is thought to have the strongest correlation to the charge on the downward leader. However, even though the first stroke does not result in a flashover, subsequent strokes may have larger currents that can produce flashover. Two primary methods—the IEEE Std 1243-1997 (IEEE 1997b) and CIGRE Technical Bulletin 63 (CIGRE 1991a) methods—are in use to estimate the SFFOR. Calculations with the two methods for the shielding angle values for different tower heights appear to agree for the lower tower heights, but can differ by more than 2:1 for larger heights. As a result, the user has to be cautious when applying either method. The required shielding angle decreases as the ground flash density increases for both methods.

Backflash

A lightning stroke terminating on the overhead ground conductor creates waves of current and voltage, which produce potential differences across the line insulation. If the potentials are in excess to the line insulation strength, flashovers occur. Such an event is referred to as a "backflash," from the tower to the phase conductor, and the number of flashovers per 100 km per year is defined as the backflash rate (BFR). In order of sensitivity the BFR is a function of the insulation strength (length of the insulator string length and strike distance), surge arresters (if used), number of shield wires, tower footing resistance, ground flash density (Ng), span length, tower height, and type of conductors (single bundle) used. As in the case of shielding failures, the backflash event can produce overvoltages that travel to the substations and cause permanent damage in solid insulation. In the case that a low BFR cannot be attained by minimizing the tower footing resistance or other measures, surge arresters can be applied across the insulation.

The BFR of present lines varies significantly with the system voltage; 345- and 500-kV lines often have BFRs in the range of 0.3 to 0.6 flashovers per 100 km-year. The BFR for 138- and 230 kV may be in the range from 0.6 to 2.

As with the SFFOR, the methods of IEEE and CIGRE differ. The IEEE method is more conservative because it makes less allowance for ionization of earth electrodes which is appropriate for large transmission towers.

Improving Performance of Existing Lines

Generally the primary method of improving the flashover rate of an existing design is by use of supplemental grounding, which almost universally consists of a combination of radial counterpoise buried rings, or driven drilled rods. However, in cases where counterpoise cannot be installed because of soil conditions (rock formations), or because towers are on public areas such as roads, improvements in performance may be achieved by doing the following:

- Using transmission line surge arresters
- Increasing the number of insulators and strike distance (overinsulation)
- Chemical treatment of the soil if environmental rules permit.

Effect of Power Frequency Voltage on Lightning Overvoltages

The power frequency voltage, although small in magnitude compared to the surge voltage, is to some extent responsible for determining which phase insulation has the largest voltage and will flashover. Therefore, the voltages across the insulators may be calculated throughout the 360-degree phase rotation, and the flashover rate is determined by averaging these values. Backflashes usually occur on a phase with power frequency voltage that is opposite in polarity to the surge voltage. The maximum longitudinal overvoltage is the difference between the lightning overvoltage on one terminal and the power frequency voltage of opposite polarity on the other terminal of the switching device. For shielding failures, the voltage on the struck phase is random.

3.6.4 Switching Surge Performance of Transmission Lines

Prior to the appearance of 500-kV transmission lines in the early 1960s, little was known about switching overvoltages and switching impulse strengths. Insulation strength was defined only by its lightning impulse and power frequency voltage strengths. With the introduction of 500-kV, switching surges became an important consideration in line insulation design. Analytical studies and field investigations revealed that insulation requirements for switching surges exceeded those required for lightning and power frequency. To overcome such a problem, the breaker design was changed by inserting a resistor in the closing stroke to reduce the switching surges. From that time on, switching overvoltages became an important point in transmission-line design. This section addresses design for switching.

Origins of Switching Surge Overvoltages (SOVs)

The magnitude and waveshape of SOVs vary considerably with the system parameters. Even for the same system configuration, SOVs vary as a function of the characteristics of the breaker (including the characteristics of the breaking media, the mechanical tolerances between the three poles, etc.) and the point-on-wave where the switching operation occurs.

Typically there are three kinds of SOVs:

1. SOVs due to fault initiation
2. SOVs due to fault clearing
3. SOVs due to line energization or reclosing

The important sources of SOVs on EHV and UHV systems are associated with the following events:

1. Line energization, with the line open circuited at the far end or terminated with an unloaded transformer or a shunt reactor
2. Line re-energization, with trapped charge
3. Load rejection
4. Transformer switching at no-load, or with inductive load

Three-phase energization or reclosing of a power line may produce switching overvoltages on all three phases. The overvoltages are dependent on trapped charges left on the phases without fault in the case of high-speed reclosing. In the worst case, each switching operation produces three phase-ground and three phase-phase overvoltages. The magnitudes of the SOVs can be usually be fitted to a probabilistic distribution, often of Gaussian or Extreme value nature. (The variation of the magnitude of the SOVs is due to the point of switching and the electrical and mechanical tolerances of the breaker.) The upper tail of such a distribution is important to quantify in line design, because it is directly compared to the insulation strength. From this comparison, the switching surge outage rate or flashover rate is calculated. Today virtually all EHV and UHV lines are designed using the probabilistic method.

Determining the SOV Probabilistic Distribution

Two methods are in universal use for characterizing the overvoltage probability distribution function: the case-peak method and the phase-peaks method, as described in Table 3.6-2. These methods are used to determine both a phase-ground and phase-phase overvoltage distribution.

The phase-to-phase insulation strength of transmission lines requires determining the distribution of the phase-to-phase overvoltages. Usually only peak (case-peaks or phase-peaks) phase-to-phase voltages are tabulated. A more complete characterization of the phase-to-phase overvoltages also requires the knowledge of the magnitude of the lowest of the two phase-to-ground voltages occurring at the instant of the phase-to-phase peak.

Switching Surge Flashover Rate (SSFOR)

The switching surge flashover rate (SSFOR) of a transmission line is determined by calculating the probability that the stress along the line exceeds the line insulation

Table 3.6-2 Two Methods for Characterizing Switching Overvoltages

Case-Peak Method	Phase-Peaks Method
From each switching operation, the highest crest overvoltage of the three overvoltages is selected, tabulated, and included in the probability distribution. Each switching operation contributes only one value to the overvoltage distribution. This results in the distribution of switching surge overvoltages per each three-phase energization or reclosing operation, and is used to calculate the probability of flashover per three-phase switching operation.	From each switching operation, the crest switching overvoltage on each of the three phases is tabulated and included in the probability distribution. Each operation contributes three crest values to the probability distribution. This results in a per-phase distribution of overvoltages that can be used to calculate a per-phase probability of flashover for the switching operation.

strength. The flashover rate is shown in Equation 3.6-3 (Hileman 1980).

$$SSFOR = \frac{1}{2}\int_{E1}^{EM} f_s(V)\left[1-\prod_{i=1}^{n} q_i\right]dV \qquad 3.6\text{-}3$$

Where:

SSFOR is the flashover rate in terms of flashover per number of switching operations.

$fs(V)$ is the probability density function of the switching overvoltages at the open end of the line.

q_i is the probability of no flashover (withstand) at the i-th tower, which is equal to $(1–p_i)$ where p_i is the probability of flashover corresponding to $\alpha(i)\cdot V$, where $\alpha(i)$ is the ratio between the overvoltage at the i-th tower and the overvoltage at the open end of the line.

n is the number of towers.

$E1$ is the minimum SOV usually set at 1.0 p.u. of crest system line-ground voltage, and Em is the maximum SOV.

The factor $^1/_2$ accounts for the fact that only the positive polarity overvoltages, which are one-half of the total overvoltages, are considered potential cause of a flashover.

The equation may be visualized from Figure 3.6-4. The probability density function at the open end of the line is illustrated in the figure by the solid line, where $E1$ is the minimum SOV usually set at 1.0 p.u. of crest system line-ground voltage and Em is the maximum SOV. The SOV density function may be obtained through the use of a transient computer program with the breakers randomly switched within their pole closing

Acceptable practice is to design for approximately one flashover per 100 switching operations. However, a better design criterion is to consider all switching operations (energization, reclosing with trapped charge, etc.) and the expected number of operations per year. For lines with grounded metal structures between the phase conductors, the phase-to-ground strike distance dictates the SSFOR.

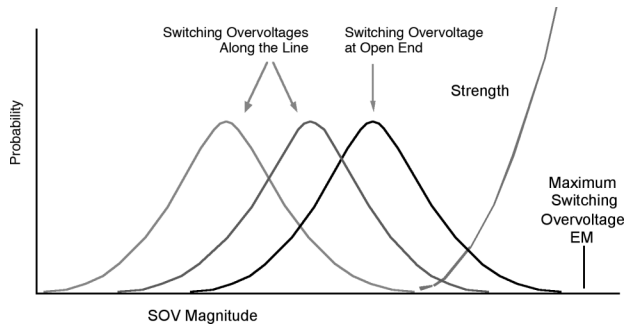

Figure 3.6-4 Switching overvoltages probability densities along a line vs. switching overvoltage strength (Abi-Samra 2000).

For compact line designs where insulators separate phases, the phase-phase strike distance may dictate the design.

3.6.5 Power Frequency Performance of Transmission Lines

The power frequency voltage controls the design of insulator strings in contaminated conditions. The degree of contamination and the associated factors of contamination type and incidence of moisture determines the insulation string design. In addition, the power frequency voltage controls the air clearance between the conductors and the tower when the conductor and insulator string swing in conditions of extreme winds toward the tower or other conductors.

Designs may be obtained by deterministic or statistical methods for power frequency. A detailed description of these alternate methodologies is given in Appendix 3.3.

Design Approach

The power frequency requirements for the design of transmission lines are specified by the creepage distance per kV of line-to-ground voltage (based on the maximum system voltage) needed for contamination. The best known and most reliable method to meet the contamination requirement is to analyze data from existing lines. The thought process here is that if an existing line has a satisfactory 60-Hz performance, its design in terms of creepage cm/kV can be copied for the new line. This is a linear phenomena and it follows that the required creepage/kV is constant regardless of the voltage level of the line. Recommended creepage using standard $5^3/_4$ x10 in. is shown in Table 3.6-4, from IEEE Std 1313.2-1999 (IEEE 1999a).

Contamination decreases the insulators' power frequency voltage strength. The design for the decreased strength can be based on simple historical data, if available, or on a simple deterministic design approach. The deterministic design rule is to set the statistical withstand voltage (V_3) equal to the maximum phase-ground voltage (Em), which includes temporary overvoltages as shown in Equation 3.6-4:

$$V_3 = \mathrm{Em} \qquad 3.6\text{-}4$$

$$V_3 = V_{50\%}\left[1-3\sigma/V_{50\%}\right] \qquad 3.6\text{-}5$$

Where:

$V_{50\%}$ is the power frequency flashover voltage in kV under contaminated conditions.

σ is the standard deviation, and the coefficient of variation,

$\sigma/V_{50\%}$, is assumed to be 10%.

Effect of Contamination on Lightning and Switching Impulse Strengths

Because of the short duration of the impulse, the lightning impulse strength is unaffected by contamination. The decrease in switching impulse strength is a function of the degree of contamination and of the time-to-crest of the

impulse (see Section 5.12.2 for greater details). For heavy contamination and long times-to-crest, the switching surge flashover voltage is not much greater than the crest of the power frequency flashover voltage. The design of insulators for heavy contamination should be based exclusively on withstanding the power frequency voltage with a high degree of reliability, since line re-energization may not be successful.

Insulation Strength—IEEE Recommendations

Table 3.6-3 (IEEE 1999) gives the recommended number of standard insulators in a string for system voltages from 138 kV to 765 kV.

Insulation Strength—IEC Recommendation

It is noted that use of Table 3.6-4 with creepage distance is a useful simplified approach and it does not cover all cases. A more involved dimensioning process is described in Chapter 4.

IEC Standard 60071-2 (IEC 1996) recommends creepage distance for ceramic or glass insulators for different levels of contamination severity, as shown in Table 3.6-4.

Reduction of Airgap due to Wind

For insulator strings not constrained from movement, wind may move the conductor closer to the grounded tower metalwork, thus decreasing the strike distance. The movement can be estimated by calculating the swing angle, with Equation 3.6-6, and as shown in Figure 3.6-5 (from Appendix 5.1).

The swing angle of free-swinging insulator strings is a function of the parameter:

$$K = \frac{D}{W} \cdot \frac{H}{V} \qquad 3.6\text{-}6$$

Where:

D is the diameter of the conductor (mm).

W is the weight per unit of length of the conductor (kg/m).

H is the horizontal span (m).

V is the vertical span (m).

Table 3.6-3 Number of Standard Insulators (146 mm x 254 mm and a leakage distance of 292 mm)

System Voltage (kV)	Number of Standard Units for a Contamination Severity (I-strings/ V-strings)			
	Very Light	Light	Moderate	Heavy
138	6/6	8/7	9/7	11/8
161	7/7	10/8	11/9	13/10
230	11/10	14/12	16/13	19/15
345	16/15	21/17	24/19	29/22
500	25/22	32/27	37/29	44/33
765	36/32	47/39	53/42	64/48

Table 3.6-4 IEC Recommendations for Unified Creepage Distance (revision of IEC 815 1985) (Copyright © 1996, Geneva, Switzerland. www.iec.ch.)

Pollution Level	Examples of Typical Environments	Minimum Unified Specific Creepage Distance (mm/kV)
I Light	• Areas without industries and with low density of houses equipped with heating plants. • Areas with low density of industries or houses, but subjected to frequent winds and/or rainfall. • Agriculture areas. • Mountainous areas. All these areas shall be situated at least 10–20 km from the sea, and shall not be exposed to winds directly from the sea.	28
II Medium	• Areas with industries not producing particularly polluting smoke and/or with average density of houses equipped with heating plants. • Areas with high density of houses and/or industries, but subjected to frequent winds and/or rainfall. • Areas exposed to wind from the sea, but not too close to coasts (at least several kilometers distant).	35
III Heavy	• Areas with high density of industries, and suburbs of large cities with high density of heating plants producing pollution. • Areas close to the sea or in any case exposed to relatively strong winds from the sea.	44
IV Very Heavy	• Areas generally of moderate extent, subjected to conductive dusts and to industrial smoke producing particularly thick conductive deposits. • Areas generally of moderate extent, very close to the coast and exposed to sea spray or to very strong and polluting winds from the sea. • Desert areas, characterized by no rain for long periods, exposed to strong winds carrying sand and salt, and subjected to regular condensation.	55

For high-voltage lines, 60% of the 100-year mean recurrence wind is used. The 100-year wind is the wind speed with a mean recurrence interval of 100 years.

In the presence of wind and the subsequent swinging of the insulators toward the grounded tower downlead or metalwork, the voltage distribution is modified on the individual insulator discs due to the proximity of the grounded members. During power frequency overvoltage conditions, the buildup of voltage across the string is slow (compared to lightning or switching), allowing more time to ionize the air near the surface of the insulator string, with the highest voltage stresses closer to the conductor. These higher-voltage stresses will trigger a flashover at a lower level of voltage than when the string is in the vertical position. The swing of the conductor also has a significant effect on flashover characteristics due to switching surges and lightning because of the higher voltage present on the conductor-end insulator discs, and the proximity to the tower of the conductor. However, it is prudent to assume that the likelihood of having high wind speeds and high SOVs is low, and hence extreme swings are not typically used for switching designs.

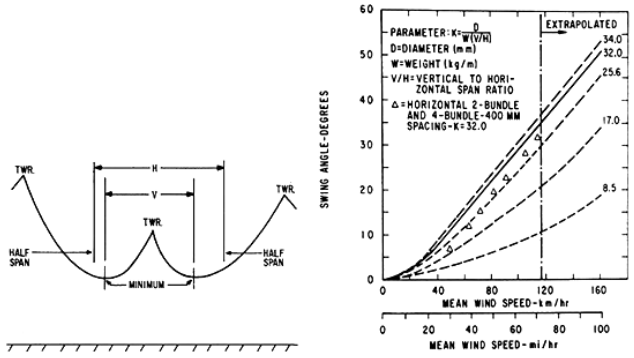

Figure 3.6-5 Swing angle as a function of mean wind speed.

Hence the power frequency design of insulators under wind conditions is done in conditions of extreme winds. However, the wind pressure used for switching surge design is generally assumed to be much lower than for power frequency voltage.

3.6.6 Consolidation of Design Requirements

Hileman (Hileman 1980, 1999) offers a great overview of line design requirements. This is illustrated in Figure 3.6-6. In this figure, the strike distance is shown as a function of maximum system voltage for the three criteria—lightning, switching surge, and power frequency voltage. Table 3.6-5

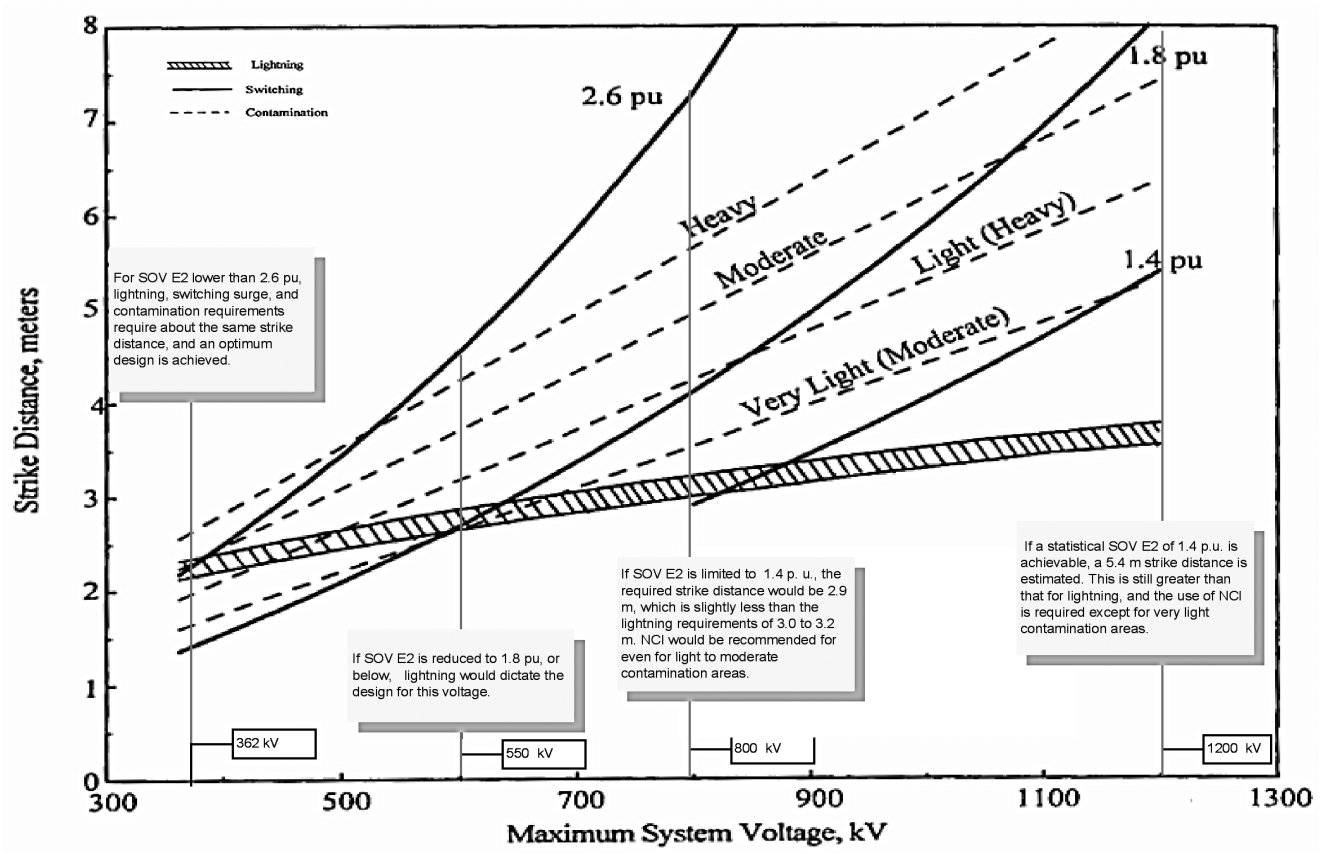

Figure 3.6-6 Comparison of insulation coordination requirements (Hileman 1980, 1999).

Table 3.6-5 Assumptions for Figure 3.6-6

Lightning	• Flashover rate of 0.6 flashover per 100 km-years. • Tower footing resistance of 20 ohms with a soil resistivity of 400 ohm-meters. • The upper portion of the band assumes a ground flash density of 4.0 flashes/km^2-year and the lower portion, 8.0 flashes/km^2-year. Note that the lightning curves are relatively flat, since the lightning requirements should be relatively constant with system voltage. Tower heights increase, and coupling factors decrease with increasing system voltage. These effects, along with the increase in power frequency voltage, combine to produce a gentle increase in the curve.
Switching Surge	Gaussian stress distribution and for statistical overvoltages E_2 of 2.6, 1.8, and 1.4 per unit. (E_2 of 2.6 per unit represents a typical value for high-speed reclosing of breakers without a preinsertion resistor; 1.8 per unit represents a typical value for high-speed reclosing with a single preinsertion resistor; and 1.4 per unit represents a value for a breaker with possibly one or two preinsertion resistors or with controlled closing.). A line with 500 towers is assumed. Each of the curves sweeps sharply upward, portraying the plot of the strike distance as a function of the $V_{50\%}$.
Power Frequency	The power frequency voltage requirements are shown as a function of the IEEE contamination levels of: Very Light 0.03 mg/cm^2, 20 mm/kV Light 0.06 mg/cm^2, 24 mm/kV Moderate 0.10 mg/cm^2, 28 mm/kV Heavy 0.30 mg/cm^2, 32 mm/kV • Use of ceramic 146 x 254 mm insulators in V-strings is assumed.

summarizes the assumptions used to derive the data used for Figure 3.6-6. Refer also to Applet IC-1.

3.6.7 Alternate Method for Line Design: Storm Outage Rate

The performance/reliability criterion for lightning is normally specified as the number of flashovers per 100 km-years. For switching surges, the flashover rate is normally specified in terms of flashovers per number of switching operations. However, the highest magnitude switching surges typically occur when reclosing the line. Such a condition can be caused by a fault associated with lightning. Thus the two separate criteria (lightning and switching) may be combined in one rate known as the Storm Outage Rate in specifying the line reliability.

For transmission lines, lightning flashover rates vary with system voltage, and may range from 0.5 for EHV systems to 20 per 100 km-year for HV systems, although lines are being designed for switching surge flashover rates between 1 and 10 flashovers per 100.

The SSFOR and the lightning LFOR can be combined together to form the storm outage rate (SOR). An outage during a storm may be thought of as having the following scenario:

1. Lightning hits the line and causes a flashover.
2. The flashover causes a fault, leading to the operation of the breaker.
3. After a predetermined time, the breaker recloses, creating a switching overvoltage.
4. The SOV causes a flashover, which brings about another fault.
5. For EHV systems, the breaker reopens and is locked-out, resulting in an outage.

The SOR for the line is essentially obtained by multiplying the lightning flashover rate in units of flashovers per year by the switching surge flashover rate in terms of flashovers per switching operation. For example, assuming the lightning flashover rate to be two per year, and the switching surge flashover rate to be one per 100 switching operations, the storm outage rate is two per 100 years, assuming one reclosing operation per year.

Hileman (Hileman 1980) extends the "logic" of using the SOR to practical terms in determining line insulation coordination: in areas with low-lightning activity, the SSFOR may be selected as high as 0.1, since the probabilities of lightning flashovers are low. Similarly, in the areas of high-lightning activity, the SSFOR may need to be selected very low (i.e., 0.001) for reliable line operation. (The lightning flashover rate [LFOR] is essentially the backflashover rate [BFR] for effectively shielded lines.)

3.6.8 Summary

The absolute protection of transmission lines against overvoltages (lightning, switching, and power frequency) is impossible, even with the use of the most conservative approaches. Hence the designer should strive to design transmission lines based on probabilistic methods that combine low risk (not no risk) with economy of design.

Good line insulation coordination is not only important to achieve high reliability of transmission lines, but also is a focal element in station insulation coordination to obtain acceptable mean time between failures (MTBF). Well-coordinated designs in both lines and stations are crucial for attaining a reliable bulk transmission system, and because such designs are probability based, this goal is achieved at an affordable cost. This approach is becoming increasingly important under deregulation.

Line insulation coordination is the specification of all the dimensions or characteristics of the transmission line tower that affect its voltage withstand. These dimensions include:

1. Strike distance, or clearance between the phase conductor and the grounded tower sides and truss
2. Insulator string length (number and type of insulators)
3. Location and number of overhead ground (shield) wires
4. Specification of supplemental tower grounds
5. Phase-phase strike distances
6. Phase-to-ground clearances at midspan

The goal behind line insulation coordination is to specify the minimum line insulation for a specific degree of reliability at minimum cost. This specification is determined through:

- Determining the electrical stress that is applied to the transmission line.
- Comparing the stress to the insulation characteristics.
- Applying ameliorating measures such as surge arresters, shield wires, breaker-closing resistors, etc., when the insulation strength requirements are excessive.

The consolidation of such requirements is referred to as line insulation coordination. Figure 3.6-7 summarizes a methodology for performing line insulation coordination for lines of various voltages.

3.7 ECONOMIC CONSIDERATIONS

3.7.1 Introduction

Previous sections in this chapter have described the stress on line insulation and how to design lines with appropriate strength to achieve reliability goals. However, an additional important goal for designers is to minimize cost.

Changes in line design affect the line cost. Increased clearances may improve line reliability, but at a higher price. This section attempts to provide some insight into the economic consequences of design changes, and to compare costs of some alternatives such as TLAs versus increased clearance or grounding. However, it is recognized that cost analysis is complex. Costs can vary significantly between different designs, terrains and soil conditions, and atmospheric conditions. Also, cost sensitivities may be considered less important than design standardization. Therefore, this section is primarily an introduction to techniques and options that designers may use.

It should be noted that the tools used for assessing the effects of design changes on line cost are the same as those used for the life-cycle cost analysis of the most appropriate technology, including selection of line voltage, conductor type and size, and whether ac or HVDC. These tools evaluate the present worth of alternatives to provide the optimum design and determine the sensitivity to parameter changes.

3.7.2 Insulation Coordination and Cost

Design of a transmission line includes the following parameters:

- The type of structure—single or multiple circuit, wood or metal, phase geometry
- Airgap clearances, including phase-to-tower, phase-to-phase, and phase-to-ground at midspan
- The amount, type, and configuration of insulators
- Grounding, including paths to ground and grounding resistance
- The number and location of overhead shield wires
- The need for, rating, and location of voltage-limiting devices, such as line surge arresters and breaker insertion resistors
- Possible use of wood in lightning flashover paths for arc quenching

Changes in any of these parameters affect the line cost. In insulation coordination, the goal of the designer is the optimum combination of insulation, clearances, and voltage control to achieve a reliability target at least cost. As an example, increasing the length of the insulator strings requires that the tower height be increased to provide the same conductor-ground clearance at midspan. This additional height not only requires additional steel for the tower, it also increases the overturning moment on the tower and the torsional load in the event of a broken conductor. The taper of the tower may require a larger footprint for a higher structure. The end result is not simply that the tower is higher—the tower, together with its foundation, must also be made stronger. Similar consequences arise from different phase conductor or shield wire size and material; changing conductor tensions; using V strings instead of I strings to reduce conductor swing; designing for different phase-ground, phase-structure, or phase-phase clearances; adding shield wires or changing shielding angles; and different phase geometries. Changing tower heights and loading may result in a different placement or even in a different number of towers spotted along the right-of-way, and use of a different mix from the family of structures (tangent, angle, and deadend types, each with additional subcategories) available. Soil conditions vary along a line, so foundations may differ for the same loading capability. Thus a design change might lie within the capabilities of a particular structure with no changes, while in another location the design change might force the use of a heavier and more expensive choice. Design detailing, or small adjustments in the member location in a design, can also make a disproportionate difference to the strength required for a particular load.

In addition, there are independently costed items that may result from different tower insulation or clearances, such as grounding, line arresters, and breaker resistors.

Optimizing the cost implications of insulation coordination is, therefore, an interactive process. Similar issues are encountered when designing a compact line. However, it is important to consider practical issues and the design process as a whole when adjusting a line design. For short lines, for example, it is usually cheaper to use an overdesigned standard design drawn from stock than to attempt an

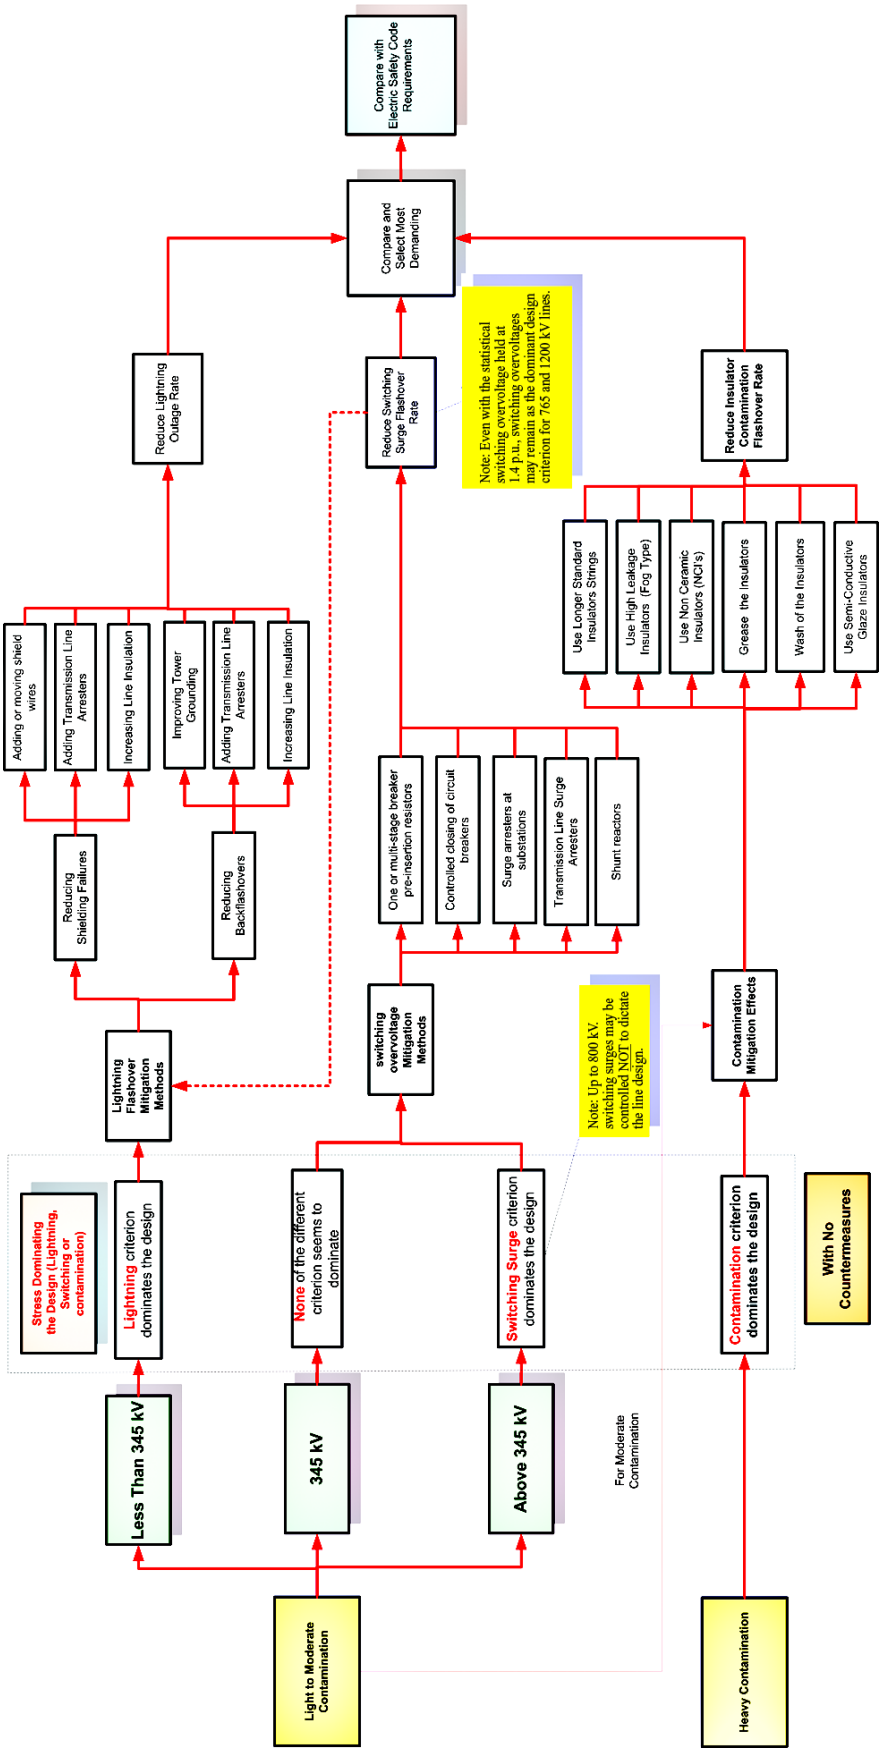

Figure 3.6-7 Line insulation coordination methodology.

optimized design. The advantages of lower cost for an optimized structure are offset by the design and engineering costs, testing, and increased need for spare parts. Smaller clearances may also present difficulties for hot line maintenance. If regional contamination is uncertain, it is less costly to design for one or two extra insulators or for insulators with better performance in contaminated conditions than to wrestle with a continuing contamination problem and hot line washing, greasing, or insulator retrofitting.

Yet another complication is determining the worth of the benefits of improving insulation performance. The consequence of designing for (say) a lower level of switching surge failures can be expressed as a reduction in line tripouts—although, as discussed elsewhere, the precision of predicting actual improvement in performance is limited. But what is the cost of a line tripout? If no load is interrupted, the cost may be negligibly low, but conversely if the tripout triggers a series of consequential events leading to a blackout, the cost may be very high. Chapter 6 explores some possible cost strategies by reverse-engineering some costs of line protection using overhead groundwires. Even if a predictable amount of load is lost, the value of lost electricity sales by the supplier may be very different from the costs of interrupting a critical industrial process, the possibility of civil disturbance, or political or regulatory consequences following loss of confidence in the supplier. In practical terms, sophisticated analysis procedures should sometimes be put aside in favor of simplifying the process.

Nevertheless, considerable savings can result from cost optimization on lines of any significant length, and this section outlines some considerations for a designer in estimating the cost consequences of insulation coordination.

3.7.3 Line Component Costs

Before exploring cost sensitivities, it is useful to consider the magnitudes of the basic components of a line. A broad international survey is provided in (CIGRE 1991b). As an example of the information provided, Table 3.7-1 compares the cost breakdown for lines between 150 and 300 kV, and > 300 kV.

The values in the table are based on international surveys carried out in 1989-90, and may vary with time, geographic location, and specific designs. However, the numbers obtained from the survey are relatively insensitive to differences over a wide range of alternative parameters.

3.7.4 Cost Sensitivities

As noted above, changes in line design parameters are often highly interactive, so it is misleading to consider the cost of a single modification. Each change should be considered for its effect on the total line.

Table 3.7-2 shows some typical values for a 400-kV single-circuit horizontal-phase configuration line (CIGRE 1991b; CIGRE 1991c). As can be seen, the net effect of a change may be partially offset by consequential changes in other parameters. Also, the change in structure cost is itself an incomplete indicator, as there remains the possibility of changes in tower spotting that can be unique as a function of the actual terrain, route angles, etc.

As shown in Table 3.7-1, the structure cost is approximately 36% of the total cost of the line (including only materials and erection), so this additional factor should be applied to arrive at the overall effect on cost.

It should also be noted that in mature transmission systems, new lines are often short and highly constrained by route and permit issues. In extreme examples, a new line may have mostly angle or deadend structures despite their much higher cost, because the route has been selected to go around individual properties rather than cross them, and a short line with the costs of land and permitting included may be 10-20 times costlier per km or mile than the same line in a remote location—levels at which underground cables may be an option.

Table 3.7-1 Summary of Line Component Costs (Values in Percent)

Category	Material	Construction		Conductor	Shield	Insulators	Structure	Foundation
150–300 kV	64.3	35.7		31.6	4.1	8.8	36	19.5
> 300 kV	65	35		31.5	3.5	9.3	36	19.7

Note: Numbers do not include right-of-way or permitting costs.

Table 3.7-2 Cost Sensitivities to Design Changes

Parameter	Change in Parameter	Change in Cost of Structure (%)
Phase - tower clearance	-1%	-0.3
Number of shield wires	2, 1, 0	0, -6.5, -12.9
Shielding angle	20, 10, 0, -10	0, +0.3, +0.7, +1.4
Insulator configuration	I, V	0, -1.4
Insulator string length	+1%	0, +1

3.7.5 Independent Cost Items

As noted above, it is possible to improve line performance with grounding augmentation, line arresters, or circuit breaker insertion resistors. While the need for these items may be a consequence of decisions on the structure parameters, they are applied independently, and are not directly linked with the interaction of structure parameters and costs. Table 3.7-3 illustrates some typical values.

3.7.6 Base Line Costs

Line costs vary as a function of electrical and mechanical loading requirements, terrain, route, soil type and conditions, regional labor and materials costs, design practices and codes, and permitting and environmental requirements. The costs in Table 3.7-4 are "typical" costs only, and do not include significant land or permitting amounts. Line costs can change significantly with mountainous terrain, rocky or marshy soil, and a need for frequent angle structures.

3.7.7 Cost Analysis Methods

Estimation of line costs in sufficient detail for use in insulation coordination considerations can be difficult, since it requires relationships between costs and design parameters that are both highly interactive with other parameters and also not normally available to electrical designers. The most accurate method for determining the cost of a design change to meet insulation coordination requirements is to carry out a ground-up design for the specific line in question. This is normally, of course, lengthy and expensive. More typically, a limited amount of redesign based on typical examples is used.

Table 3.7-3 Typical Costs of Independent Items

Category	230 kV	500 kV	765 kV
Grounding augmentation (note that this varies widely with local conditions)	$900-$1500 per structure	$900-$1500 per structure	Augmentation not normally required
Line arrester	$3400/arrester. Use 1-3 per structure	$9000/arrester—not normally used due to cost	Not used
Breaker resistors	Not normally used	$25-30k per 3-phase breaker	$30-40k per phase

Table 3.7-4 Base Line Costs

Category	230 kV	500 kV	765 kV
Cost per mile	800 k$	1.2 M$	1.4 M$

A useful and versatile tool developed by EPRI is described in (EPRI 1986). The TLOP component of EPRI's TLWorkstation™ uses regression analysis to model the relationship between each member of the tower family with its foundation and cost, and then either combines a tower spotting calculation or a pre-sited design with mechanical loading calculations and conductor characteristics to produce a complete table of structures for the line and thus the total cost. The software includes a limited ability to calculate the effect of tower dimension changes on cost, as input to the regression analysis. Commercial software with similar capabilities is available, such as the PLS-CADD program (Peyrot et al. 1992).

Another useful alternative is supplied in (CIGRE 1991b), based on international surveys of transmission line costs. This reference includes sensitivity analyses of the effects on cost of the principal parameters of interest including conductor tension, structure clearances, and the number and positioning of shield wires. While this data is limited to typical structure types and voltages, it is sufficiently accurate for most design purposes. Similarly (CIGRE 1996) provides cost data on foundations.

The EPRI TFLASH transmission line lightning analysis program includes an optimizing algorithm to search for the least cost to attain a specified transmission line lightning performance or the strategy to gain the maximum lightning performance improvement for a fixed cost. It is frequently the case that the most cost-effective improvement in line lightning performance is not to concentrate on improving the performance of the structure with the highest flashover rate, but to apply the money to the structure that can show the greatest improvement per dollar expended.

3.7.8 Summary

Insulation coordination is the optimum combination of insulation, clearances, and voltage control to achieve a reliability target at least cost. Estimation of the costs of design changes resulting from insulation coordination is complex, but can readily be handled by available software tools and data. However, the line cost optimization may be secondary to use of standard components and designs or to permitting and routing constraints.

APPENDIX 3.1 INSULATION COORDINATION ANALYSIS TOOLS

Introduction

Knowledge of overvoltages for line insulation coordination may be obtained in two ways: by measurement (or past history on similar lines) or by modeling and analysis. Field measurements are the preferred way to obtain data, such as performance for lightning and contamination, but such measurements are not always possible or affordable. There are numerous cases of validation with field measurements.

With the development of modeling and simulation techniques in the last two decades, almost all kinds of transient problems related to insulation coordination can be analyzed. Modeling for line insulation coordination can be performed with a number of tools, which can be grouped into three distinct areas shown below. The order shown also depicts the chronological introduction of such tools in the design of transmission lines:

1. Analog tools—e.g., Transient Network Analyzer
2. Multi-purpose software tools that can be adapted to the calculation of overvoltages—e.g., EMTP
3. Specialized software tools—e.g., EPRI TFlash, which was especially formulated for the sole purpose of calculating the performance of the transmission lines under lightning.

The following sections discuss the above tools. At the present, the dominant method of analyzing insulation coordination is through digital simulation. Digital simulations have always dominated lightning studies due to the range of frequencies involved.

Analog and Hybrid Modeling

Transient Network Analyzers (TNA)

It should be noted that although TNAs are rarely used today, a brief description is helpful to the understanding of the historical evolution of electromagnetic transient simulations, and a number of TNA-developed techniques are being used in the digital simulations.

Basically, the TNA represented scaled models of the actual electrical systems. The models duplicate the electrical response of the actual devices. The various models are physically assembled by the operator and interconnected with wires. The network is then energized in an appropriate way, and measurements are made at the desired points. Conventional TNA modeling was ideal for switching surge and temporary overvoltage calculations, and to a much lesser extent, for lightning studies, due to the required time scaling. Today digital TNAs have been developed and can represent power system components in some cases more accurately than the scale analog components.

Modeling Considerations for the TNA

- **Transmission-Line Modeling.** Transmission lines in the TNA were modeled as lumped-constant ladder networks, called pi, π sections. Each π section would model the resistance, reactance, and line charging of transmission (R, L, C) line segments. A good model would be made of many such sections, and would be able to represent phase transpositions, earth return frequency dependency, variations of line parameters as the line transverses different terrains, and other variations. The number of elements required in the model depends on the amount of traveling wave distortion that may be permitted. The more elements used, the less distortion there is, but at the expense of having to model a smaller system, since the number of elements is limited. This challenge compelled the engineer to become very cognizant of power system behavior, and what needs to be modeled, and what can be equivalenced, and to what degree. (This is somewhat lost with digital simulations, which can model thousands upon thousands of busses and branches. The capabilities of these simulations seem limitless, and hence the need for some decision-making is reduced.) Also, the TNA was the "real-time simulator" and the perfect method to perform a sensitivity analysis on the variables. (Changes were made by the turning of one or two dials, and the consequences were instantly apparent, even faster than digital simulation. It was straightforward, for example, to learn the consequences of changing the rating of a shunt reactor, or selecting a different arrester. Such features made collection of statistical data so cost-effective with TNAs.) On the other hand, analysis of data from earlier TNAs (up to and through the 1970s) used to be time-consuming. In the 1980s, the situation changed dramatically with the introduction of digital computers to control the TNA and to organize and analyze the output.
- **Other Models.** Transformers were generally represented by a network of single-phase units, with one branch representing the magnetizing effects and another representing the impedance between windings. Coupling between phases, either through the core or through a tertiary winding, was accomplished with auxiliary windings. Magnetization and saturation effects could be studied because the magnetizing branches were wound on steel cores that had saturation effects similar to those of real transformers, which made these miniature transformers very expensive. Reactors were represented either by actual air core reactors or by electronic circuits that injected currents into the model circuit of the same amplitude and phase as those in the actual reactors. Surge arresters were modeled by electronic circuits that duplicated the nonlinear resistances and gaps. Circuit breakers and switches were represented by relays that were closed and opened at preselected times by an electronic control device. Generally the relays employed

contacts that were wetted with mercury in order to have low contact resistance and eliminate contact bounce. Opening and closing resistors in actual breakers were represented, but the dynamic arc resistance of the breakers was seldom duplicated.

- **Time Scaling.** Most TNAs were operated with a unity time scale and a unity impedance scale. This means that the TNA operated at the same frequency as the actual system and that impedances (in ohms) on the TNA were the same as on the actual system. Often different time scales were used to fine-tune the electrical lengths of transmission lines or to make a model transformer more closely match the impedance of an actual transformer. This is no longer needed in digital simulations.

Digitized TNA (DTNA)
Although most electrical transient simulations have been taken over by digital models, the digitalized TNA (DTNA) continues to gain attention due to its high speed, quick setup, and reproducibility, aided by parallel processing techniques and state-of-the-art digital signal processors (DSP). DTNAs are also referred to as "real-time digital simulators" (RTDS). RTDS has overcome most of the problems faced by traditional TNAs. The RTDS is currently applied to many areas of development, testing, and studies including:

- Protective relaying schemes
- Integrated protection and control systems
- Control system for HVDC, SVC, synchronous machines, and FACTS devices
- General ac and dc system operations and behavior
- Interaction of ac and dc systems
- Interaction of various electrical installations (e.g., between two HVDC systems)
- Demonstration and training

An RTDS has been developed and is maintained by the Manitoba HVDC Research Centre (Mathur and Wang 1989; McLaren et al. 1991; Durie and Pottle 1993; Pratico and Eitzmann 1994).

General-Purpose Digital Programs
From the 1970s, a number of digital programs have been developed for analysis of transients (Thoren and Carlsson 1970; Ametani 1973). One that is widely used is the Electromagnetic Transients program (EMTP) developed by Dommel and Meyer (Dommel 1969). Other popular programs include: ATP (Alternative Transients Program: the public domain version of the EMTP), PSCAD/EMTDC (Power Systems Computer Aided Design, a Graphical User Interface for the EMTDC—ElectroMagnetic Transients including DC), and the Matlab/Simulink/Power System Toolbox. Most are time-domain programs, which have many features in common, at least with regard to methods of use.

As for the TNA, digital programs use models of actual physical devices. The individual models are interconnected by the user to build a composite model of the system to be studied. While the analog modeling (e.g., TNA) is mainly applied for switching surge and temporary overvoltages—due to the frequency response and model complexities—the digital programs are used for lightning, switching, and temporary overvoltage calculation aspects of line insulation coordination.

Electromagnetic Transients Program (EMTP)
The EMTP is a comprehensive computer program designed to solve electrical transients on power systems, regardless of their nature, as long as the user specifies the correct models and time frames. Its development started in the early 1960s by H. W. Dommel. The program attracted much attention and was widely used by engineers in the United States and elsewhere. Individuals and groups have subsequently adapted, expanded, and generally augmented the techniques, increasing the program's capability. (By 1980, EMTP had become very popular in the electric power industry. For better improvement and maintenance, an EMTP development coordinating group (DCG) was established in 1982. Two years later, EPRI reached an agreement with DCG to take charge of documentation, conduct EMTP validation tests, and add a more user-friendly input processor. In 1996, an EMTP96 version with graphic user interface was released. EPRI/DCG continuously updates the EMTP program to make it more flexible and user-friendly.)

Transient analysis using EMTP can be carried out in circuits with any arbitrary configurations. Transmission lines with distributed parameters, transposed or untransposed, can be included in the network. Losses in such lines are approximately modeled to good effect by lumped resistance. Frequency dependence of line parameters can also be represented, as well as nonlinear resistance (for surge arresters) and nonlinear inductors (for saturable devices). It is also possible to open and close switches to simulate breaker operations, flashovers, etc.

Some of the EMTP operating principles are summarized below:

- The trapezoidal rule of integration is used to solve differential equations of system components in the time domain.
- Nonzero initial conditions can be determined either automatically by a steady-state phasor solution, or they can be entered by the user for simpler components.

- Symmetric or unsymmetric disturbances are allowed, such as faults, lightning surges, and any kind of switching operations including commutation of valves.

Both voltage and current sources are available to model switching and lightning studies. There can be sinusoidal, ramp, or step functions. Alternatively, arbitrary waveforms can be applied from a point-by-point description. Trapped charges can be recognized.

Alternative Transients Program (ATP)
In 1984, Drs. W. Scott Meyer and Tsu-huei Liu, the co-Chairmen of the Canadian/American EMTP User Group, started a derivative program from a copy of BPA's public-domain EMTP, called Alternative Transient Program (ATP). ATP has been developed through international contributions. EPRI/DCG's EMTP and ATP are similar in many ways. For all practical purposes, for line insulation coordination, the ATP can do everything the EMTP can do, and hence no further discussion on this will be made here. There are differences in program interfaces, graphical user interfaces, and ancillary programs.

PSCAD/EMTDC
EMTDC™ stands for ElectroMagnetic Transients including DC. PSCAD™ or Power Systems Computer Aided Design is used as a Graphical User Interface for the EMTDC™. EMTDC was developed by Dennis Woodford in 1975 to study the Manitoba Hydro Nelson River HVDC Power System. The program is now used extensively for many types of power simulation studies including ac, lightning overvoltages, and power electronics.

Specialized Programs
EPRI TFlash
EPRI and EPRIsolutions, under a multi-year project, with the participation of many utilities, have developed a special program, TFlash, exclusively to predict the performance of transmission lines designs for lightning. TFlash uses a traveling wave simulation to calculate voltage and current distributions on power systems. The software provides statistical results for complete coverage of lightning stroke locations and currents. The results can be used to analyze relative performance of different line configurations and to identify problem areas where excessive lightning flashovers may occur along a line. TFlash is used for the evaluation of the lightning performance of new and existing overhead transmission lines, and is also utilized to optimize new designs and improve the performance of new lines. With TFlash, one can study the advantages, tradeoffs, and cost justification of applying various structure, conductor, arrester, and grounding techniques to improve lightning reliability.

The latest version of this program can:

- Create computer models of multiple lines in a single right-of-way (ROW).
- With its automatic optimization function, it can compare specific cost and performance improvements of various options and determine the most cost-effective changes to the line.
- Import lightning stroke data from Fault Analysis and Lightning Locating System (FALLS) to calculate line performance.
- Fly the line with TFlash 4.0's 3-D line model viewer.

Aids to Calculation of Transients
Engineers who perform transient simulations typically spend a disproportionately small amount of time actually running the simulations. The bulk of their time is spent on:

- Obtaining parameters for component models (and benchmarking the component models to confirm proper behaviors), and
- Constructing the overall system model (and benchmarking the overall system model).

Only after the component models and the overall system model have been verified can one confidently proceed to run meaningful simulations.

With digital solution techniques, it is easier to simulate perfect components than actual frequency-dependent components. For example, an actual transmission line has distributed resistance, and it continuously distorts a surge traveling along the line. A transmission line in a time domain digital program could be either lossless or distortionless, but real lines do have losses, and these losses must be accounted for by some means. For a transmission line digital model, the losses may be approximated by breaking the line into two pieces and placing resistances at the middle and two ends of the line. However, when high frequencies or rapid rates of change are involved, such simple means may not be sufficient to prevent spurious results or numerical instabilities. More sophisticated line models with frequency-dependent losses have been developed to address this issue.

Transient phenomena in power systems are caused by switching operations, faults, and lightning strokes. The frequency range of these phenomena extends from dc to several MHz. An accurate simulation of a power system requires an adequate representation of its components, taking into account the frequency of the transients. An acceptable representation of all equipment throughout the complete frequency range is very difficult, and for most components is not practically possible. To solve this problem, the representation of a component can be made by

developing mathematical models that are accurate for a specific frequency range. According to the CIGRE Working Group 33-02, model frequency ranges are classified as four groups, with overlapping between them:

- Group I: Low-frequency oscillations, from 0.1 Hz to 3 kHz
- Group II: Slow-front surges, from 50/60 Hz to 20 kHz
- Group III: Fast-front surges, from 10 kHz to 3 MHz
- Group IV: Very-fast-front surges, from 100 kHz to 50 MHz.

Especially in the high-frequency range, data of stray inductances and capacitances are always required to be taken into account. These data are difficult to calculate precisely, but rough estimates are often sufficient. As a rule of thumb, one may say that the inductance of a conductor is about 1 μH/m. The inductance of a small wire is greater, perhaps 1.5 μH/m, and the inductance of a busbar less, perhaps 0.7 μH/m.

Generally, stray capacitance is more important than stray inductance. Both bushings and transformer windings have considerable capacitance. The capacitance of a bushing is often shown on the nameplate, but if not, it may be estimated from tables given in IEEE C37.011-1994 (IEEE 1994). Usually capacitance is on the order of 300 pF for small or low-voltage bushings and 500 pF for large or high-voltage bushings. Greenwood (Greenwood 1991) gives a more comprehensive discussion of inductances and capacitances to use in the calculation of transients.

In high-frequency transient simulation, a large transformer is usually modeled as a capacitance. The input capacitance may be quite large—5 to 25 nF. This capacitance depends on the type and size of the transformer. It is neither given on nameplates nor routinely measured. IEEE C37.011-1994 gives some information on capacitance as a function of transformer size (IEEE 1994). More precisely, modeling of a large transformer can be simplified according to the frequency range of interest. The CIGRE WG document considers different models for power transformers, distinguishing between studies in which surge transfers are not of interest and those for which these transfers have to be taken into account. For more detail, refer to (Martinez-Velasco 1998; CIGRE 1990; Arturi 1991; Stuehm 1993; Mork 1998).

Example Use of the EMTP for Backflash Design: Modeling Guidelines

The following are some modeling guidelines for performing backflash calculations with the EMTP. Although the information presented in this book generally refers to the EMTP, the modeling requirements are general enough to be equally applicable to the other digital transient programs.

- **Transmission-Line Models.** For backflash studies, the most important model needed to construct is the model of the transmission line. Hence, for such studies, overhead lines are represented by multiphase, distributed parameter, untransposed, and "traveling wave" models. Conductor (phase and shield wire) data and configuration, and physical line and tower configurations are needed to derive "modal" surge impedance and velocities for the transmission lines. Either a frequency-dependent or a constant parameter model can be used. If the constant parameter model is selected, it is recommended to calculate parameters at a frequency of 500 kHz.
- **Line Termination.** Two or three spans must be represented at each side of the strike point or point of impact. A line termination is needed at each side of the above model to avoid unrealistic reflections. This can be achieved by inserting a resistance matrix at each termination whose values equal the line modal surge impedances. This can be also obtained by adding a long enough section, several miles (or kilometers) at each side.
- **Steel Tower Representations.** Steel towers can be represented as a single conductor distributed parameter line terminated at their footing impedances. Tower surge impedance values range from 100 to 300 ohms.
- **Tower Grounding.** A waveshape-dependent, or a frequency-dependent representation, is recommended. If not available, a resistance in the range of 10 to 100 ohms can be used. One difficulty is representing the nonlinear impedance of grounding systems with surge current.
- **Lightning Stroke.** The lightning stroke is typically represented as a current source with negative polarity and a specified waveshape for backflash calculations, as described in Chapter 6. The lightning stroke is not represented by a log-normal current source. Its cumulative probability of occurrence can be represented by a log-normal probability curve; the stroke itself is represented by an infinite impedance current source.
- **Power Frequency Voltage (Initial Conditions).** Phase voltages at the instant of the lightning stroke should be included. One simplified approach used for statistical calculations, is to select phase voltages every 30 or 60 degrees and average the results. More rigorous analysis assumes the phase voltages selects the phase voltages by considering a uniform distribution between 0º and 360º. For a deterministic calculation, worst-case conditions should be determined and used. A value of phase voltage equal to 105% of the crest value of the phase-to-ground voltage and of opposite polarity to the tower voltage can be used as the most conservative number.
- **Insulators.** Insulators are represented as voltage-dependent flashover switches in parallel with capacitors. Every time a flashover is produced, a counter is increased and the flashover rate is updated.

The flowchart in Figure A3.1-1 depicts the process of using the EMTP in doing lightning study for backflash over analysis.

Summary

With the development of modeling and simulation techniques in the last two decades, almost all kinds of transient problems related to insulation coordination can be analyzed. This appendix reviewed some of these tools that can be used by transmission line designers today. Some other tools are also described in several sections in this book, and are not repeated here.

An accurate simulation of a power system requires an adequate representation of its components, taking into account the frequency of the transients. An acceptable representation of all equipment throughout the complete frequency range is very difficult and for most components is not practically possible.

APPENDIX 3.2 SURGE ARRESTER APPLICATIONS ON TRANSMISSION SYSTEMS: STATION AND LINE ARRESTERS

Introduction

This appendix describes the application of surge arresters on transmission systems. It covers both applications of surge arresters: the more classical applications of surge arresters at substations as well as the applications on the transmission lines themselves, which is gaining in popularity as a countermeasure for reducing lightning as well as switching overvoltages. It is noted here that the two types of arresters are different in construction and energy capabilities. This appendix starts with a description of the different types of station surge arresters, and then it tackles the application to transmission lines and associated considerations.

Station Surge Arresters

The use of modern surge arresters has made possible the reduction of the required basic impulse-insulation levels of much transmission system equipment. The primary function of early arresters was to protect the system insulation from the effects of lightning. Modern arresters not only dissipate lightning-caused surges, but also control other system surges caused by switching or faults. Surge arresters are seldom called upon to dissipate full lightning current, because transmission systems are generally shielded with ground wires, thus reducing the possibility of direct strokes to the phase conductors. (The ground wires are usually connected to earth through the tower structure with ground rods or mats. Ideally, tower footing resistance is kept to minimum practical levels so that lightning currents may be conducted to earth without unduly causing high voltages on the structure. If the tower footing resistance is high, a stroke to the ground wire or tower momentarily raises the tower voltage sufficiently so that an insulator flashes over. A portion of the lightning current then flows onto the phase conductor, and a surge begins to travel along the transmission line. Even a lightning stroke that does not impinge on either ground wires or phase conductors may induce traveling surges on the line. Because induced surges are unimportant for transmission voltage levels above 69 kV, the usual lightning effect that an arrester is intended to dissipate is the surge along the transmission line into the substation.

The modern surge arrester is a metal-oxide surge arrester (MOSA), which has largely replaced the older type silicon carbide arrester that was widely used. The MOSA is fabricated from nonlinear resistance metal-oxide (zinc oxide) materials.

Metal-oxide arresters fall into three categories:

- Gapless Arresters
- Shunt-Gapped Arresters
- Series-Gapped Arresters.

Nonceramic housed gapless arresters have the majority of TLSA market share at transmission voltages below 200 kV, but above this level other topologies offer increasing advantages of cost versus complication. To date, series-gapped arresters have been applied widely at 500 kV, and gapless topologies have been applied in spot applications outside stations at 765 kV. The shunt-gapped topology is described for completeness.

Gapless Arresters

Gapless arresters utilize stacked column(s) of metal-oxide valve elements, as shown in Figure A3.2-1 with the corresponding arrester volt-ampere characteristic. The arrester discharge voltage for a given surge-current magnitude is directly proportional to the height of the valve element stack, and is a function of the rate of rise of the current surge, with higher voltages occurring for faster rates of rise and vice-versa. At the maximum continuous operating voltage (MCOV) of the arrester, the arrester current is usually not more than a few milliamperes (mA), typically less than 10 mA. On the arrival of a surge, the increasing surge current is accompanied by a rise in arrester voltage to a maximum level determined by the volt-ampere characteristic.

Shunt-Gapped Arresters

The discharge voltage of a column or columns of metal-oxide valve elements can be reduced by shunting a portion of the stack as shown in Figure A3.2-2. On the arrival of a surge, the arrester voltage initially increases with increasing surge-current magnitude, according to the volt-ampere characteristics A-B. When the surge current magnitude reaches the B-C region, sparkover of a gap in parallel with a few metal-oxide valve elements occurs. This shunts the surge current around these valve elements, and proportionally lowers the discharge voltage (in the range D-E). For further increases in surge current, the voltage increases according to the characteristic E-F.

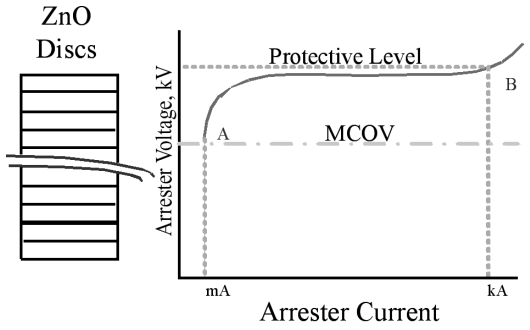

Figure A3.2-1 Gapless metal-oxide surge arrester.

Series-Gapped Arresters

Further reduction of the protective levels of arresters can be achieved by using fewer valve elements in conjunction with series-connected spark gaps as shown in Figure A3.2-3. On the arrival of a surge, the arrester voltage begins to rise (A-B). At a level of current in the vicinity of 1 A (depending on the rate of rise in the range B-C), the gaps spark over, and the arrester voltage is reduced to the discharge voltage of the metal-oxide elements only. For further increase in surge current, the voltage increases according to the characteristic D-E-F (Hileman 1999).

The voltage across the terminals of an arrester depends on two main factors: the magnitude of the current through the arrester and the waveshape of the current. The magnitude of the current is strongly influenced by the impedance of the circuit between the arrester and the source of the surge, as shown in Figure A3.2-4. If the impedance is low—for instance, near a large capacitor bank—the current through the arrester, and hence the voltage across the arrester, may be excessive and may damage the arrester. Because the arrester is in fact a nonlinear circuit element, a direct solution for the current and voltage is not possible.

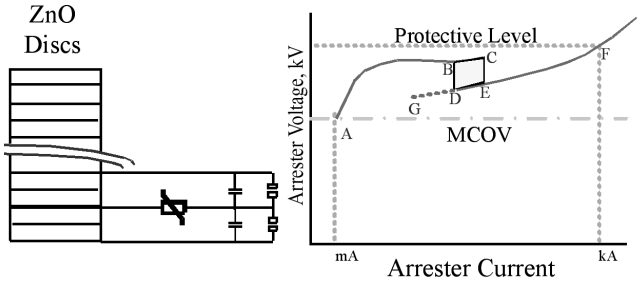

Figure A3.2-2 Shunt-gapped metal-oxide surge arrester.

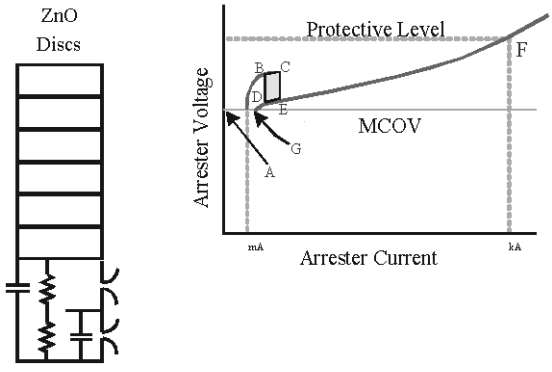

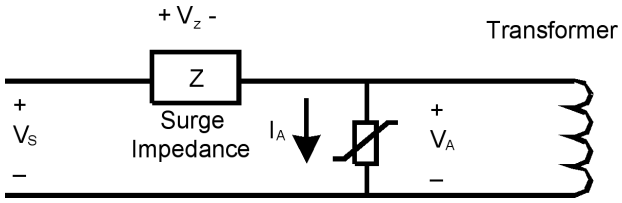

Figure A3.2-3 Series-gapped metal-oxide surge arrester.

As may be seen in Figure A3.2-4, the arrester current depends on V_S, Z, and V_A—the latter being a function of the desired current. This problem may be solved by either iterative or graphical means. Very fast-rising currents of a given magnitude produce higher voltages across the arrester than more slowly rising currents. In part, this is due to the inherent characteristics of the nonlinear resistance material of the arrester. Figure A3.2-5 indicates the magnitude of the voltage rise that may be expected. The values for silicon carbide and metal oxide are each normalized to unity at a time-to-crest of 10 μs because the standard current wave for the testing of arresters crests at 10 μs (IEEE 1999a).

Inductance in series with the arrester also produces higher voltage for fast current waves than for slow current waves. Long ground leads can contribute a significant inductance

V_s = Surge Voltage
V_z = Voltage Across the Surge Impedance of the line
V_A = Protective Level of the Arrester
Z = Surge Impedance of the Line
I_A = Arrester Current
$V_s = V_z + V_A$
$V_S = I_A Z = V_A$

Figure A3.2-4 The role of system impedance on arrester current.

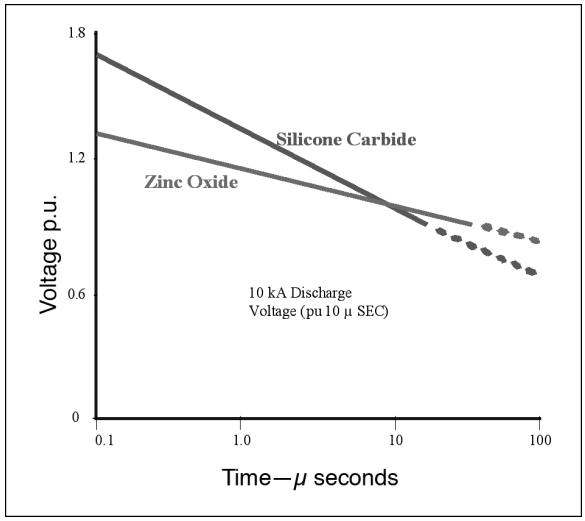

Figure A3.2-5 Effect of rise time on voltage.

so surge currents that rise to crest faster than 10 μs will cause higher voltages of shorter duration than those produced by the standard current test wave. Fortunately, the insulation in most oil-filled equipment such as transformers is able to withstand higher voltages if the duration is short. Some types of insulation, notably SF_6, do not exhibit much rise in insulation strength for voltages of short duration, and therefore arresters must be applied carefully to ensure that proper protection is provided for all types of surges, fast or slow.

Temporary Overvoltages (TOVs)
It is possible to control temporary overvoltages with surge arresters. When a temporary overvoltage occurs on the system—for instance, because of a fault—an arrester may be able to protect the equipment for the short time it takes to operate the applicable breakers. Because arresters cannot withstand high levels of overvoltage indefinitely, the timing of breakers may be of critical importance. Metal-oxide devices have greatly improved capabilities in this regard.

Switching-Surge Overvoltages (SSOVs)
It is possible to use surge arresters to control switching-surge overvoltages along a transmission line and thereby reduce the length of the required insulator strings. An example is shown in Figure A3.2-6 for the switching of a 280-km (175-mile) line having metal-oxide arresters at the receiving end. It is clear that the arresters can reduce the switching overvoltage along the entire line, from a maximum of 2.2 p.u. to 1.8 p.u. If the line can be energized from either end, arresters must be provided at both ends. Also see the section on Transmission Line Arresters below.

Arrester Selection
For a given application, the selection of an appropriate arrester involves considerations of many factors such as:

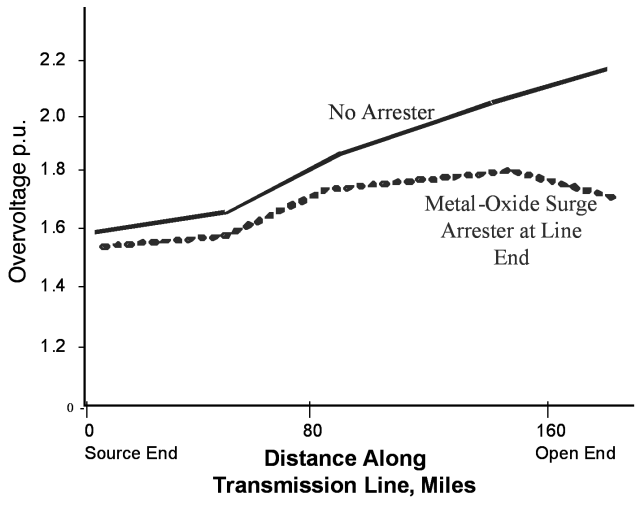

Figure A3.2-6 Typical effect of a surge arrester in controlling switching-surge overvoltages along a line.

- The maximum continuous operating voltage (MCOV) to which the arrester is subjected.
- The protective characteristics of the arrester for lightning and switching impulses
- Temporary overvoltages in the system—that is, durability
- Service conditions under which the arrester is applied.

The flowchart in Figure A3.2-7 explains how surge arresters are selected for substation equipment protection. The reader is also encouraged to refer to IEEE Std C62.22-1997, IEEE Guide for the Application of Metal-Oxide Surge Arresters for Alternating-Current Systems, New York, 1997 (IEEE 1997a). At present, there is no equivalent industry-standard approach for selecting TLSA for transmission lines.

Transmission Line Arresters (TLAs)
Transmission-line insulators may be protected from lightning flashover by overhead shield wires. However, the effectiveness of the shield wire depends on many factors. Prime among these are shield angle and structure ground footing resistance.

Strokes to the shield wire cause surge voltages to be induced in the phase conductors. The magnitude of the induced voltage is a function of the current magnitude, resistance, and geometry. Stroke currents exceeding a critical current value develop sufficient voltage between the structure and the phase conductor to cause an insulator flashover. The phase with the poorest coupling to the shield wire is the most highly stressed and therefore most likely to flash over in most cases. The possibility of a flashover of the line insulation and subsequent service interruption may be significantly reduced through the application of line arresters. Line arresters may also be applied on one circuit of a double-circuit line in order to reduce double-circuit interruptions due to lightning. Line arresters may be installed phase-to-ground, either in parallel with the line insulators or built into the insulators. While the failure rate of these arresters is low, the user should consider the failure mode of the arrester. After failure, the arresters should be disconnected by some form of disconnecting device from the line to allow for successful line reclosing.

The protective level of the line arresters should be greater than the protective levels of the adjacent substation arresters. This precaution reduces the energy absorbed by the line arresters due to switching surges and therefore reduces the possibility of a line arrester failure.

The appropriate location of the surge arresters depends on many factors, including lightning ground stroke density, exposure, span length, conductor geometry, footing resistance, insulation level, and desired line performance goals.

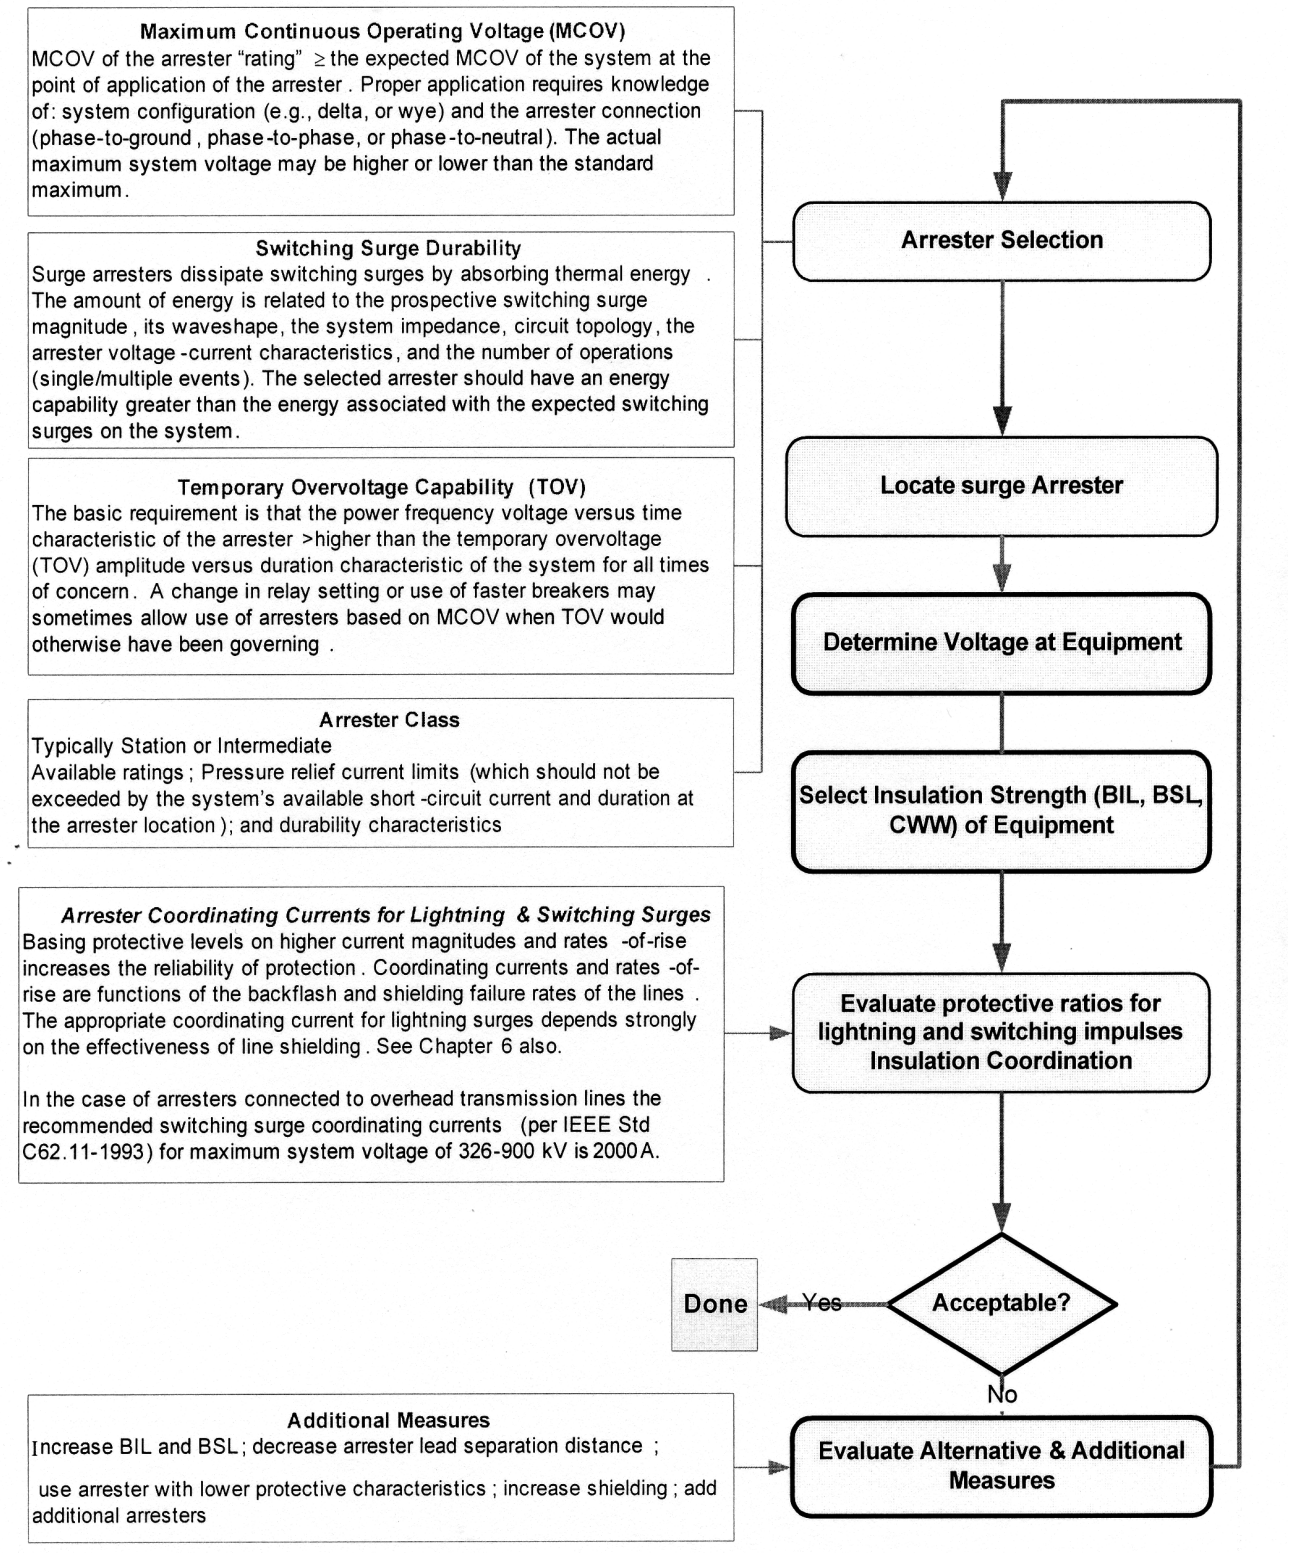

Figure A3.2-7 Flowchart for selection of surge arresters.

In general, the more frequently arresters are installed, the better the performance. Several computer models are available to assist in selecting the location of surge arresters, or the arrester manufacturer may be contacted for a recommendation.

In some cases, arresters are being used successfully in place of shield wires. The user should consider energy, mechanical strength, and weight requirements in developing the system design. The arrester manufacturer should be contacted for recommendations.

Line arresters are now manufactured for application in localities where lightning exposure is high and soil conditions limit installation of counterpoise or other ground electrode configurations. If applied properly, they can be very effective in reducing flashover rates, but if applied improperly, they simply transfer flashovers to structures with no arresters (Shih et al. 1985). They can also serve to inhibit shielding failures on critical spans, but again only if properly applied following the application theory to be described in this section.

Transmission-Line Arresters (TLAs) are now used to address lightning-related phenomena with the intent of improving the reliability of transmission lines. Transmission-line surge arresters also offer an efficient alternative for limitation of switching surges along transmission lines instead of using closing resistors or controlled closing schemes. Line arresters limit maximum lightning voltages across line insulators to values below the flashover value.

Hence the following functions of the systems can be improved by using TLAs:

- Reduction of line-to-ground and line-to-line lightning outage rates
- Reduction of backflashover rate on unshielded transmission lines
- Improved reliability of shielded and unshielded transmission lines
- Upgrading of system voltage on an existing transmission line
- Building new compact transmission lines
- Switching overvoltage control along transmission lines
- Reduction of the need for controlled closing of circuit breakers
- Reduction of the need for preinsertion resistors

Line Arrester Construction

Transmission-line arresters consist of a series of metal-oxide varistor blocks usually encased in a polymer weatherproof shell. The shell is designed to vent high-pressure gasses in case of a failure so as not to scatter fragments over a wide area. The varistor blocks can be substantially smaller than station arrester blocks because the lightning energy is usually shared by several arresters, or distributed along the stricken phase conductor in case of a shielding failure.

Important mechanical issues affect the use of TLAs. The first is the fact that practical TLAs tend to be about 30% longer than the insulators that they are protecting and need to be mounted at an angle to get the extra length. The physical reasons for this are as follows. For a typical lightning surge current of 31 kA, a column of large arrester blocks with 6.4 cm ($2^1/_2$ in.) diameter develops a voltage of about 380 kV/m. To protect a 230-kV insulator with length of 2 m and BIL of 1080 kV, the arrester column would need to be shorter than 2.8 m. However, the arresters have only a limited ability to withstand temporary overvoltage, so the columns are manufactured to be as long as possible. The connection from the transmission line to the arrester is also an area of potential weakness. Most connections incorporate current-limiting protection (see next section) that separate the arrester from the power system in the event of failure. This connection is often made using live-line work methods, which tend to have a wider distribution of installation forces than barehand work. The connection must also tolerate a range of conductor motion and, at the same time, avoid transfer of vibration energy or static forces that could distort the TLA housing and break open seals.

The ability of the TLA to radiate heat without damaging the polymer housing may also be an issue in some applications. Standard test methods for polymer insulators (CEA 1996) include boiling for 100 h in saltwater, followed by steep-front impulse application to establish the integrity of seals. This gives some guidance that the intended steady-state temperature of TLA in nonceramic housings should also be maintained below 100°C, based on existing construction methods.

TLA Failure Modes and Their Implications

Transmission-line surge arresters are relatively complicated components that may be susceptible to a number of long-term failure modes. Also, substitution of TLAs for overhead shield wires may only be practical if a low but nonzero arrester failure rate is used in the design process. Also, TLAs typically fail short rather than open, and need to be disconnected from the line to allow line reclosing. For these reasons, many manufacturers provide fuse-type disconnecting devices that can physically remove the connection from the power system, leaving sufficient distance between the phase conductor and the arrester so that there is no subsequent reduction in electrical insulation strength. (Such devices are placed on the ground terminal of the arrester and connected between the ground terminal and

the ground lead. TLAs mounted directly in the tower or parallel to insulators typically have the disconnector mounted on the high-voltage clamp between the high-voltage terminal and the line clamp. Operation of the disconnector physically separates the arrester ground connection from the failed arrester and gives a visual indication of failure.) With co-ordination between the breaker operation time and the I-t characteristics of the disconnector, the failed arrester does not cause a momentary outage. Disconnect operation can be identified from terminal transients or by visual inspection.

Some manufacturers provide fault-tolerance through the use of a series air gap rather than a fused disconnect. On distribution systems, this practice was well established because it was necessary to protect silicon carbide nonlinear elements from normal power frequency operation. For newer arresters, the improved voltage-current characteristics of metallic oxide elements make this unnecessary, but in some conditions, the series gap gives advantages of lower weight and cost.

Since conductors tend to swing laterally under different wind conditions, for transmission line suspension insulators, it is usually necessary to provide a ring of some sort to maintain a constant series gap. This approach has given satisfactory results in one EHV field trial (Kawamura et al. 1994).

Transmission Line Arrester Energy Capabilities

The surge arrester metallic-oxide elements tend to have higher energy absorption capability under lightning surge conditions than under ac conditions. Ringler et al. (Ringler et al. 1997) reported a mean for three manufacturers of 400-600 Joules / cm^3 at low current, typically from a single hole through the bulk material. When surge currents were increased to typical lightning levels of 35 kA, the arresters were able to absorb between 1600 and 2000 J/cm^3, and failures showed many small pinholes. A typical set of parameters from this test-to-destruction work included:

- Cylindrical block: 3.2 cm radius, 2.3 cm tall, area 32.2 cm^2, volume 74 cm^3
- Average test condition: 8.7 kV at 36.5 kA (318 MW)
- Average test results: 540 μs time to failure, 172 kJ, 2320 J/cm^3

The product of test current and time-to-destruction in experiments with power frequency ac and pulse voltage is remarkably constant for each type of arrester over more than five orders of magnitude. The increase in arrester voltage with higher current nearly exactly compensates for the increase in energy absorption capability. Since the product of arrester current and time is simply the charge, the parameters described in Section 6.2 for positive and negative flash charge will be relevant to the engineering applications below. In routine applications, with long life and multiple exposures to lightning, the energy level that causes a significant change in the arrester voltage-current relationship in terms of the application environment may be more limiting than the ultimate time-to-destruction result. This will be particularly true if there is little margin between the arrester maximum continuous operating voltage (MCOV) and the system overvoltage level.

Arrester manufacturers specify the maximum energy capability of each arrester sold, and experience has shown that some of these ratings are very conservative. Nevertheless, before any application to unshielded lines is evaluated, it is essential that a careful lightning energy analysis be made via computer programs dedicated to the probabilities of arrester failures on lines with no shield wires. The EPRI TFlash program has this capability.

Line Arrester Application Theory

The application of TLA is explained in a simple example, involving three towers (A, B and C) and a simplified transmission line consisting of only one shield wire and one phase conductor. Because of high footing resistance, a lightning flash terminating on the shield wire near the top of tower A will impress transient voltages across the tower A insulator far in excess of the critical flashover voltage. To avoid flashover, a line arrester can be connected across this insulator. Suppose the tower top voltage is 3000 kV, and the arrester limits the insulator voltage to 800 kV. The difference of 3000 kV– 800 kV = 2200 kV is then injected by the arrester onto the phase conductor at tower A. This 2200 kV then travels in both directions along the phase conductor and arrives at tower B. If the footing resistance at tower B is high, the difference between the tower top voltage and phase voltage at B may be sufficiently small, so that no flashover occurs at the tower B insulators, but in the usual case—if tower B insulators are not protected by arresters—they will fail. If arresters are also installed at tower B and the tower B footing resistance is high, the phase transient can still travel to tower C with sufficient magnitude to flash those insulators, unless arresters are present. However, if towers C have a low-footing resistance to conduct the lightning current to ground, the tower top voltage at C will collapse, the arresters will limit the transient voltage leaving towers C to less than the insulator CFO, and arresters will not be required beyond towers C. Low-footing resistance towers C are called “drain towers,” and their function is to dump the energy and to carry the stroke currents to ground through low-resistance paths so that flashovers will not occur beyond them. Between the two drain towers, flashovers can be expected to occur unless arresters are applied. Each drain tower must have low-footing resistance. For short distribution spans, arresters can sometimes be applied on every other support structure, but only after careful analysis using a computer

program written to evaluate all the traveling-wave effects, such as the EPRI TFlash program or an EMTP analysis. For double-circuit applications, arresters applied to one circuit can often reduce the flashovers on the companion circuit by coupling. Applet L-1 does not have capability to evaluate line arrester effectiveness.

To install line arresters without a careful traveling-wave analysis and without knowing the tower footing resistances can often result in little or no benefit for a large expenditure of time and money. Conversely, if problem areas exist where lightning flashovers are frequent, proper installation of line arresters after a careful analysis can be very effective.

For long EHV lines, TLAs usually are located at line ends. In addition, by locating arresters at one or more points along the line (e.g., at the midpoint or the one-third and two-thirds points), switching surge overvoltages and thus line insulation requirements can be limited without preinsertion resistors. Arresters used for this type of application should be designed for high-energy capability. Usually a class 2 or 3 arrester is sufficient, but higher arrester classes may be necessary at the receiving end of a line.

By the application of TLAs there are also possibilities for compacting lines and for upgrading of existing lines. The majority of TLAs presently used in North America are gapless metal-oxide arresters in polymeric housings, although there may be some that have gaps and/or porcelain housings. Polymer-housed high-energy transmission line surge arresters suitable for switching surge control are available for all EHV system levels up to and including 800 kV. The energy requirements for TLAs due to switching surges are considerably less for line arresters than for arresters located at the receiving end of the switched line. Figures A3.2-8 and A3.2-9, respectively, show the applications of gapless and gapped surge arresters on 275-kV lines at Eskom. In the case of Figure A3.2-9, the gapped arrester application, note the use of counterweights to keep the arrester in its proper placement. The gap is selected so that it does not flash over under switching surges. This means that, in the event of surge arrester failure, it is still possible to switch the line back (with the faulty arrester still present).

Figure A3.2-10 (Stenström and Mobedjina 1998) illustrates that, with a reasonable number of arresters, it would be possible to obtain an average overvoltage (2% value) of approximately 2 p.u. along an entire 100-km 550-kV line.

Application Considerations of TLAs

TLAs can help reduce the number of backflashovers and shielding failure flashovers on a transmission line. To a lesser extent, they are also used to reduce switching surge overvoltages. Table A3.2-1 discusses some common applications of TLAs.

Effects of Tower Footing Ground Resistance on TLAs

For shielded lines with no line arresters, the lower the ground resistance, the better the backflash performance. On the other hand, when TLAs are applied, a lower ground resistance in some cases may worsen the lightning performance, as explained here. When a lightning stroke terminates on the phase conductor due to a shielding failure (or the lack of the shield wire) most of the current will discharge to ground through the nearest TLA. Adjacent arresters, on adjacent towers, will discharge some amount of the energy based on the span length. The sharing is more pronounced on the slower tail of the surge where more of the energy is concentrated. The energy sharing is affected by

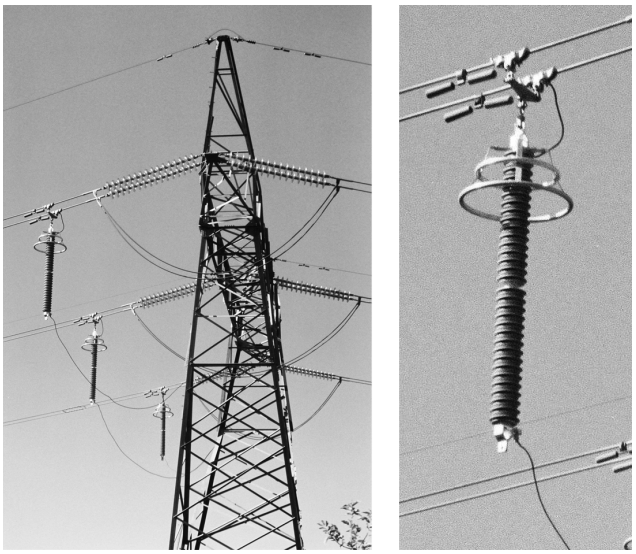

Figure A3.2-8 275-kV transmission-line surge arresters (Courtesy Eskom and ABB).

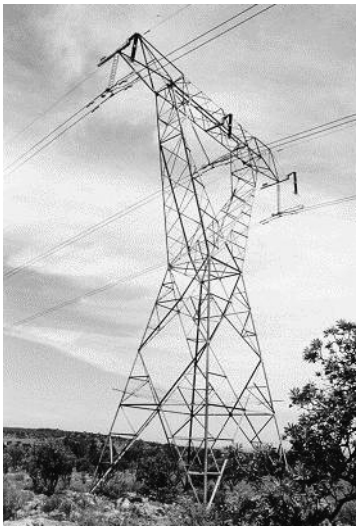

Figure 3.2-9 275-kV gapless arresters on an Eskom line (Courtesy Eskom and NGK).

Table A3.2-1 Common Applications of TLAs

Topic	Usage and Application Considerations
Handling	TLAs are typically more delicate than other equipment used on transmission lines and require special handling (storage, tools, torque requirements, etc.).
Installation	TLAs may be installed phase-to-ground, either in parallel with the line insulators or built into the insulators
Double-circuit lines	TLAs have been applied on single circuits of a double-circuit line in order to reduce double-circuit interruptions due to lightning.
Unshielded lines	TLAs have been used in areas of moderate ground flash densities on unshielded lines on the topmost phase, effectively transforming the phase into a shield wire to protect the other phases. This approach to lightning protection could be cost-effective in areas where the following conditions exist: • Difficult grounding, with resistivity in excess of 1000 Ω-m • Relatively low ground flash density • Relatively high incidence of icing or (ice + wind) loading • Areas of environmental sensitivity where line height is an issue
Vertical phase configurations	Since for vertical phase configurations the lowest phase would experience the lowest coupled voltage and the highest insulator voltage stress, for strokes on the shield wire, some apply TLAs on the bottom phases only. This would improve the performance against backflashovers of shielded vertical configurations. In such configurations, TLAs can effectively create another grounded conductor and hence improve the coupling to the remaining phases, which reduces the probability of a backflash on the phases without TLAs.
Poor grounding	TLAs may be installed on just the sections of line that have poor grounding due to soil conditions, or that have exceptional exposure to lightning strokes (e.g., river crossings, lakes). However, care is required in applying TLAs in such a fashion, or protecting adjacent segments with good ground impedance may be problematic. See discussion later.
Protective levels of TLAs vs. line CFO	The protective level of TLAs should be below the CFO of the line insulators. The selection of energy requirements depends on the application and whether the line is shielded or not. If a lightning stroke terminates on the overhead shield wire, most of the lightning current will discharge through the tower footing, with relatively little current flowing through the TLA. Hence, for a well-shielded line, the energy duty on the line arresters can be reduced compared to nonshielded lines. Even in the event of a shielding failure (i.e., some lightning strokes terminating directly on a phase conductor), for low-current magnitudes (5 to 20 kA), the TLA energy duty is still relatively low. Therefore line arresters may be applied to shielded lines to improve the backflashover performance with little concern for energy duty on the arresters. Protection with line arresters of unshielded lines often requires station class arrester types, as these lines have a higher probability of being subjected to direct strokes. TLAs in all phases on each tower eliminate the need for both shield wires as well as good footing resistance. In areas with moderate ground flash densities, one arrester in the top phase may be used instead of shield wires.
Protective level of TLA vs. substation arresters	The protective level of TLAs should be greater than the protective levels of the adjacent substation arresters to reduce the energy absorbed by the line arresters due to switching surges. Hence TLAs should have slightly higher MCOV than arresters applied in the substation.
Benefits to substation protection	Placing TLAs on the towers closest to a substation results in a reduction of steepness and amplitude of incoming surges to the substation. This dramatically improves the protection of the substation against backflashovers.
Reduced insulation levels	TLAs may be used to protect transmission line structures, or spans, with reduced insulation levels.
Open points	TLAs may be used on certain open points on the system exposed to voltage surge doubling.
Switching overvoltage control	For switching overvoltage control, line arresters are usually installed in all phases. Protection against switching typically requires one energy class lower for TLAs, than what is used for arresters installed at the substations. TLA can be used instead of closing resistors on circuit breakers. They can either replace, or supplement, controlled switching (see needs to be looked at carefully for compensated lines). For switching overvoltage control, TLAs are usually installed in all phases. The number of TLAs needed is dependent on the length of the line. For shorter lines, it may be sufficient to have TLAs at both line ends. For longer lines, studies need to be conducted to determine how many are needed. (Experience has shown that TLAs close to the middle or at one-third plus two-thirds of the line length have resulted in noticeable improvement over no TLAs.) The lower the protection level of the surge arrester, the lower are the overvoltages. However, the temporary overvoltage capability of the arrester is lower for a reduced protection level, and the energy to be absorbed is higher.
Reduction of insulation	TLAs can be used to intentionally reduce the insulation on certain structures, resulting in increased clearances to ground along the span. This is a recommended use.
Upgrading	Upgrading or compacting new lines may need TLAs in every tower for one or all phases, depending on the system requirements.

the tower ground resistance, with less sharing at lower resistance.

Application of TLAs on segments of the line with high grounding resistance: If there are differences in the ground resistance between different towers (for example, a struck tower having a TLA while the adjacent towers have a lower resistance and no TLA), it can be shown that the insulation stress will transfer to the adjacent tower that has no TLA. Hence it is recommended that, if TLAs are to be used only on a section of line with poor grounds, they should also be applied on at least the next one or two towers with good grounds. The above illustrates that lower ground resistance does not always improve the lightning performance of an overhead line with arresters.

Special Considerations Related to Standards and Specifications for TLAs

TLAs are not specifically addressed in IEEE Standard C62.11-1999 (IEEE 1999b), although the arresters used in these applications are part of the standard. Most of the test requirements that apply to line arresters are based on station-class requirements. When specifying line arresters, it should be noted that the following points are inherent to C62.11-1999.

1. Lightning energy-handling capability can be a major factor in selecting line arresters. The requirement of lightning-related energy is typically much more significant for lines than stations. Although present standards do contain some lightning-related tests, there is not presently an accepted test to quantify the lightning energy handling capability of surge arresters. The published energy-handling capability of arresters is typically based on switching-related tests.
2. Short-circuit tests permit polymer arresters to fall apart as long as the pieces fall within specific areas. The tests allow 2 minutes before the arrester must self-extinguish. These allowances in the present standards may not be acceptable for certain areas on a line right-of-way.

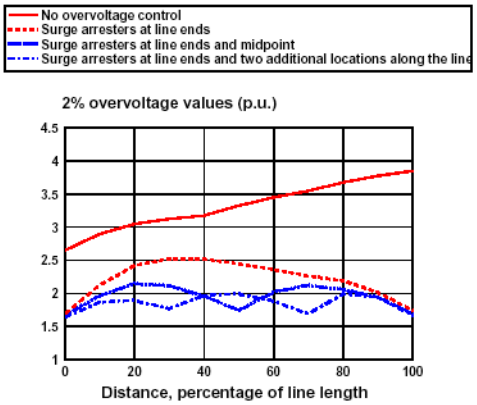

Figure A3.2-10 2% overvoltage values, line to ground, for 100-km line with different measures to control switching surge overvoltages (Stenström and Mobedjina 1998).

Analytical Requirements for TLA Applications

Most line arrester applications for lightning protection should be preceded by computer simulations to assess:

1. Which sections of the line should be protected by TLAs
2. Lines containing major differences in resistance and grounding methods
3. Only certain phases (typically top) being protected
4. Multiple circuits on the same tower

The following are some recommendations for performing a TLA application for lightning studies:

1. **Number of towers:** Start with at least 10 to 20 spans.
2. **Time Step Selection:**
   - For energy calculation, time steps can be as long as one-half span travel time (approximately 1 μ s for every 300 m), time steps of 0.25-0.5 μs have been used.
   - Shorter time steps must be used for the flashover calculation.
3. **Run Time:**
   - Typically several hundred μ s for arrester energy discharge calculations
   - 25-75 μ s for flashover calculations.
4. **Line model:** Start with a constant distributed parameter model. Add frequency dependence and corona to the final runs for more accurate answers.
5. **Current Levels:** Many currents must be run to determine a critical current level for both flashovers and arrester energy duty. These results may be used with stroke current probability distributions and ground flash density to obtain flashover and arrester failure rates.

Use of Line Arresters to Reduce Line Flashover Frequencies for Power Quality Considerations

Recent industry experience has shown that transmission-line surge arresters are reliable and effective as designed at voltage levels of 115 kV and 138 kV. Programs have been initiated to apply TLAs on 230-kV lines with both shielded and unshielded conditions. The effectiveness of arrester application is generally being monitored by comparing the number of "challenges" (nearby ground stroke terminations) before and after treatment. One interesting development at some utilities is the execution of performance improvement contracts with key customers, who fund the purchase and installation of transmission-line surge arresters in order to obtain premium power quality.

Arresters can be applied to unshielded lines as a substitute for overhead shield wires—advantages being that shield wire losses are eliminated, line compaction is improved, and the maximum expected turning moment of support structures (and consequently cost) is reduced. For this application, arresters must absorb energies from the complete spectrum of lightning flashes to the line, with a substantially higher risk of failure than the same arresters on lines with shield wires to attract and divert most of the stroke currents to ground.

Software for Selecting Arrester Locations

For cases where the span lengths and footing impedances are known, a number of modeling tools can be applied to analyze the effectiveness and reliability of transmission-line surge arrester applications. EPRI's TFlash, and the Electromagnetic Transients Program (EMTP) have been used by a number of researchers (Tarasiewicz et al. 2000; Lambert 1988; Zanetta 2002).

Summary

The modern surge arrester is a metal-oxide surge arrester (MOSA), which has largely replaced the older silicon-carbide arrester that was widely used. The arrester discharge voltage for a given surge-current magnitude is directly proportional to the height of the valve element stack, and is a function of the rate of rise of the current surge, with higher voltages occurring for faster rates of rise and vice-versa. Line arresters may be installed phase-to-ground, either in parallel with the line insulators or built into the insulators. While transmission-line arresters were initially envisioned for control of lightning overvoltages, they can (and have) also be used for the control of switching surge and temporary overvoltages. The energy requirements for TLA applications vary based on applications.

Recent industry experience has shown that transmission-line surge arresters are reliable and effective as designed. TLA applications are available for all HV and EHV systems up to and including 800 kV. Application of TLA opens up the possibilities for compacting lines and upgrading of existing lines.

TLAs offer a robust, efficient, and cost-effective alternative for minimizing/eliminating outages due to lightning surges and for limitation of switching surges along transmission lines.

APPENDIX 3.3 INSULATION COORDINATION METHODOLOGIES

Introduction

As previously described, line insulation coordination includes the selection of phase-to-ground and phase-to-phase clearances, tower strike distances, tower footing resistance, insulator lengths, and the leakage or creepage distance of insulators. Any overvoltage countermeasures, such as surge arresters and breaker-closing resisters, must also be selected if required. The lowest values of the withstand voltages of the insulation must meet desired line performance criteria when subjected to service conditions.

Two approaches to insulation coordination for transient overvoltages are in use today: a deterministic method and a probabilistic or statistical method. Many commonly-used procedures, however, are a mixture of both methods. Both are discussed extensively in the reference literature (EPRI 1982; IEC 1996; IEEE 1999a; Greenwood 1991). Obviously the universal availability of computers and software such as the applets in this Reference Book allows designers to use sophisticated probabilistic techniques as easily as the simpler deterministic methods, providing that appropriate stress and strength data are available. It is also recognized that many utilities simply continue to use old proven designs rather than risk potential savings against problems with new optimized designs, unfamiliarity of workers with new configurations for construction and maintenance, and requirements for new families of spare parts.

The principles described here are applicable to all three types of voltage stress and insulation strength—namely, lightning, switching surges, and power frequency voltage.

Deterministic Method

The deterministic method assumes that there is a known maximum overvoltage, V_{max}, which may stress the insulation, a known minimum insulation withstand voltage V_W, and that these occur simultaneously. Insulation is designed so that V_W is larger than V_{max} by a safety margin, as shown in Figure A3.3-1 (EPRI 1982). This safety factor covers only the uncertainties involved in the designer's evaluation of V_{max} and V_W. The safety factor should not be confused with

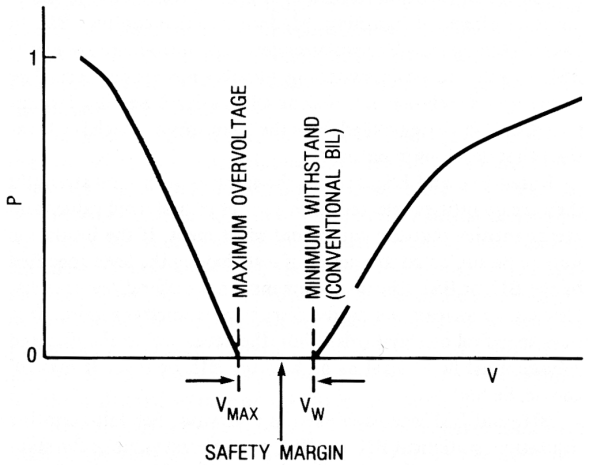

Figure A3.3-1 Illustration of deterministic method for insulation design (EPRI 1982).

the protective ratio, which is used in connection with internal insulation that is protected by an external surge arrester (Greenwood 1991).

Transmission lines designed in the past using the deterministic method characteristically have very conservative clearances and strike distances. Designs based on such an approach can be more expensive than those obtained from modern probabilistic methods. Today the deterministic method is usually applied when no statistical information on stress or strength is available, especially for coordination and design of non-self-restoring insulation.

Probabilistic (Statistical) Method

In actuality, both the stress (overvoltage) and the strength (insulation withstand) exhibit probabilistic behavior. The potential benefit of a probabilistic approach is that the combination of maximum overvoltage and minimum insulation strength rarely occurs. Therefore considerable economy may be achieved for self-restoring insulation by modeling the probabilistic nature of both the voltage stress and the insulation strength. This approach nearly always results in a substantial decrease in line insulation, tower dimensions, weight, width of right-of-way, and cost. That decreased cost must then be weighed against the increased risk of failure and the costs of such failures.

The probabilistic method is applied by modeling and combining the probability distributions of the overvoltages and the insulation strength. By repeating the calculations for different types of insulation and for different states of the network, the total outage rate of the system due to the insulation failures can be estimated. The application of probabilistic insulation coordination makes it possible to estimate the failure frequency directly as a function of the selected system design factors. In theory, optimization of the insulation could be possible, if outage costs could be related to the different types of faults. In practice, it is very difficult to evaluate the consequences of insulation faults in different operation states of the network and the uncertainty of the cost of the undelivered energy. Hence it is usually better to slightly overdimension the insulation system rather than optimize it. The design of the insulation system is then based on the comparison of the risks corresponding to the different alternative designs. Detailed computation is discussed below.

Virtually all probabilistic calculation methods embody a nonzero risk of failure. This results from the inability of statistical models to precisely represent insulation strength or insulation stresses. As an example, the typical statistical model for air gap behavior gives a flashover rate that is never zero, even for very small voltages. Designers recognize that in designing for nonzero levels of failure, limitations in modeling techniques result in conservatism in the designs. As will be described later, even designs with a relatively high 10% failure rate for switching surges have never in practice flashed over.

Statistical Properties of Withstand Voltage of System Components (EPRI 1982)

The withstand voltage of system components can be defined in statistical terms. Suppose that a number, *n,* of tests is performed with each of the voltages V_{T1}, V_{T2}, V_{T3} ...., V_{Tr}. The relative frequencies of failure, v_k/n, where v_k denotes the number of failures at the voltage V_{Tk} (k = 1,…, *r*), would then represent the estimates of probabilities of failure for the voltages V_{T1}, V_{T2},...., V_{Tk}. The graph expressing the dependence of the failure probability estimate, $p = v_k/n$ on V_{Tk}, would approach a curve continuously increasing from 0 to 1. At small voltages, there would be no failures, and at high voltages, all tests would lead to failure. This function, denoted $F(V_T)$, represents a probability that at a given instance the withstand voltage would be smaller than the applied voltage (i.e., the probability of disruptive discharge). This function is a cumulative distribution function,

$$F\left(V_T\right) = P\left\{V_W < V_T\right\} \qquad \text{A3.3-1}$$

and its derivative,

$$f\left(V_T\right) = \frac{d}{dV_T} F\left(V_T\right) \qquad \text{A3.3-2}$$

is the corresponding density function (see Figure A3.3-2).

For high-voltage gaps, this function is well approximated by the normal distribution (Gaussian) function:

$$F\left(V_T\right) = \frac{1}{\sigma\sqrt{s\pi}} \int_{-\infty}^{V_T} \exp - \frac{1}{2\sigma^2}\left(t-\mu\right)^2 dt = \Phi\left(\frac{V_T-\mu}{\sigma}\right) \qquad \text{A3.3-3}$$

where:

$$\Phi\left(u\right) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{u} \exp\left(-\frac{z^2}{2}\right) dz \qquad \text{A3.3-4}$$

with:

$$z = \frac{V_T-\mu}{\sigma} \qquad \text{A3.3-5}$$

The function $\Phi(u)$ is given in tables. The constant μ is the mean value or median of the withstand voltage, and for lightning is called the critical flashover voltage (CFO). CFO is the crest value of the impulse that under specific conditions causes flashover of the insulation on 50% of the applications.

The voltage withstand strength is quite often expressed in terms of basic insulation levels, BIL and BSL. BIL, an abbreviation of basic insulation level, was originally related to the short-duration effects of lightning. Modern practice confines BIL to basic lightning impulse insulation level, and introduces the newer BSL to refer to basic switching impulse insulation level. Rated BIL and BSL are not the same as withstand strength; they are quantities that the equipment must meet, selected from a series of preferred values. If the insulation were to be subjected to a series of tests having the level specified by the BIL or BSL, the insulation must not suffer disruptive discharges, or at least not suffer disruptive discharges more often than specified by standards. Thus the actual value of withstand voltage must be at least as high as the BIL or BSL. It may, of course, be higher.

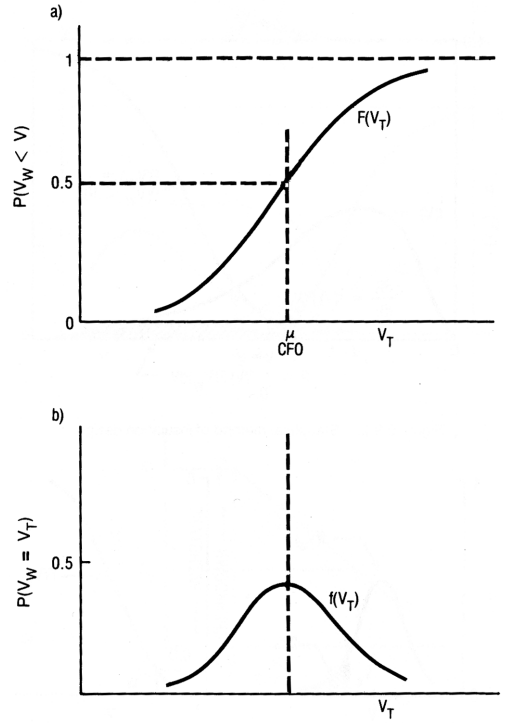

Figure A3.3-2 Probability functions: (a) cumulative distribution; and (b) density-derivative (EPRI 1982).

BIL and BSL are each used in two ways. For self-restoring insulation, statistical BIL (or BSL) is the crest value of the standard impulse for which the insulation exhibits 90% probability of withstand (or 10% probability of failure). On the other hand, conventional BIL (or BSL) used for non-self-restoring insulation is a value for which the insulation shall not exhibit disruptive discharge when subjected to a specific number of impulses. A summary of the recommended voltage-withstand characteristics is shown in Table A3.3-1. Table A3.3-2, from IEEE Std 1313-1993 (IEEE

1993), shows the preferred values of BIL and BSL for equipment. The recommended values apply both to statistical and conventional quantities. The BIL shall be chosen from the list in Table A3.3-2, and the associated BSL, as determined by the relationship, may differ from the values in the list.

Probability of Overvoltage Occurrence

The magnitudes of the overvoltages occurring in the system are also statistical in nature. This section clarifies some of the statistical concepts used in describing overvoltages. To illustrate the practical meaning, consider the example of overvoltages when energizing a line with a transformer from a given system (see Figure A3.3-3[a]). The three phases of the line are energized by a breaker, whose poles are not mechanically linked. When a command to close is given, generally by energizing the closing solenoids, the three poles begin to close independently. The timing of the closing impulse is usually random with respect to the timing of the supply-side power frequency voltage (see Figure A3.3-3[d]). The actual closing occurs after the solenoids are energized, and the actual closing times of the breaker poles—t_A, t_B, and t_C—display some statistical variations from operation to operation. Moreover, even the mean values of those times may be different, depending on the manufacture and adjustment of breakers in the field. It cannot be predicted exactly when the breaker poles will actually close and energize the circuit. There are other random variables—such as prestrike in the breaker, or functions of the circuit depending on the past history of the circuit (e.g., trapped flux in the transformer or charge on the line). All of these influence the overvoltages that are developed as the breaker closes.

Of interest are the observed overvoltages at the end of the line, V_A, V_B, and V_C. These voltages may be treated as an outcome of a statistical experiment, although the voltages in the three phases are not really independent variables. For simplicity, consider as an example voltages V_a of phase A as they would be measured in $n = 300$ tests. Instead of recording the voltages according to the sequence in which they were measured, they may be tabulated in order of their amplitudes. The table could be simplified by selecting some voltage interval and showing the number, v, of voltages that occurred in the interval $V < V_a < V + \Delta V$. This could be plotted in the form of a bar chart, such as in Figure A3.3-4, in which the vertical axis gives the number, v, of overvoltages in each voltage interval, ΔV, in relation to the total number of tests, n. It is noted that the ratio of v/n may be used as an estimate of the probability that the overvoltage will be in the given interval, ΔV, that is:

$$p\{V < V_a < V + DV\} = \frac{v}{n} \qquad \text{A3.3-6}$$

Of course, the higher the number of tests, n, the closer that estimate P would be to the true probability, which by definition is:

$$P\{V < V_a < V + DV\} = \lim_{n \to \infty} \frac{v}{n} \qquad \text{A3.3-7}$$

With n sufficiently high, ΔV approaches dV, and the histogram of Figure A3.3-4 approaches the continuous distribution function shown in Figure A3.3-5(a).

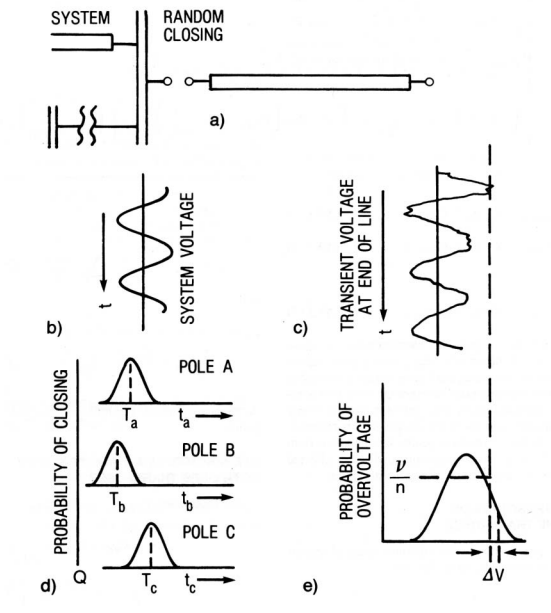

Figure A3.3-3 Statistical overvoltages: (a) circuit; (b) voltage on bus; (c) voltage at end of line; (d) probability of pole closing times; and (e) probability of indicated overvoltages (EPRI 1982).

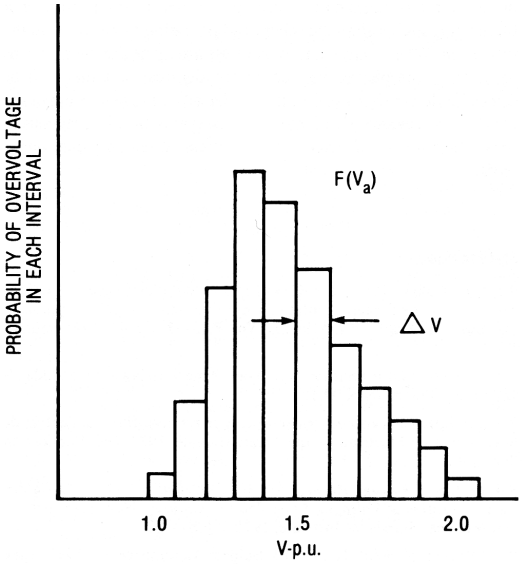

Figure A3.3-4 Histogram of overvoltage.

The cumulative distribution function is commonly defined by mathematical statistics as the function that gives the probability that the random variable V_a will be smaller than the value of interest, V. In this case, the cumulative distribution function (disregarding the polarity of the voltage) would be:

$$F(V_a) = P\{V_a < V\} = \sum_{v=0}^{n} \frac{v}{n} \quad \text{A3.3-8}$$

as shown in Figure A3.3-5(b), or:

$$F(V_a) = P\{V_a < V\}' = \int_0^v f(V_a)dV \quad \text{A3.3-9}$$

As far as insulation is concerned, it is really more appropriate to know the probability of a given voltage being exceeded. If the insulation were able to withstand exactly the specified or a lower voltage, that probability would also give the probability of failure. Such a probability function complementary to the cumulative distribution is:

$$P\{V_a > V\} = Q(V_a) - 1 - F(V_a) \quad \text{A3.3-10}$$

where:

$$Q(V_a) = V\int_V^{\infty} f(V_a)dV \quad \text{A3.3-11}$$

which is a monotonically decreasing function in the interval $Q(V_a)$ between 0 and 1.

A Monte Carlo procedure can be performed to obtain the probability distribution of switching overvoltages. From the repetitive simulation, a histogram of switching overvoltages and a cumulative probability curve are obtained. An example is shown in Figure A3.3-6. If the overvoltages were characterized by a purely Gaussian distribution, the plot would be a straight line, giving a definite, though perhaps small, probability of very large overvoltages, and giving a definite, though perhaps small, probability that some of the overvoltages would have amplitudes less than the crest value of the system voltage. Overvoltages are, by definition, greater than the supply voltage. Furthermore, there are fundamental limits to the maximum overvoltage that may be obtained, limits in addition to the fact that the extreme overvoltages may be limited by surge arrestors, corona, saturation, or other physical effects. Because the distribution may be only approximately Gaussian, and is in

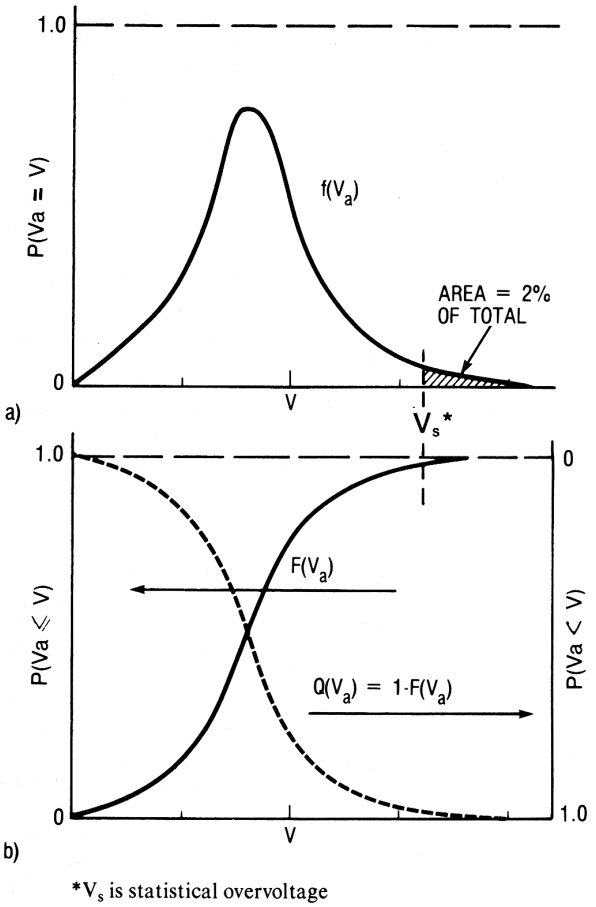

Figure A3.3-5 Probability of overvoltage: (a) overvoltage density $f(V_a)$; and (b) cumulative function $F(V_a)$.

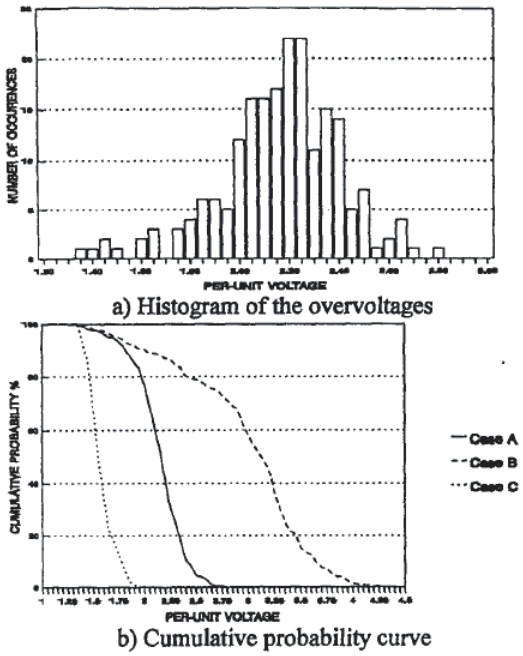

Figure A3.3-6 Cumulative probability of switching overvoltage (Martinez et al. 2000)

any event likely to be truncated at its upper and lower extremes, it is perhaps unwise to place much reliance on any calculated value of deviation as a measure to estimate the probability of occurrence of extreme overvoltages. If an analytic approximation to the measured distribution is needed, it is probably best to fit a straight line (or lines) to the curve. A straight-line approximation of the upper end of the distribution is generally possible, and it is usually only the upper end that is of importance.

The measured distribution, since it is from a limited number of tests, is only an approximation of the actual distribution. Truax et al. (Truax et al. 1978) give some quantitative data on how the number of experiments affects the maximum estimated overvoltages. In the case of TNA studies, it is quite common practice to base the output data on 300 switching operations.

The preceding explanations define only the basic terms. It should be noted that these terms may deserve further study, depending on how the data are used. For example, an explanation was given for voltages in one phase. Overvoltages in different phases could be treated separately (insulators in each phase are stressed only by the overvoltage in that phase) or in some relationship. One common practice is to rank the overvoltages without regard to the phase in which they occur. (If there is a flashover, it is not really of importance on which phase it occurs or whether it occurs simultaneously on more than one phase.) Figure A3.3-7 presents an example of how the final distribution may differ depending on the method of evaluation. The curves *A, B*, and *C*, give the distributions separately for 300 points measured in each specific phase *A, B*, and *C*, during 300 operations. Curve D represents the distribution of all 1900 measurements in all three phases during the 300 operations. Even though the overvoltages in the three phases are not really independent, it may be seen that the likelihood of closing angles, α, β, and γ, may be the same for any sequence of phases. This may be justified by considering not the distribution for one specifically adjusted breaker but the probability of the adjustments of any breaker in the field.

This statistical treatment is open to further refinement, depending on how the data are to be used. For example, most of the treatments have been single-phase analyses. Commonly, when a statistical analysis of overvoltages is made, the highest voltage on any of the three phases is selected. The statistical ranking of voltages from a number of tests is then made using only that highest voltage. This analysis implies that each of the phases is equally likely to flash over. Actually, for any particular operation of the breakers, the voltages on the three phases will be different, one of them being higher than the others and providing more stress on the insulation. When a large number of tests are made, the distributions for each of the phases may be nearly identical, but they will be somewhat lower than the distribution based on the maximum of the three phases as shown in Figure A3.3-7. It may be advantageous to make the analyses of strength versus stress on an individual-phase basis.

Combining Stress and Strength

The probabilistic method of insulation coordination is based on matching the probabilities of insulation stress and strength, as discussed above. The criterion is the acceptable risk of failure. The risk of failure may be calculated as shown in Figure A3.3-8. The probability of insulation breakdown is given by the function $F(V_W)$. The probability distribution or density of the overvoltage is given by the function of $f(V_a)$. The probability that the overvoltage V_1, will occur is $f(V_1)$. The probability that the insulation will fail at the voltage V_1 is $F(V_1)$. Hence the probability of both experiencing the overvoltage V_1 and not being able to withstand it indicates the probability of failure at that voltage as

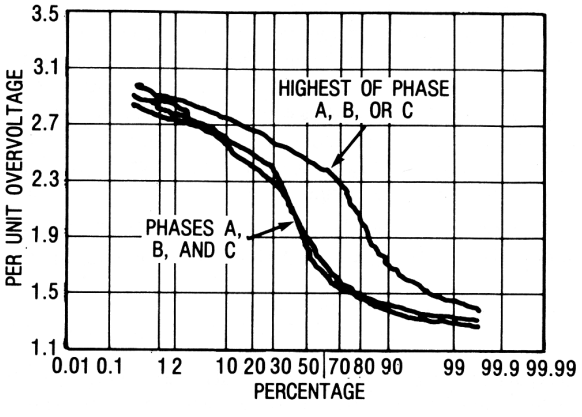

Figure A3.3-7 Distribution on a phase-by-phase basis (based on 300 breaker operations).

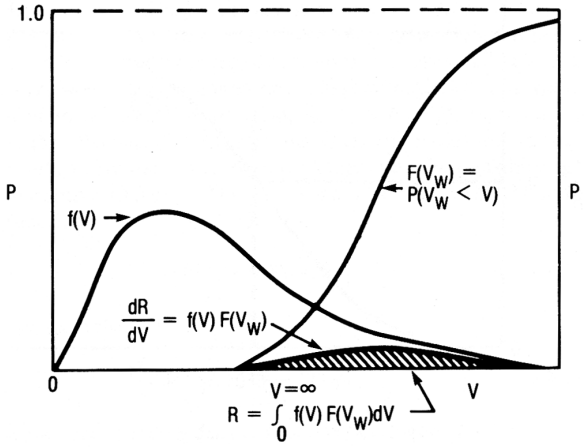

Figure A3.3-8 Statistical method of insulation coordination (EPRI 1982).

$f(V_1)$ x $F(V_1)$. The risk of failure R of the insulation, as shown by the shaded area in Figure A3.3-8, is the sum of all the preceding probabilities for all the possible voltages.

$$R = \int_0^\infty F(V) f(V) dV \qquad \text{A3.3-12}$$

The preceding explanation lays the groundwork for economic considerations, but it is rather elementary, principally because the functions that describe the probability of breakdown and the probability of overvoltage occurrence depend on many factors. There is no assurance that either function can be expressed in any analytical form. Computer techniques are needed to calculate the risk of failure and to optimize the line design.

If the actual distributions of overvoltage and withstand are not known, an approximation of the risk may be obtained by the simplified statistical method. This method is based on the premise that the actual shape of the low-voltage end of the overvoltage distribution is not too important, because those low overvoltages will not cause failure. Likewise, there is little need to keep accurate track of how likely it is that the insulation strength is greater than normal. Accordingly, the actual distributions are replaced by simple distributions, generally Gaussian, that may be characterized by the standard deviation σ and one measured point. The overvoltage distribution is characterized by the term "statistical overvoltage," V_S, this being the overvoltage at the 2% point. The distribution of withstand voltages is described by V_W, the statistical withstand voltage measured at the 90% withstand, or 10% breakdown, point. These points are illustrated in Figure A3.3-9. The ratio of the two values defines the quantity γ, the statistical safety factor, which is analogous to the conventional safety factor:

$$\gamma = \frac{V_W}{V_S} \qquad \text{A3.3-13}$$

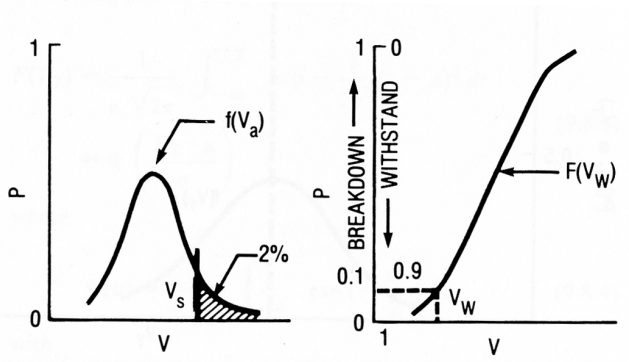

Figure A3.3-9 Reference probabilities: (a) probability of system overvoltage; and (b) probability of withstand voltage (EPRI 1982).

If V_S and V_W are known, and the rest of the distribution is assumed, it is possible to evaluate the risk and to plot a curve relating the statistical safety factor and the risk. The procedure is illustrated in Figure A3.3-10.

The actual numerical value of the risk depends on the shape assumed for the distributions. This shape may be described in terms of the standard deviations of the two curves. Although the standard deviation may not be known from test, it may sometimes be estimated from experience on similar tests. The curve relating statistical safety factor and risk, Figure A3.3-10(c), is valid only for the particular set of standard deviations assumed.

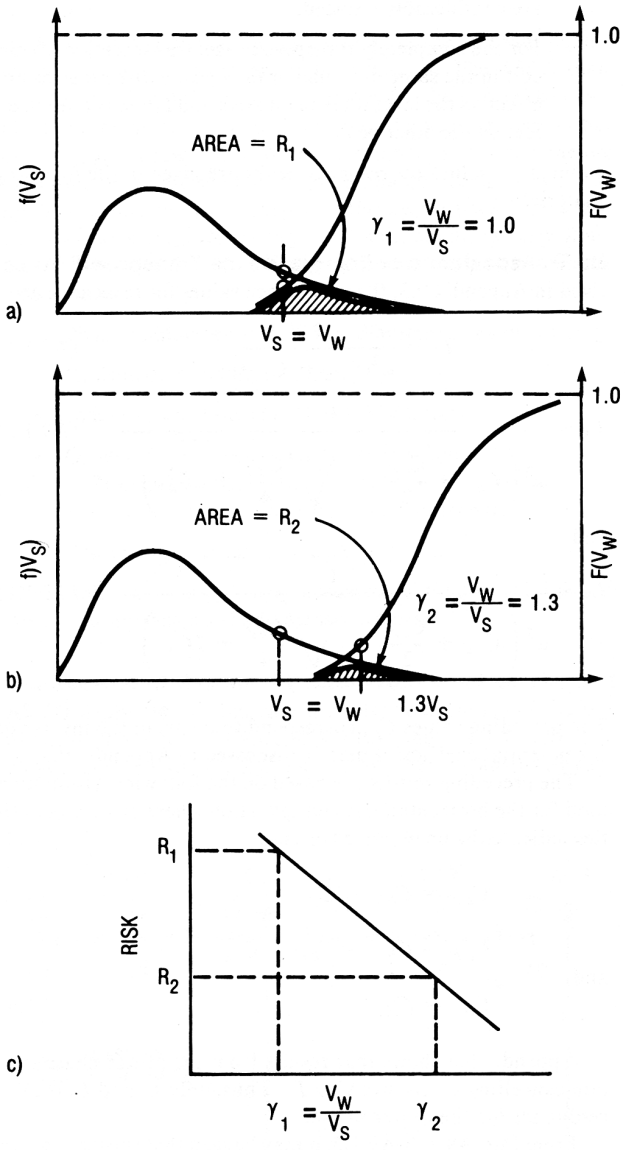

Figure A3.3-10 Simplified statistical method: (a) small statistical safety factor; (b) large statistical safety factor; and (c) risk versus safety factor (EPRI 1982).

Figure A3.3-11 shows one set of relationships between risk and statistical safety factor. The figure, for switching surges, assumes a standard deviation of 6% for the withstand voltage and various standard deviations for the stress. The effect of truncating the distributions of stress is also shown. Figure A3.3-12 shows a similar correlation for lightning surges.

It should be noted that the discussion above gives a general description of the line insulation coordination procedure. Detailed implementation should consider the characteristics of system overvoltages, system components, and environment factors, especially for operating voltages and temporary overvoltages, switching overvoltages, and lightning overvoltages. Comprehensive coverage of this can be found from references (IEC 1996; IEEE 1999a; IEEE 1997a; IEEE 1999a; Hileman 1999).

Summary

As previously described in the main body of this chapter, line insulation coordination includes the selection of phase-to-ground and phase-to-phase clearances, tower strike distances, tower footing resistance, insulator lengths, and the leakage or creepage distance of insulators. Two approaches to insulation coordination for overvoltages are in use today:

1. Deterministic method
2. Probabilistic (or statistical) method

The probabilistic method is applied by modeling and combining the probability distributions of the overvoltages and the insulation strength. The application of probabilistic insulation coordination makes it possible to estimate the failure frequency directly as a function of the selected system design factors.

Today, the universal availability of powerful computers and software (such as the applets in this Reference Book) allows designers to use sophisticated probabilistic techniques as easily as the simpler deterministic methods that were used in the past, providing that appropriate stress and strength data are available. Yet probabilistic techniques are not used across the board above 200 kV, due to the fact that many utilities continue to use old "proven designs," which are based on deterministic approaches because sufficient probability distributions are not known or are of dubious accuracy.

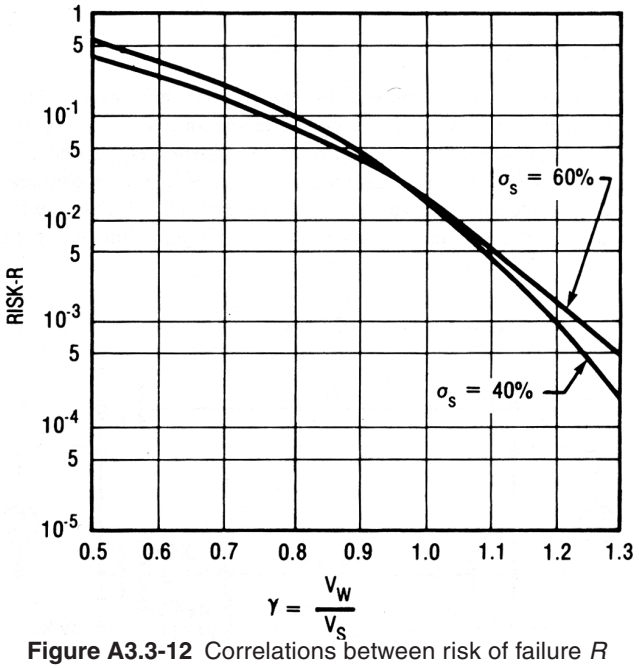

Figure A3.3-12 Correlations between risk of failure *R* and statistical safety factor γ for various lightning surge distributions (IEEE 1976).

APPENDIX 3.4 APPLICATION OF INSULATION COORDINATION ACCORDING TO IEC 71-2 INSULATION COORDINATION APPLICATION GUIDE

Introduction

This section is extracted from IEC 71-2 (Copyright © 1996, Geneva, Switzerland. www.iec.ch.), Insulation Coordination Application Guide, with minimum changes. It is intended to give the reader a roadmap to follow in the line insulation coordination procedures according to the IEC.

According to IEC 71-2, transmission-line insulation coordination follows to a great extent the same procedure used for other equipment, which is described more fully in IEC 71-1 (IEC 1993). Line insulation coordination is a simplified version (it stops at step 3 of 5 steps) of the general procedure (due to the self-restoring characteristics of line insulation). Hence the line insulation coordination follows the following steps.

Table A3.4-1 General Procedure for Insulation Coordination per IEC-71-1

General Procedure per IEC-71-1	Applicable Overhead Transmission Line
Step 1: Determination of the representative overvoltages (Urp)	**Yes**
Step 2: Determination of the coordination withstand voltages (Ucw)	Yes
Step 3: Determination of the required withstand voltages (Urw)	Yes
Step 4: Determination of the standard withstand voltages (Uw)	No
Step 5: Selection of standard insulation levels	No

IEC 71-2 provides the following guidelines for transmission-line insulation coordination:

- The operating voltage and the temporary overvoltages determine the required insulator string length and the shape of the insulator unit for the pollution site severity.
- In directly grounded neutral systems with ground fault factors of 1.3 and below, it is usually sufficient to design the insulators to withstand the highest phase-to-ground system voltage.
- For higher ground-fault factors, and especially in isolated or resonant grounded neutral systems, consideration of the temporary overvoltages may be necessary.
- Where consideration must be given to free-swinging insulators, the clearances should be determined under extreme swing conditions.
- An insulation failure due to ground-fault overvoltages causes a double phase-to-ground fault.
- Ground-fault overvoltages should be taken into account in systems with high ground-fault factors—i.e. for transmission lines in resonant grounded-neutral systems.
- As a guide, acceptable failure rates between 0.1 and 1.0 flashovers/year are typical.
- Special considerations are necessary for lines where energization and re-energization overvoltages are normally controlled to low amplitudes, since in this case the slow-front overvoltage generated by ground faults may be more severe.
- An insulation failure due to re-energization overvoltages causes an unsuccessful reclosure.
- As a guide, suitable acceptable failure rates for energization are on the order of 0.005–0.05 flashovers/year.
- Re-energization overvoltages require attention for transmission lines when fast three-phase reclosing is applied, because of trapped charges. Acceptable failure rates of 0.005–0.05 flashovers/year may be suitable.
- Re-energization overvoltages can be disregarded when single-phase reclosing is used on transmission lines.
- Slow-front overvoltages are among the factors determining the air clearances and, for some types of insulators, the insulator fittings. Usually their importance is restricted to transmission lines in the higher system voltage range of 123 kV and above. Where free-swinging insulators are applied, air clearances for slow-front overvoltages are generally determined assuming moderate (mean) swing conditions.

The IEC procedure is outlined in Figure A3.4-1. This is extracted from Figure 1 of IEC 71-1.

Insulation Coordination for Power-Frequency and Temporary Overvoltages

The coordination withstand voltage for the continuous (power-frequency) voltage is equal to the highest phase-to-phase system voltage, and this voltage divided by the square root of 3 for phase-to-earth insulations.

For coordination using the deterministic method, the short-duration withstand voltage is equal to the representative temporary overvoltage. When a statistical procedure is adopted, and the representative temporary overvoltage is given by an amplitude/duration distribution frequency characteristic, the insulation that meets the performance criterion is determined, and the amplitude of the coordination withstand voltage is equal to that corresponding to the duration of 1 min on the amplitude/duration withstand characteristic of the insulation.

When contamination is present, the response of external insulation to power-frequency voltages becomes important,

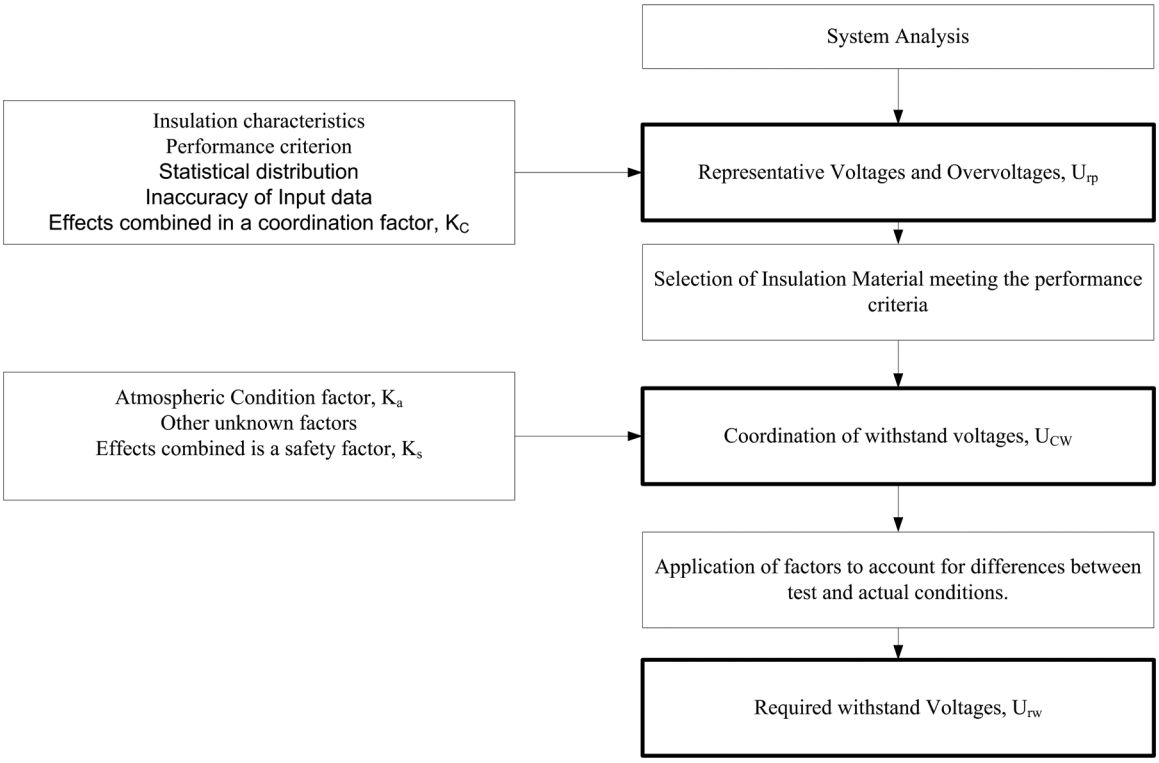

Figure A3.4-1 Insulation coordination procedure according to IEC 71-1. (Copyright © 1993, Geneva, Switzerland. www.iec.ch.)

and may dictate external insulation design. Flashover of insulation generally occurs when the surface is contaminated and becomes wet due to light rain, snow, dew, or fog without a significant washing effect.

Insulation Coordination for Slow-Front Overvoltages

Deterministic Method

The deterministic method involves determining the maximum voltage stressing the equipment and then choosing the minimum dielectric strength of this equipment with a margin that covers the uncertainties inherent in the determination of these values. The coordination withstand voltage is obtained by multiplying the assumed maximum value of the corresponding representative overvoltage by a safety factor called the deterministic coordination factor.

Statistical Method for Slow-Front Overvoltages

The statistical method for slow-front overvoltage is the same as discussed above. Slow-front overvoltages of interest for overhead lines are phase-ground fault overvoltages and energization and re-energization overvoltages.

Insulation Coordination for Fast-Front Overvoltages

Deterministic Method

For fast-front lightning overvoltages, a deterministic safety factor of 1 is applied to the assumed maximum value of the overvoltages. This is because, for lightning, the representative overvoltage includes probability effects. For fast-front switching overvoltages, the same relationships apply as for slow-front overvoltages.

Statistical Method

The statistical method recommended in this guide is based on the probability distribution of the representative lightning overvoltages. For internal insulation, the assumed withstand voltage has a withstand probability of 100%. The withstand probability at higher voltages is assumed to be zero. This means that the coordination withstand voltage is equal to the representative lightning overvoltage amplitude at a return rate equal to the adopted acceptable failure rate.

For external insulation, the conventional deviation of the discharge probability is usually small as compared to the dispersion of overvoltages. As a simplification, it can be neglected, and the same formula as for the internal insulation applied.

Insulation Coordination Example for a System with Nominal Voltage of 735 kV (Phase-Ground Only)

The general procedure is illustrated with an example, also extracted from IEC 71-2, for a system with a nominal voltage of 735 kV. In matching the voltage stresses with the electric strength, it is necessary to take into account the various types of voltage stresses and the corresponding response of the insulation. This involves making a distinc-

tion between self-restoring (external) insulation and non-self-restoring (internal) insulation. For non-self-restoring insulation, the stress-strength coordination is made using deterministic methodology, whereas for self-restoring insulation (e.g., transmission-line insulation), a statistical methodology can be used where this is convenient. For illustration purposes, the following example attempts to present all considerations about external insulation. The reader can refer to IEC 71-2 for details about internal insulation. The insulation performance of overhead lines has a large impact on the insulation performance of substations. The transmission-line outage rate due to lightning primarily determines the frequency of re-energization operations, and the lightning performance rate close to the substation determines the frequency of fast-front overvoltages impinging on the substation.

Furthermore, procedures of surge arrester selection and associated insulation coordination are described to protect the transmission systems. Insulation coordination of the transmission line is also discussed, and results from deterministic and statistic methods are compared.

For the purposes of illustrating the insulation coordination process, an example from the application guide is shown here. Assume the following basic data:

- Highest system voltage is: U_s = 765 kV.
- Pollution level is low to medium.
- Altitude is: H = 1000 m. (for all locations).

The pollution level is assumed sufficiently mild that the standard insulation levels (and clearances) can be determined by the voltage stresses (usually the slow-front overvoltages for systems with nominal voltage of 345 kV and above).

For overhead line insulation coordination, and where the design employs free-swinging insulators, the dielectric strength of air clearances should take into account conductor movement.

Step 1: Determination of the Representative Overvoltages—Values of Urp
The representative temporary and slow-front overvoltages are usually determined from system studies. For this example, results from such studies confirmed the following values:

- Temporary overvoltages: U_{rp} = 660 kV (r.m.s., phase-to-ground);
- Slow-front overvoltages: U_{e2} = 1200 kV (peak, phase-to-ground; phase-peak method).

Power-Frequency and Temporary Overvoltages
The high level of temporary overvoltage (1.5 p.u.) is associated with situations involving long lines radially fed after a major load rejection. For systems with nominal voltage of 345 kV and above, the two standard withstand voltages normally specified are the lightning and the switching impulse levels.

Slow-Front Overvoltages
The slow-front overvoltage is related to line reclosing, and is limited to about 2.0 p.u. by the use of closing resistors on line circuit breakers.

The surge arrester rating is also determined from these same system studies (normally from the temporary overvoltage characteristics: amplitude and duration) and, for the particular case of this example, the following protection levels were determined:

- Switching impulse protective level: U_{ps} = 1300 kV (peak value);
- Lightning impulse protective level: U_{pl} = 1500 kV (peak value).

Fast-Front Overvoltages
The simplified statistical method for fast-front overvoltages will be used, leading directly to the coordination withstand voltage.

In this step and those that follow, only the phase-to-ground insulation is considered. Phase-to-phase insulation coordination will be treated at the end of the example as a separate item.

Step 2: Determination of the Coordination Withstand Voltages–Values of Ucw
The coordination withstand voltage is obtained by applying a coordination factor (K_c) to the representative overvoltages, this factor being either K_{cd} for the deterministic method or K_{cs} for the statistical method.

Determination of the coordination withstand voltage for external insulation is carried out for slow-front overvoltages using the statistical method because of the nature of the insulation. A statistical method could also be applied to fast-front overvoltages, but this is generally not necessary for systems with nominal voltage of 345 kV and above.

Ucw for Temporary Overvoltages
For this class of overvoltages, the coordination withstand voltage is equal to the representative temporary overvoltage—in other words, the coordination factor K_c = 1. Therefore phase-to-ground U_{cw} = 660 kV.

Ucw for Slow-Front Overvoltages
The value of the statistical coordination factor K_{cs} comes from choosing a risk-of-failure of the insulation that has

been proven from experience to be acceptable. For a usually acceptable value of R in the range of 10^{-4}, the value of K_{cs} is 1.15. Hence the coordination withstand voltage is U_{cw} = 1200 kV x 1.15 = 1380 kV:

- Statistical overvoltage: U_{e2} = 1200 kV;
- Statistical coordination factor: K_{cs} = 1.15;
- Coordination withstand voltage: U_{cw} = 1380 kV.

Ucw for Fast-Front Overvoltages

The determination of the coordination withstand voltage for fast-front overvoltage is not necessary since the lightning impulse withstand voltage of the minimum clearances that result from the switching impulse withstand voltage will be far in excess of those that should be determined solely by the lightning impulse withstand voltage required for the non-self-restoring insulation.

Step 3: Determination of the Required Withstand Voltages – Values of Urw

The required withstand voltage is obtained by applying a safety factor K_s to the coordination withstand voltage. The values of K_s are given as:

- For external insulation: K_s = 1.05.

For external insulation, an atmospheric correction factor K_a is also applied.

For power-frequency voltage, determine the atmospheric correction factor assuming a short-duration power-frequency test on polluted insulators, for which m = 0.5 and assuming H = 1000 m, K_a = 1.063.

Hence U_{rw} = 660 x 1.063 x 1.05 = 737 kV:

- U_{cw} for temporary overvoltages: U_{cw} = 660 kV;
- Atmospheric correction factor: K_a = 1.063;
- Safety factor: K_s = 1.05;
- U_{rw} for temporary overvoltage: U_{rw} = 737 kV.

The atmospheric correction factor K_a for slow-front overvoltages is based on the assumed altitude. For H = 1000 m and m = 0.6, then $K_a = e_{0,07}$ = 1.07. Hence U_{rw} = 1380 kV x 1.07 x 1.05 = 1550 kV:

- U_{cw} for slow-front overvoltages: U_{cw} = 1380 kV;
- Atmospheric correction factor: K_a = 1.07;
- Safety factor: K_s = 1.05;
- U_{rw} for slow-front overvoltages: U_{rw} = 1550 kV.

Summary

This section described line insulation coordination procedures according to IEC 71-2, Insulation Coordination Application Guide. Since this section has been extracted from the IEC guidelines, the reader is urged to obtain the full standards from the IEC.

Presentation of the information in this appendix is intended to complement the information presented in the main body of this chapter. It provides some guidelines, as well as typical design figures or targets.

CHAPTER 4

Insulation for Power Frequency Voltage

Andrew Phillips
Christiaan S. Engelbrecht

This chapter provides an overview of insulator technology and its relationship with the ac performance of the line. It includes information on insulator types and components, the contamination flashover mechanism, the long-term performance of insulators, laboratory test methods, the electrical performance of insulators and air gaps under power frequency voltage, performance in freezing conditions, insulation design, and the distribution of the electric field along insulators.

Dr. Andrew Phillips is a project manager, Transmission and Substations, Power Delivery and Markets Group at the Electric Power Research Institute (EPRI) in Charlotte, North Carolina. His responsibilities are mainly with the Overhead Transmission Program, with special areas of interest in polymer insulators, lightning and grounding, inspection and assessment of components, sensor developments, and daytime corona inspection. Dr. Phillips joined EPRI in January 1998.

Before joining the Institute, Dr. Phillips worked with J. A. Jones Power Delivery, where he was a project manager and lead researcher in the fields of insulation, aging, and lightning. Prior to that, Dr. Phillips worked at the University of the Witwatersrand, performing research for the South African electric power industry.

Dr. Phillips received his BSc, MSc, and PhD degrees in Electrical Engineering from the University of the Witwatersrand in Johannesburg, South Africa. Dr. Phillips holds one U.S. patent and is the author of over 60 journal and conference publications. He is a member of the IEEE, SAIEE, and CIGRE, and is a registered professional engineer.

Christiaan S. Engelbrecht is a Senior Consultant with KEMA based in Arnhem, The Netherlands. He has more than 15 years experience in the contamination design of insulators and insulation co-ordination studies, having also worked with ESKOM in South Africa and STRI in Sweden. He is convener of the newly formed CIGRE Working Group C4AG03-03, "Pollution and Environmental Influence on the Electrical Performance of Power Systems," and a member of IEC TC36 WG 11, which deals with the revision of IEC 60815, "Selection and Dimensioning of High-Voltage Insulators for Polluted Conditions." He has also been involved in insulation coordination audits of transmission and distribution systems and the study of corona losses due to hoarfrost.

4.1 INTRODUCTION

Traditionally the external insulation design of high-voltage transmission lines in the EHV and UHV range has been dominated by the requirements to withstand switching or lightning overvoltages. It was assumed that the insulation designs based on these requirements were also sufficient for power-frequency voltage because of the high relative strength of the air under ac even during rain. However, it has become apparent that the line performance might be severely affected if the insulation was not adequately dimensioned to withstand the effects of insulator contamination. This phenomenon has been studied extensively over the years and has resulted in a number of important review documents (Looms 1988; CIGRE 2000; IEEE Working Group on Insulator Contamination 1979; Lambeth 1971). Furthermore, standardized laboratory test methods for evaluating the contamination performance of ceramic and glass insulators have been developed (IEC 1991; IEEE 1978); guidelines for the selection of insulators with respect to contamination conditions have also been developed (IEC 1986).

Insulator technology has also seen many developments to improve its electrical and mechanical characteristics. Notable in this respect is the development of polymer insulators and the use of hydrophobic properties of insulating materials to improve the flashover performance of insulators under contamination conditions (Houlgate and Swift 1989). The introduction of this new technology has not been without problems, as the polymeric insulating materials are more sensitive to the effects of aging than the traditionally used ceramic and glass materials (CIGRE 1986; CIGRE 1990). Furthermore, it was also found that the guidelines and test methods developed for ceramic and glass insulators are not directly applicable to polymer insulators. Although much progress has been made in addressing these issues (Gorur et al. 1999), more work is needed to obtain general agreement on test procedures and rules for dimensioning.

This chapter provides an overview of the present understanding of the ac performance of transmission lines. This overview also covers insulator technology because of the intimate relationship between the selected insulator and the ac performance of the line.

Background information on insulator technology, typical applications, and important concepts are discussed in Section 4.2. This section starts with a concise description of the history of insulator development, highlighting important milestones. Insulator types and important terms, such as the “unified specific creepage distance” and “hydrophobicity” are defined and explained. The section closes with a description of typical insulator components and the materials and concepts used in manufacturing of insulators. The focus in this section is more on polymeric than glass and porcelain insulators.

Section 4.3 describes the contamination flashover mechanism for both hydrophilic and hydrophobic insulator types. It covers the buildup of contaminants on the insulators, as well as wetting processes and the development of discharges into flashover under critical levels of contamination. The effect of insulator profile and the material characteristics on the flashover process is highlighted.

The long-term performance, or aging characteristics, of various insulator technologies are discussed in Section 4.4, with many photographs illustrating examples from service and laboratory testing experience. The section closes with a summary of failure rates and dominant failure types as experienced by the users of polymer insulators.

Laboratory test methods for insulators are described in Section 4.5. The section starts with a description of the general requirements for laboratory testing, which is followed by summary descriptions of common methods used to verify the long-term performance of polymer insulators. This is followed by a discussion of presently used contamination flashover test methods and developments to establish a representative test method for polymer insulators.

In Section 4.6, a summary is presented of the electrical performance of air gaps and insulators under power frequency voltage. Information is presented on the effect of rain on clean hydrophilic and hydrophobic insulators, as well as the effect of rainfall rate and resistivity on the flashover strength. The latter part of the section concentrates on the contamination flashover strength of both hydrophilic and hydrophobic insulator types. Important influencing factors such as the contamination severity level, type of contamination, amount of nonsoluble components, and the linearity of flashover results are presented. Some information is also provided on the flashover performance of polymer insulators and the effect of hydrophobicity on the flashover voltage. The section closes with a short discussion of the contamination performance of resistive glaze insulators.

A summary of important aspects regarding the performance of insulators in freezing conditions can be found in Section 4.7. This section highlights the importance of considering the performance under ice conditions when dimensioning insulators. Test results from different laboratories are presented.

Insulation design and the factors that influence it are discussed in Section 4.8. The section starts with a broad discussion of insulation dimensioning concepts and how they are applied to problem of insulator contamination. Information

is provided on different methods for site severity estimation and developments in the IEC to standardize these. The choice of insulator technology is discussed in some detail, as well as important aspects that should be taken into account when utilizing polymer insulators. This section closes with detailed descriptions of both the deterministic and statistical methods for selecting the insulator dimensions to obtain a good contamination flashover performance.

The final section of this chapter, Section 4.9, is devoted to the distribution of the electric field along insulators and the design of grading rings. Polymer insulators, in particular, may suffer premature aging if the E-field grading is not considered carefully. This section highlights effects that an overly high E-field gradient may have on insulators, methods to control the gradient, and calculation methods. Some guidelines are provided on the selection of grading rings for insulators.

Three applets are associated with this chapter:

- Applet I-1: "Insulator Equivalent Salt Deposit Density (ESDD) and Parameter Evaluation." This applet calculates the leakage length, surface area, and form factor of an insulator, given its profile. Top and bottom surface parameters can be evaluated separately. The applet also guides the user to the measurements of ESDD and NSDD (Non-Soluble Deposit Density) and their calculation. The recommendations for measurements and calculations are made according to international practice using the methods described in this chapter.
- Applet I-2: "Electric Field Distribution for Polymer Insulators: Effect of Dimensions and Location of Corona Ring." This applet calculates the electric field in the space near the end fittings of a polymer insulator. This parameter is important when applying polymer insulators, as highlighted in Section 4.9. In fact, the electric field needs to be kept below certain limits in order to eliminate corona under dry conditions, reduce corona and arcing under wetting conditions (as these aging mechanisms reduce life expectancy), and prevent internal discharges due to defects or voids that may initiate a failure. The factor that dominates the application and design of corona rings is the electric field magnitude on the surface of the sheath close to the energized end region. If the electric field in this region exceeds a critical value, excessive corona activity can occur under wetting conditions, resulting in premature degradation of the rubber and reduction in life expectancy. The applet solves the field problem in 3-D. It accounts for a single conductor, which must be sufficiently long so that the end effects do not affect the region near the insulator. Both energized and grounded end fittings can be simulated, as well as the tower truss from which the insulator may be suspended. The corona ring is simulated by a toroid. This applet does not account for the dielectric properties of the rubber or rod, and is intended only as an educational tool for the user. The user may change the position and dimensions of a corona ring, and observe how the electric field distribution surrounding the polymer insulator end fitting is affected.
- Applet I-3: "Statistical Method for Dimensioning Insulators to Meet Contamination Flashover Requirements." This applet applies a statistical method to evaluate the risk of flashover of a specific insulator design at a site with a given contamination severity. As input data, the applet requires the statistical parameters that characterize the contamination severity of the site, the statistical and mathematical parameters that characterize the flashover performance of the insulator selected for the site, and the number of insulators. Based on the risk of flashover, calculated by the applet, the insulator creepage distance can be adjusted until the desired performance is achieved. The algorithms used by the applet are an implementation of statistical method discussed in Section 4.8.5. The input data used in the demonstration example of the applet is the same as was used to derive Figures 4.8-20, 4.8-21, 4.8-22, and 4.8-23.

4.2 INSULATOR TECHNOLOGY

4.2.1 Historical Perspective

The manufacture, design, and application of electrical insulators have posed a challenge to electrical engineers since the beginnings of power transmission. The first insulators were developed for telegraph lines, which were introduced around 1835 (Looms 1988). These were made mostly of annealed glass, or "dry-pressed" porcelain (Berry 1995). With the advent of power transmission in 1882, the telegraph insulators were initially scaled-up for use at higher voltages and mechanical loadings (see Figure 4.2-1). The higher demands associated with power transmission soon revealed serious shortcomings in both the materials and designs available at the time. For example, dry-press porcelain insulators suffered from punctures due

Figure 4.2-1 Examples of porcelain telegraph insulators.

to the porosity of the material. This gave impetus to the development of wet-process porcelain (1896), and soon thereafter the use of a vacuum extrusion process to eliminate air from the porcelain insulating body, thereby obtaining a vitreous porcelain that is essentially the same as used in modern applications (Berry 1995). Also glass has undergone considerable developments in the choice of ground materials and the introduction of toughening in the 1930s (Looms 1988; Pyrex 1933).

The first polymer insulator designs were developed during the 1960s, with the first test installations during the 1970s (Hall 1992). The advantages of polymer insulators included their light weight, resistance to vandalism, small profile, and in some cases improved contamination performance (Burnham and Waidelich 1997; CIGRE 1986, 1990; EPRI 2003b). As with ceramic and glass insulators, the initial designs were plagued by problems and suffered especially from material-aging effects. Through a continuous evolution of designs, polymer insulators have developed into a mature product that has since the 1980s become generally accepted and used in large numbers on transmission lines (EPRI 2003b).

Another challenge to be overcome in development of insulators has concerned the mechanical demands that insulators on transmission lines must withstand. Traditional insulating materials (i.e., porcelain and glass) are much stronger under compression than tension loads, whereas the insulators are generally placed under tension on transmission lines (Looms 1988). Designs, such as the disc (or cap and pin) type, had to be developed that place the dielectric under compression, although the insulator as a whole is under a tension load.

Pin insulators, which are direct descendants of the telegraph insulator, are still being produced today, but their use is limited to distribution lines. The first successful disc insulators were introduced in 1909 (porcelain) and 1930 (glass) (Looms 1988; Pyrex 1933). Pedestal post insulators, used mostly in substations, were introduced around 1910, and longrod insulators appeared in the 1920s (Looms 1988). Porcelain post insulators were only introduced in 1940 (Looms 1988). The first polymer insulators were of the longrod type, but since the early 1980s, they have also become available as post insulators.

Nearly all designs have certain vulnerabilities. The development of insulator designs and manufacturing technology has been a process of trial and error rather than an orderly progression. The designs and manufacturing methods used for porcelain and glass insulators stabilized in the 1950s and 1960s. Insulators from reputable manufacturers are widely used since they are reliable and offer a long service life.

Development of polymeric insulators has been ongoing—with big advances, in terms of their reliability, being made during the 1980s and 1990s. Presently most manufacturers have stable designs, which is underlined by the increasing use of polymer insulators worldwide. In 2002, a polling of 70 American utilities showed that 65 utilized polymer insulators, while figures obtained from four of the major manufacturers indicated that more than 4 million polymer transmission-class insulator units had been sold in the U.S. alone (EPRI 2003b).

This survey further indicated that the percentage of utilities applying polymer insulators reduces with increasing system voltage, as shown in Figure 4.2-2. The largest percentage of the polled utilities apply polymer insulators at the 115–138 kV level, and the second largest percentage at the 220-230 kV level (EPRI 2003b).

Based on data captured from five of the major polymer insulator manufacturers, the 2002 survey indicated that the total number of suspension and post units, including and above 69 kV, sold to the North American market was 3,938,000. The total number of service years indicated was 25,163,000 (the service years indicated is based on the date of sale, not the date of installation). The average age of the polymer insulators sold was 6.4 years. For individual manufacturers, the average values varied between 2.8 and 8.7 years. It should be noted that these are average values. Although all of the major manufacturers servicing the market in 2002 were represented, one design still installed in great quantities was excluded since it was no longer marketed at the time.

National (ANSI) and International (IEC) standards have followed the developments and usage trends of the different insulator technologies (ANSI 1996, 2002b, 2002c; IEC

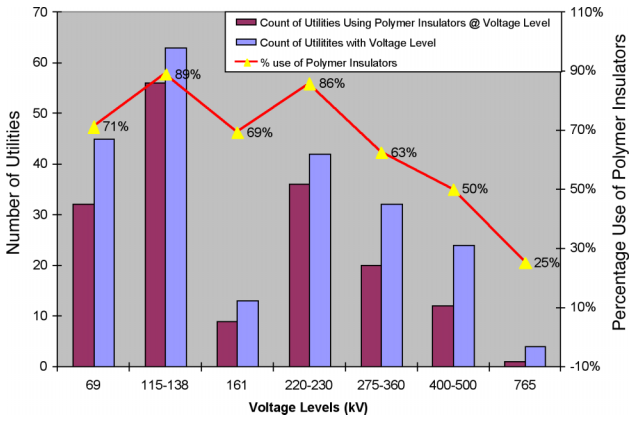

Figure 4.2-2 Number of utilities that apply polymer insulators at each voltage level, as well as the number of utilities that have transmission lines at each voltage level. The line indicates the results as a percentage.

1992, 2002a, 2002b, 2003). For glass and ceramic insulators, the standards have been available for many years, while the standards applicable to polymer insulators are still relatively new, or in many cases, are still under development.

4.2.2 General Insulator Terms and Classification

Insulators consist normally of an insulating body with one or more fixing devices. The insulating bodies have traditionally been made of porcelain or toughened glass, but with the development of polymer insulators, the insulating body may also comprise a fiber-reinforced plastic (FRP) rod that is covered by a rubber housing to provide the necessary leakage distance and to protect the rod from the environment.

The IEC names insulators according to the material from which the insulating body is manufactured. Specifications are produced for either glass and ceramic, or polymer insulators. Polymer insulators can again be subdivided into resin and composite insulator types. All transmission-line polymer insulators may be classified as composite by the IEC definition; however, a number of terms are used interchangeably in the industry when describing such insulators: composite, polymer, nonceramic insulators, or NCI. For the purposes of this Reference Book, the term "polymer insulator" will be used.

Resin insulators are not used at transmission voltage levels and are, hence, not further discussed in this chapter. For each of these general types of insulator, various designs exist, as illustrated in Figure 4.2-3.

It should be noted, however, that ANSI/IEEE standards use a slightly different naming convention. For example, what the IEC calls a "cap and pin" insulator is named "suspension disc" by ANSI. Figure 4.2-3, therefore, lists both IEC and ANSI terms, with the IEC term first. In this chapter, the naming convention of ANSI will be used.

General Classification

The standards recognize two classes of insulators according to the possibility of internal puncture (see Figure 4.2-4) (IEC 1993). For Class "A" insulators, the length of the shortest possible puncture is at least equal to half the external arcing distance. These insulators are regarded as puncture proof. Class "B" insulators, on the other hand, have a

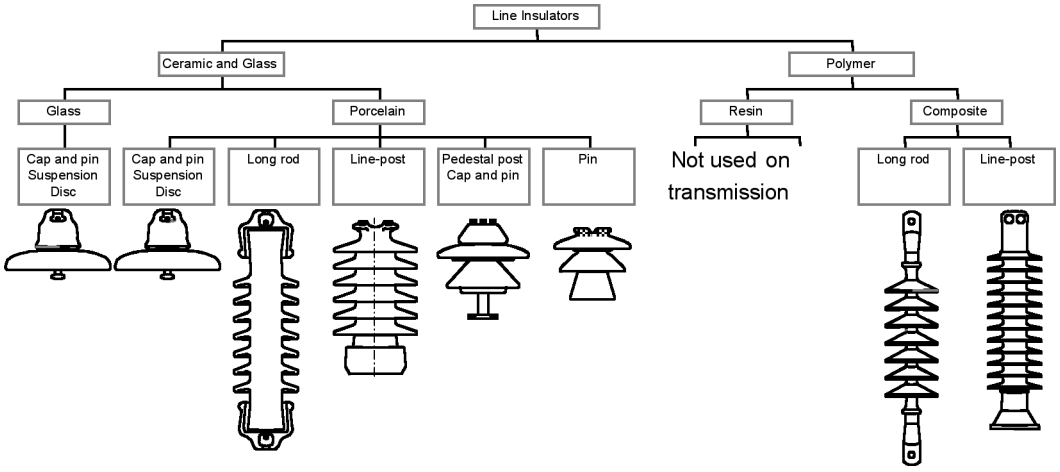

Figure 4.2-3 A general overview of insulator types used on transmission overhead lines.

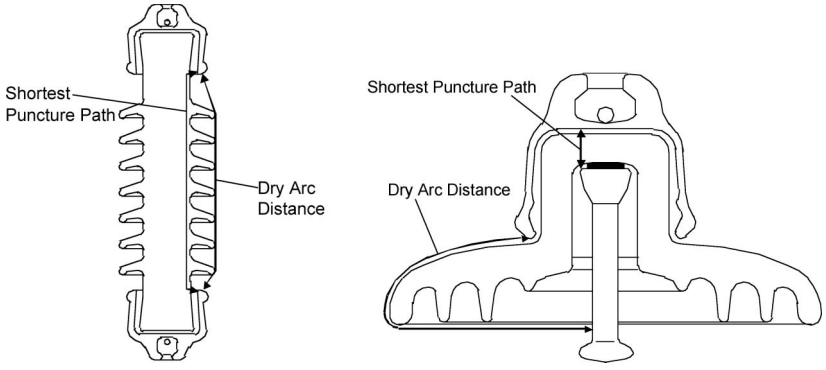

Figure 4.2-4 The general classification of insulators as Class A (*left*) or B (*right*).

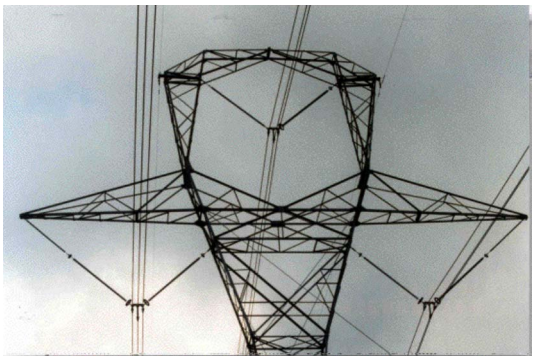
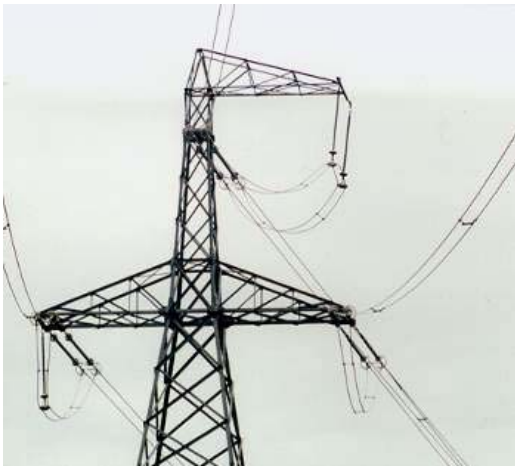
shortest puncture path that is less than half the external arcing distance. These insulators are regarded as "puncturable."

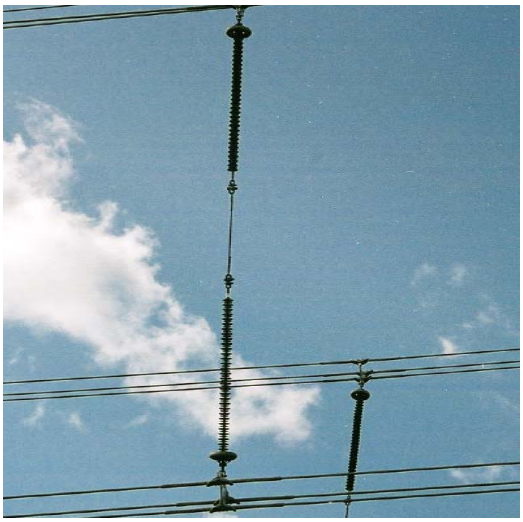


Typical Applications

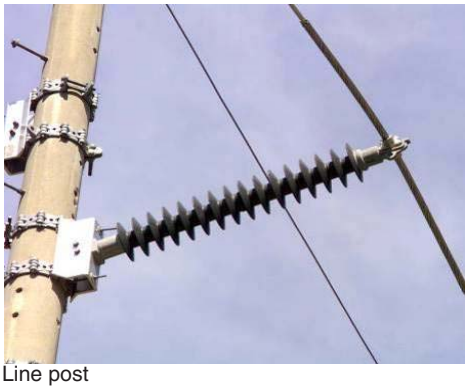
Typical applications of transmission-line insulators are shown in Figure 4.2-5. Disc, longrod, and polymer longrod insulators are utilized in dead-end, I-string, and V-string assemblies. In these assemblies, the insulators are placed under tension loads to attach the conductor to the transmission-line structure. Longrod and disc insulators are generally not designed to withstand cantilever or compression loads.



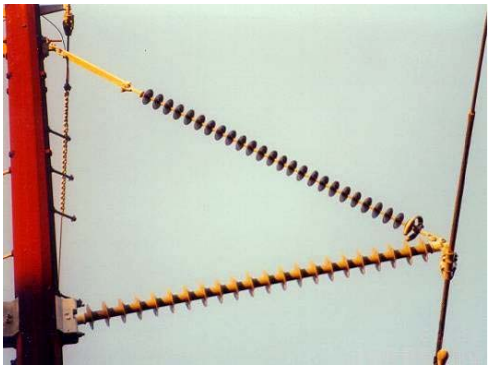
Post insulators, both polymer and porcelain, are attractive because they can be used in single-pole structures, reducing the structure footprint and in some cases, the required right-of-way. These units have to withstand cantilever, compression loads, and to a limited extent, even tension loads. The rod sizes are, therefore, larger than those of longrod insulators used at the same voltage level.



I-suspension



V-suspension



Strain or dead end

Phase spacer

Line post

Brace post or horizontal V

Figure 4.2-5 Examples of different insulator string configurations.

Post insulators can also be used in combination with longrod insulators to form a Horizontal V or braced post, as shown in Figure 4.2-5. This arrangement is used to obtain a more rigid mechanical structure to support the conductors.

Polymer or porcelain longrod insulators are also used in phase spacer applications. These applications need special consideration, since the insulators may by subject to compressive forces due to the conductor movement (Imakoma et al. 1994; Kito et al. 1975).

Parameters that Characterize Insulators

Various parameters have been defined that can be used to characterize insulator shape and dimensions. The most often used parameters are defined in this section.

- **Section length.** The section length (also known as connecting length) refers to the shortest distance between fixing points of the live and grounded (earthed) hardware, ignoring the presence of any stress control rings, but including intermediate metal parts along the length of the insulator (see Figure 4.2-6).
- **Dry arc distance.** The shortest distance in the air external to the *insulator* between those parts that normally have the operating voltage between them. The dry arc distance of various types of insulator configurations are illustrated in Figure 4.2-7.
- **Strike distance.** The strike distance is the shortest distance from the energized hardware to the grounded hardware or structure (see Figure 4.2-8). The strike distance may correspond to the dry arc distance.
- **Leakage (or creepage) distance.** The shortest distance over the insulator surface between the end fittings is the leakage or creepage distance. Since there is a linear relationship between the contamination flashover strength

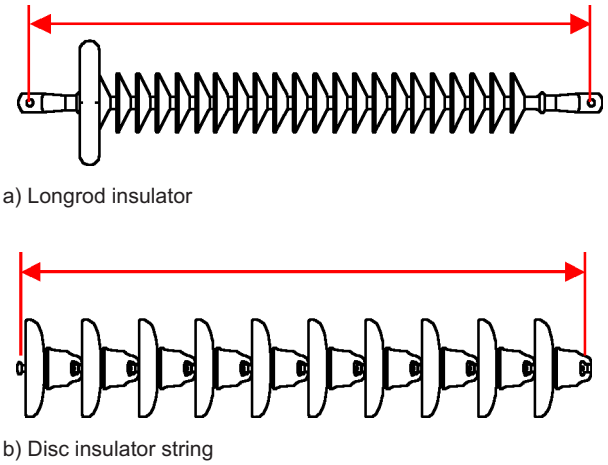


Figure 4.2-6 Definition of section length.

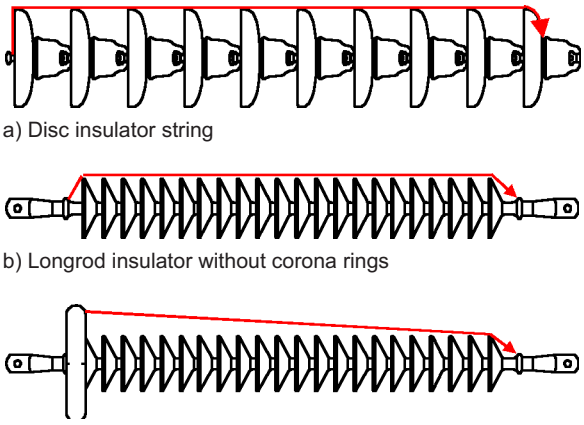

Figure 4.2-7 Definition of dry arc distance.

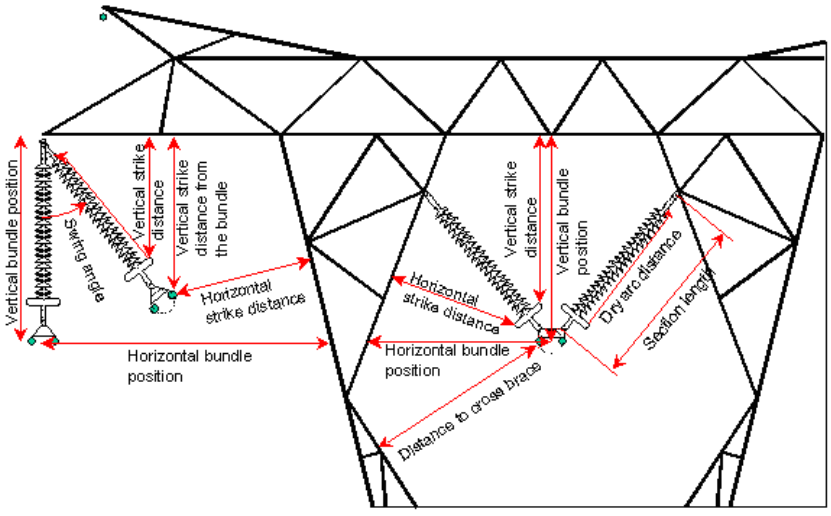

Figure 4.2-8 Definition of strike distance in comparison to dry arc distance and section length. I-string on the left and V-string on the right.

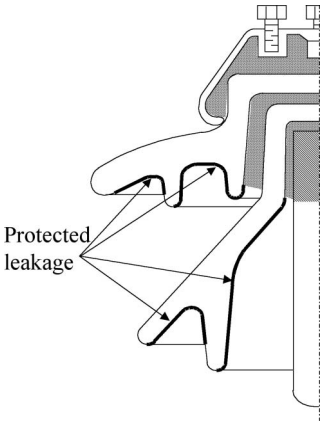
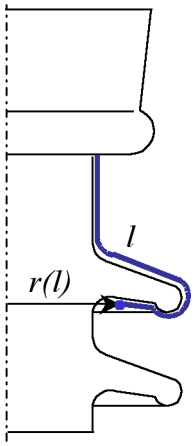
and leakage distance, the concept of specific leakage distance is commonly used. In the first edition of IEC publication 60815 (IEC 1986), the specific creepage distance was defined as the leakage distance divided by the phase-to-phase value of the maximum voltage for the equipment. This definition was based on the assumption that the insulation was installed between phase and ground, which is not always the case. To overcome this deficiency, IEC introduced the "*unified specific creepage distance*" concept, which is the leakage distance divided by the maximum operating voltage across the insulator. For the same pollution class, the *unified specific creepage distance* is √3 times the *specific creepage distance*. Both are usually expressed in mm/kV.

- **Protected leakage (or creepage) distance.** This parameter is the part of the leakage distance that is not easily accessible to natural cleaning. It is defined as the part of the creepage distance on the illuminated side of the insulator that would lie in shadow if light were projected on to the insulator at 90˚ (or 45˚ in special cases) to the longitudinal axis of the insulator (see Figure 4.2-9).
- **Form factor.** The form factor gives the relationship between the resistivity of a surface layer and the overall resistance of that same surface. This dimensionless ratio is calculated by the integral of the reciprocal value of the insulator circumference along the length of the leakage path (L) (see Figure 4.2-10).
- **Surface area.** When Equivalent Salt Deposit Density measurements are being performed, it is necessary to know the surface area of the insulator over which the measurement is performed. Evaluating the integral of the insulator circumference along the length of the leakage path (L) gives the surface area, as shown in Equation 4.2-1.

$$Area = \int_0^L 2\pi \cdot r(l) \cdot dl \qquad 4.2\text{-}1$$

Example: The insulator parameters can be obtained from the manufacturer or by using a scan of the insulator profile and a numerical evaluation of the surface integrals. Figure 4.2-11 and Table 4.2-1 show an example for a typical disc insulator used in multiple disc strings on many transmission lines. Applet I-1 provides a software implementation of the calculation of these insulator parameters based on coordinates that describe the insulating surface profile.





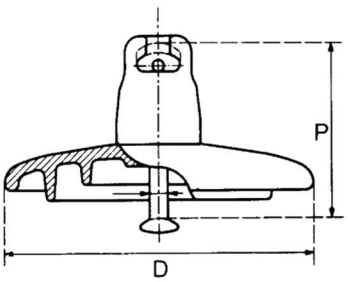


Figure 4.2-9 Protected leakage, or creepage, distance.

$$FF = \int_0^L \frac{dl}{2\pi \cdot r(l)}$$

Figure 4.2-10 Definition of form factor.

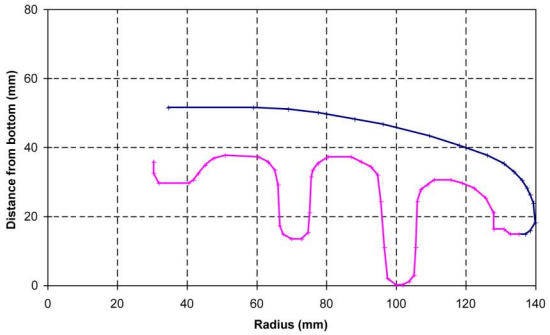

Figure 4.2-11 Insulator meaurements.

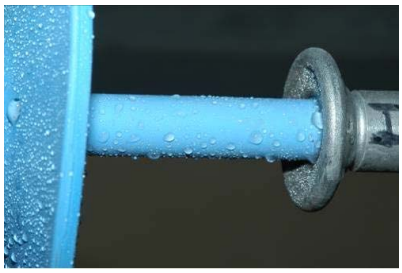

Table 4.2-1 Calculated Parameters for the Insulator Shown in Figure 4.2-11.

	Top	Bottom	Total
Section Length (mm)			146
Leakage distance (mm)	125.18	214.46	339.64
Surface area (cm^2)	746.95	1151.44	1898.39
Form Factor	0.24	0.46	0.70

For the example above, the 146-mm ($5^3/_4$ in.) spacing from cap to pin of the insulator, multiplied by the number of insulators in the string, gives a close estimate of the dry arc distance of the insulator. The sum of the top-surface and bottom-surface leakage distances (340 mm, [13.4 in.]), multiplied by the number of insulators, gives the overall leakage distance. If 25 of the insulators shown in Figure 4.2-11 are used, the dry arc distance will be about 3.65 m (143.75 in.), and the leakage distance will be 8.5 m (335 in.).

4.2.3 Hydrophobicity

One of the most important surface characteristics of an insulator is how it interacts with water on its surface. This is normally described in terms of its hydrophobicity. As illustrated in Figure 4.2-12, the surface condition may be anything between water-repellent (called *hydrophobic*) to easily wettable (called *hydrophilic*). This section provides a concise description of this phenomenon and some of the methods available to assess this characteristic on insulators. In 2003, the IEC published a guide that describes three methods for determining the wettability of insulators (IEC 2003).

a) A hydrophobic surface (i.e., high hydrophobicity).

b) A hydrophilic surface (i.e., low hydrophobicity)

Figure 4.2-12 Examples of a hydrophobic and a hydrophilic polymer surface.

Hydrophobic Surfaces

Hydrophobic surfaces have a low surface tension, which causes water to bead when coming into contact with it. In contamination conditions this provides an advantage because it inhibits the formation of a continuous water layer on such a surface. This reduces leakage currents and the likelihood for flashover.

Hydrophobic surfaces are normally associated with polymer insulators and more specifically with silicone rubber (SIR) insulators. Certain formulations containing low-molecular-weight silicone (LMWS) chains have the added advantage that through the migration of LMWS hydrophobicity may be transferred to the pollution layer, making it hydrophobic as well (Kindersberger and Kuhl 1989).

It should, however, be noted that there are conditions when these materials might temporarily or permanently lose their hydrophobicity. This occurs normally during either prolonged wetting events or under long-term discharge activity.

Hydrophilic Surfaces

A hydrophilic surface is characterized by a high surface tension that causes water to form a thin film on the surface. In polluted conditions the surface conductance of the insulator increases during wetting conditions, allowing increased leakage currents across the surface of the insulator. Under critical contamination and wetting conditions, the conductivity may become high enough to result in flashover (CIGRE 1979b).

Glass and porcelain insulators are the best examples of insulators that have a hydrophilic surface. Polymer insulators that are typically classified as hydrophilic are those with a housing of ethylene propylene rubbers (EPR). In some cases, however, silicone additives have been added to EPR material to give it hydrophobic properties for better performance in contaminated environments.

Categorization of Hydrophobicity

Because hydrophobic insulators may lose their hydrophobicity, it may be necessary to evaluate the condition of an insulator by categorizing its level of hydrophobicity. This may be done using a number of methods:

- Measuring the contact angle between the surface of the insulator and a water drop.
- Measuring the surface tension of the insulator housing.
- Comparing a section of wetted surface material against images of standard wetted surfaces.

Measurement of the Contact Angle

An indication of the surface wetting properties of a given material may be obtained by placing a water drop on a flat section of the material and measuring the static contact

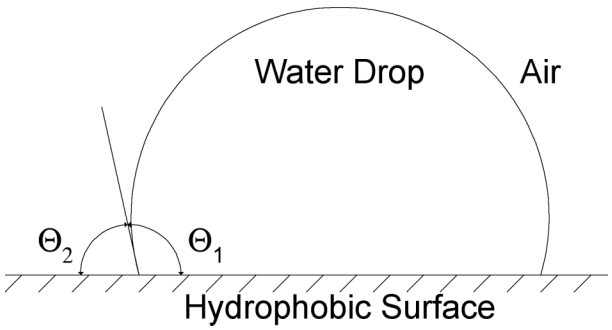

Figure 4.2-13 Definition of the static contact angle.

angle, Θ_1, as defined in Figure 4.2-13. (Although Θ_1 is usually defined as the contact angle, some publications refer to Θ_2 as the contact angle.).

The static contact angle is related to the surface tension—and therefore the degree of hydrophobicity—if the solid material is perfectly smooth and homogeneous. This relationship is given by the so-called Young's equation (Pigini and Tomba 1993). Larger angles (i.e., values of Θ_1) indicate a higher level of surface hydrophobicity, and vice versa.

Since the surfaces of polymer insulators are generally not homogeneous or smooth, the static contact angles do not conform scientifically with Young's equation, which limits the accuracy by which this method can be used to determine the wettability of the insulator surface (Pigini and Tomba 1993). However, this method is still considered as a practical alternative in determining the ability of the polymer to repel water.

Several permutations of the contact angle method have been devised to improve its accuracy and practical applicability. This was done, for example, by taking account of the effect of temperature and gravity. Some of the most commonly used alternatives are:

1. A small water drop on the material surface is viewed through a stereoscopic microscope. If the water drop is small (≈ 0.001 ml), the effect of gravitational forces can be neglected. By measuring the height of the drop and the radius at the base of the drop, as seen in Figure 4.2-14, the contact angle Θ_1 can be calculated by the formula shown in Equation 4.2-2 (Souheng 1982).

   $$\tan(\Theta_1/2) = h/r \qquad 4.2\text{-}2$$

   Where:
   Θ_1 = the contact angle.
   h = the drop height.
   r = the radius at the base of the drop.

   These measurements are usually performed at specific temperatures after the drop has been allowed to settle for a predetermined length of time.
2. Once again, a small water drop on the material surface is viewed through a stereoscopic microscope or a high-powered lens. An image is captured using either analog or digital methods (i.e., photograph or video digitizer). A line tangent to the water drop surface is projected, and the contact angle is measured as shown in Figure 4.2-14. If the image is digitized, automated software measurements are available to make this measurement (University of Oslo 1998).
3. A small water drop is placed on an inclined section of material, and the receding Θ_r and advancing Θ_a contact angles are measured as shown in Figure 4.2-15. The mean surface tension may then be calculated by subtracting Θ_r from Θ_a (Pigini and Tomba 1993).

Other methods not considered here include the use of a goniometer and extrapolation from digitized images to measure the contact angle.

Measurement of the Surface Tension

The IEC (IEC 2003) describes a method whereby the surface tension of an insulator is measured by spraying the surface with a range of organic liquid mixtures with predefined surface tension. An indication of the surface tension is obtained by measuring the time the sprayed-on liquid takes to break into distinct droplets. The surface tension of the insulator surface is lower than that of the liquid if the time to break up is less than 2 s. Different liquid mixtures are sprayed on until one is found with a breakup time that is closest to 2 s. The surface tension of this liquid can be considered to be indicative of that of the insulator.

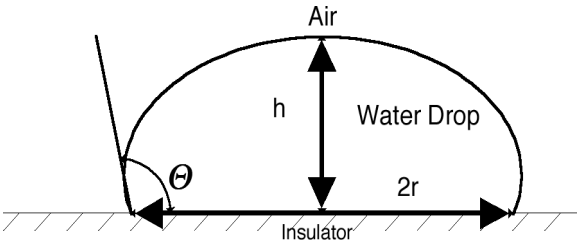

Figure 4.2-14 Measuring height and radius of a drop.

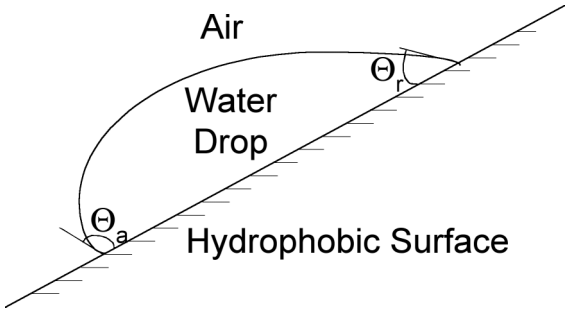

Figure 4.2-15 Contact angle on an inclined surface.

Classification Against Standard Samples

A simple and practical approach to classify the hydrophobicity of insulators has been developed (STRI 1992). This method is used extensively in the industry and has been adopted by the IEC (IEC 2003). With this method, a common spray bottle is used to spray the area of interest with a fine mist of uncontaminated water from a distance of between 10 and 25 cm for a duration of 20-30 s. Within 10 s after the completion of the spraying, the wetted surface is inspected and categorized according to standardized photographs and descriptions.

While the results are somewhat subjective, they are considered adequate in most situations. Seven hydrophobicity classes (HC) are defined, ranging from 1, which is completely hydrophobic, to 7, which is completely hydrophilic. These classes are described in Table 4.2-2, and the corresponding photos are presented in Figure 4.2-16 (STRI 1992).

4.2.4 Components of Ceramic and Glass Insulators

Suspension Disc

Glass and porcelain disc type insulators consist of a dielectric shell cemented between a cap and pin metal end fitting. The end fittings are normally a malleable or ductile cast iron cap and a forged steel pin, both hot dip galvanized. The shape of the cap-and-pin is designed so that the dielectric material is placed under compression under the normal loading condition. The dielectric material of modern insulators is either made of electrical porcelain or toughened glass. Porcelain shells have a glazed surface that provides a smooth surface and places the porcelain under compression to further enhance the mechanical strength of the porcelain. Glass shells are toughened by heating, followed by rapid cooling of the glass surface. This process produces a stress pattern that places the internal part of the shell under compression, thereby obtaining a dielectric element with a high mechanical strength. Both the porcelain and glass offer very high dielectric and mechanical strengths. Cement is used to fix the metal end fittings to the dielectric shell. Figure 4.2-17 shows the components of a disc insulator type (Gorur et al. 1999; Looms 1988).

Table 4.2-2 Relationship between the Hydrophobicity Class (HC) and Contact Angle (STRI 1992)

HC	Description
1	Only discrete droplets are formed. $\Theta_r > 80$ degrees for the majority of the droplets
2	Only discrete droplets are formed. $50 < \Theta_r < 80$ degrees for the majority of the droplets
3	Only discrete droplets are formed. $20 < \Theta_r < 50$ degrees for the majority of the droplets. Usually they are no longer circular.
4	Both discrete droplets and wetted traces form the water runnels are observed (i.e., $\Theta_r = 0$). Completely wetted areas < 2 cm^2, together they cover < 90% of the tested area.
5	Some completely wetted areas > 2 cm^2, which cover <90% of the tested area.
6	Wetted areas cover >90%, i.e., small unwetted areas (spots / traces) are still observed
7	Continuous water film over the whole tested area.

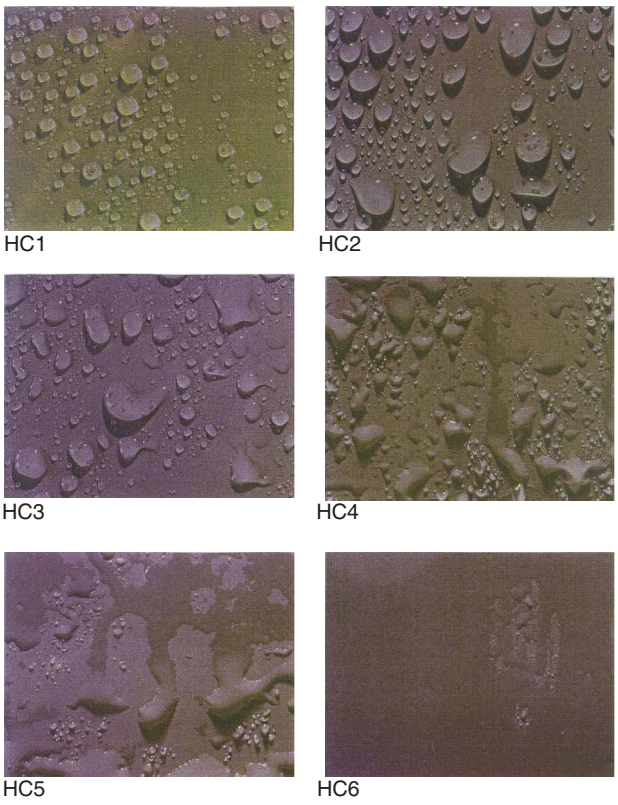

Figure 4.2-16 Standard pictures of the different STRI hydrophobicity classifications (STRI 1992). HC7, a completely wetted surface, is not shown.

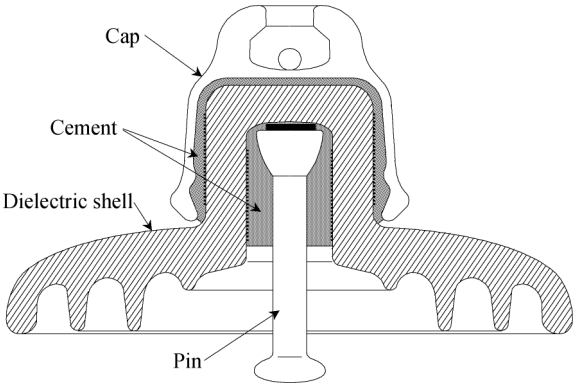

Figure 4.2-17 Components of a ceramic or glass disc insulator.

Longrod

Porcelain longrod insulators comprise a high-strength porcelain body, with metal end caps cemented to each end, as illustrated in Figure 4.2-18. As with disc insulators, the dielectric body of the longrod insulator is manufactured of glazed electrical porcelain. The end caps are fixed to the porcelain body with cement or with a lead-antimony alloy.

4.2.5 Components of Polymer Insulators

In its simplest form, a polymer insulator consists of a load-bearing core covered by a polymeric housing with sheds. Metal end fittings are provided at both ends of the core for connecting the insulator to the supporting tower, conductor, or other pieces of equipment. The main components of a polymer insulator are illustrated in Figure 4.2-19.

Core Rod

The internal insulating part of a polymer insulator is a fiberglass reinforced plastic (FRP) rod, which is designed to carry the mechanical loading of the insulator. It consists of axially aligned glass-fibers that are imbedded by a pultrusion process into a resin matrix to achieve maximum mechanical strength. The fibers are typically 5 to 25 μm in diameter and make up 75 – 80% of the total weight of the rod (EPRI 1998). E-Type glass fibers are often used, but corrosion-resistant fibers are also finding increasing use. "Corrosion resistant" refers to the ability of the glass fibers to resist stress corrosion cracking (brittle fracture), which is discussed later (Armentrout et al. 2003). This resistance is obtained by reducing the level of boron in the fibers. It should be noted that, although boron-free rods do reduce the possibility of failure by brittle fracture, they are still susceptible to the other failure modes, such as flashunder (see Section 4.4.3) and destruction of rod by discharge activity, discussed later in this chapter. A hydrolysis-resistant resin—epoxy, vinyl-ester, or polyester based—is used as the resin matrix. Figure 4.2-20 is a scanning electron microscope (SEM) image taken of a rod cross section, and shows the fibers and resin.

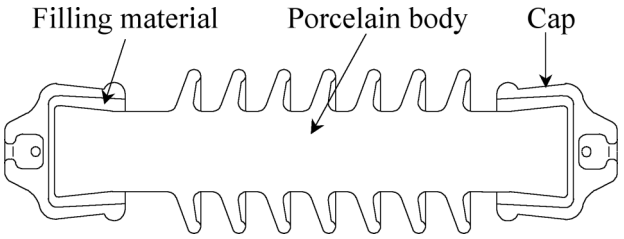

Figure 4.2-18 Components of a porcelain longrod insulator.

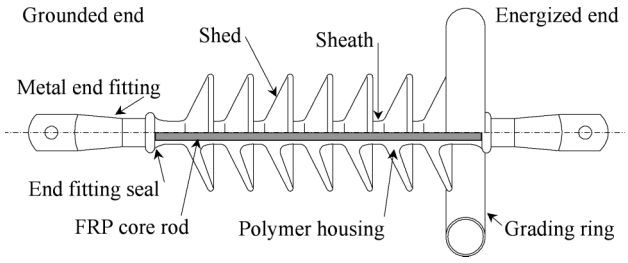

Figure 4.2-19 Basic components of a polymer insulator (note: U.S. naming convention).

The mechanical strength of a FRP rod is much higher under a tension load than it is under compression, torsion, or bending (cantilever) loads. This is evident in the much thicker rods that are required for polymer post insulators, which have to withstand compression and cantilever loads, compared with longrod units that are purely subjected to tension loads. Electrically, the rod is a good insulator as long as it is dry and uncontaminated.

Polymer Insulator Housing Material

The function of the polymer housing is to hermetically seal the rod from the environment, and to provide sufficient leakage distance to withstand both environmental and electrical stresses to which the insulator may be subjected. The housing typically comprises sheds and sheath (shank) sections. For transmission-line polymer insulators, the housing may be based on either an ethylene propylene rubber (EPR) or a silicone rubber (SIR). Distribution insulators may also utilize other materials such as cycloaliphatic epoxy or ethylene vinyl acetate.

Although housing materials are generally classified as EPR or SIR, the composition of these materials may vary considerably from one manufacturer to another. Some manufacturers even provide combinations of both. Furthermore, even the manufacturing process utilized affects the long-term performance of the rubber material. Therefore one has to be careful in making assumptions about the performance of a particular type of housing material based solely on the family of rubbers from which it comes.

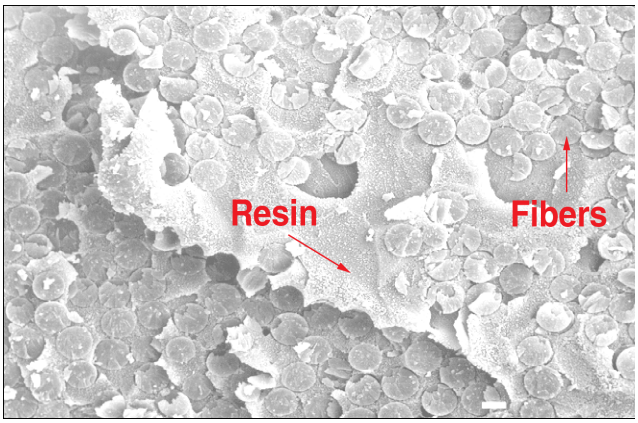

Figure 4.2-20 SEM image showing the resin fiber matrix.

In general, SIR-based materials provide a hydrophobic weathershed surface, and EPR-based materials provide a hydrophilic surface. (A more complete definition of hydrophobicity and its measurement is given in Section 4.2.3.) The implication of hydrophobic properties is discussed in more detail in the section below on silicone rubber.

It can be seen from the discussion that the choice of materials, especially for contaminated conditions, is not simple and may involve a certain degree of compromise. It is recommended, therefore, that data on previous experience with specific formulations in similar environments be obtained where possible (i.e., relevant service or outdoor test site experience).

Ethylene Propylene Rubber

There are several types of EP rubbers. The first generation of polymer insulator rubbers utilized ethylene and propylene monomers (EPM). Today most EP rubber insulators are made from three monomers: ethylene, propylene, and diene (EPDM). Some manufacturers also add small amounts of silicone polymer and indicate this by naming the material an "alloy" (Gorur et al. 1999).

Various additives are added to the polymer compositions to improve performance and satisfy manufacturing processes. For example:

- Inorganic powders such as Aluminumtrihydrate (ATH) are added to improve resistance to discharges, arcing, and tracking.
- UV stabilizing agents such as zinc oxide or titanium oxide are used.
- Cross-linking agents, such as dicumyl peroxide, may be used for vulcanizing.
- Chemicals are also added to obtain the required color.

The chemical structure of EP rubbers consists of a backbone of organic carbon molecules, and the side chain consists of hydrocarbon elements, as shown in Figure 4.2-21. The carbon content in EPDM is considerably higher than in silicone-based rubbers, and therefore, it is critical that it is prevented from degrading as the by-products are more likely to be carbon. Carbon can form a conductive path or track. To increase the tracking resistance, EPDM rubbers have large quantities of inorganic fillers—e.g., ATH (Gorur et al. 1999). One of the methods by which ATH increases tracking resistance is by forming moisture, which, in turn, cools the discharge activity (Meyer et al. 2004).

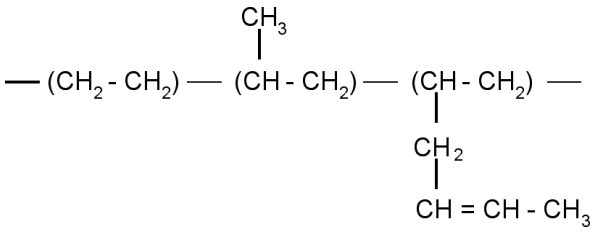

Figure 4.2-21 Chemical building block of an EPDM rubber.

EP-based rubbers have been shown to have good resistance to degradation due to surface discharges, and have performed well in many applications. Furthermore, EPDM usually have a higher tear resistance than silicone rubbers (Gorur et al. 1999). On the other hand, EPR surfaces wet out more easily, which permits a greater level of leakage current activity and a reduced flashover performance under contaminated conditions. Even so, leakage current and the associated discharge activity do not degrade EPR materials as significantly as silicone-based units. This is only a consideration when units are installed in environments where contamination is a concern. It should further be mentioned that EPR-based materials often show hydrophobic properties initially, but this may deteriorate significantly with exposure to the environment.

Silicone Rubber (SIR)

Three broad categories of silicone rubber used for insulation are:

- High Temperature Vulcanizing (HTV), also known as High Temperature Cured Rubber (HCR)
- Room Temperature Cured Vulcanizing (RTV)
- Liquid Silicone Rubber (LSR), also referred to as Liquid Injection Molding (LIM)

Most transmission-line applications today utilize HTV or LSR rubbers.

The chemical building block for silicone rubber is shown in Figure 4.2-22. It consists of an inorganic silicon-oxygen (Si-O) backbone and two organic side chains attached to the silicon atom. A methyl group (CH_3) is most often utilized for high-voltage applications, but other organic groups, such as phenyl or vinyl, may also be used.

Aluminumtrihydrate (ATH) or silica is added to improve resistance to discharges, arcing, and tracking. The proportion of filler compounds to silicone rubber and the form in

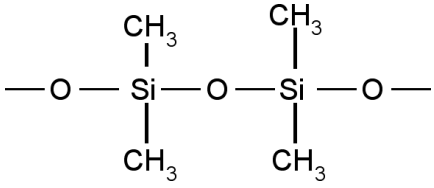

Figure 4.2-22 Chemical building block of silicone rubber (Gorur et al. 1999)

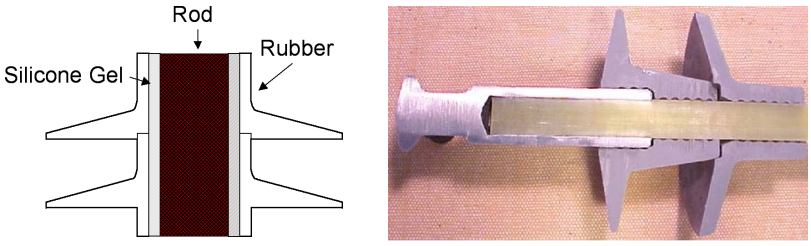
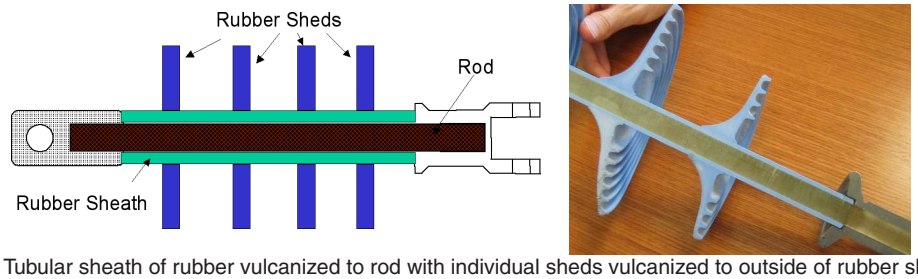
which they are added is an ongoing area of research (Meyer et al. 2004).

Silicone rubbers are characterized by having a low surface energy that results in highly hydrophobic surfaces. This property is considered important because it prevents the insulator surface from becoming completely wet, thereby suppressing leakage currents under contaminated conditions. Consequently, silicone rubber insulators generally offer a high contamination withstand and good aging properties, as long as they retain their hydrophobicity. Additionally, silicone rubbers have a unique property whereby lightweight silicone molecules continuously migrate to the rubber surface and can encapsulate contamination, resulting in a transfer of hydrophobicity. There are, however, conditions during which the silicone rubber may temporarily lose its hydrophobic properties. If the insulator is subjected to significant levels of discharge activity for long periods of time, the result may be a significant degradation of the rubber material and in extreme cases the exposure of the core rod (Phillips et al. 1999a, 1999b).



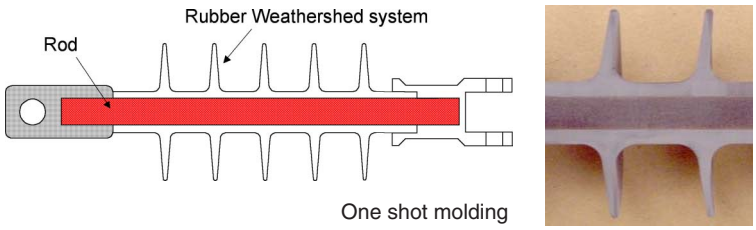
A unique feature of silicon rubber insulators is their ability to regenerate surface hydrophobicity once it has been lost. It is generally believed that after hydrophobicity is lost, if the factors causing this loss are removed, then the insulator will regain its surface hydrophobicity within 24 to 48 hours.

Housing Core Interface



Some common methods for attaching the housing to the core rod are (EPRI 2002b):

- One-shot compression molding the rubber weathershed system onto the rod.
- High-temperature vulcanizing a tubular sheath of rubber to the rod to form the sheath. Individual sheds are then vulcanized to the outside of the sheath.
- One–shot, high–temperature, and pressure molding of the rubber weathershed system onto the rod.
- Sliding individual or multiple shed/sheath units over the rod with an active silicone gel interface between the rod and rubber.



These methods are illustrated graphically and with photos in Figure 4.2-23.

Single or multiple shed units slipped over rod with a silicone gel interface

Tubular sheath of rubber vulcanized to rod with individual sheds vulcanized to outside of rubber sheath.

One shot molding

Figure 4.2-23 Different methods of constructing polymer insulators (note photographs of dissections of actual insulators) (EPRI 2002b).

Metal End Fittings

The metal end fittings serve two functions. The first function is that they provide the mechanism by which the fiberglass rod is attached to the structure and conductor hardware. The second function is to act as part of the ceiling system designed to prevent moisture ingress into the insulators' rod and rod-rubber interface. These components are made of hot-dipped, galvanized, forged steel or ductile iron. Transmission polymer insulator end fittings are not manufactured from aluminum since the melting point of aluminum is lower than the arc root temperature of a power arc (EPRI 1998).

A range of connection methods are available that can be fitted to longrod insulators. Some of the most often used include socket, ball, oval eye, and Y clevis. For post-type units, both rigid and bendable bases are used at the grounded end and are manufactured from ductile iron, rolled steel, or aluminum. The conductor is attached to the energized end of the post insulator, utilizing either a horizontal clamp top, as shown in Figure 4.2-24, or a drop tongue.

Today, metal end fittings are generally swaged or crimped onto the rod by a compression process, but in the past, other fixing methods, such as epoxy cones or metal wedge designs, have also been used. The crimped end fitting design is preferred because the stress concentrations inherent in the other designs can be avoided by grading the compressive forces during fitting attachment. Figure 4.2-25 shows typical cross-sections of swaged, epoxy, and cone end fittings (EPRI 2002b). Care needs to be taken to avoid over-compressing during manufacture, resulting in stress concentrations and possibly rod fracture. Care also needs to be taken to avoid under-compression, resulting in a mechanically weak insulator that may fail due to pull-out (Mobasher 2003).

f. Dissection of metal wedge end fitting

Figure 4.2-25 Dissection of different end fittings / rod attachment methods (note: most insulators in service are of crimped, or swaged, end fitting design) (EPRI 2002b).

End Fitting Seal

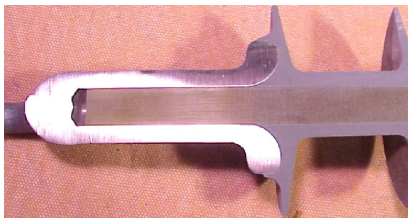
One of the most vulnerable regions of a polymer insulator is the interface between the end fitting, polymer housing, and the core rod, known as the end fitting seal. Its function is to prevent moisture or contamination from penetrating to the FRP rod, an event that is likely to precipitate a failure.

End fitting seals may be made in a number of ways, including (EPRI 2002b):

- Direct bonding of the rubber weathershed system to the metal end fitting.
- Single or double O-rings.
- A compression seal between the polymer housing and the metal end fitting.
- A metal connection piece between polymer housing and the metal end fitting.
- An external or internal sealant applied in the interfacial region. In some cases, a so-called metastable sealant is utilized, which is one that does not fully cure and remains "tacky." This allows for different coefficients of expansion between the materials used in the sealing interface.

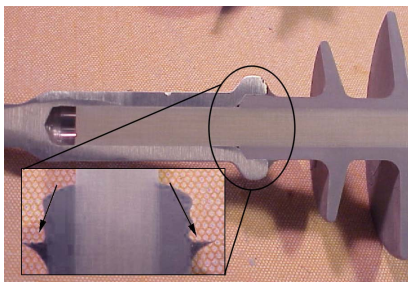
Some designs incorporate more than one of the above sealing methods. Figure 4.2-26 shows examples of the different approaches.

E-field Grading Devices



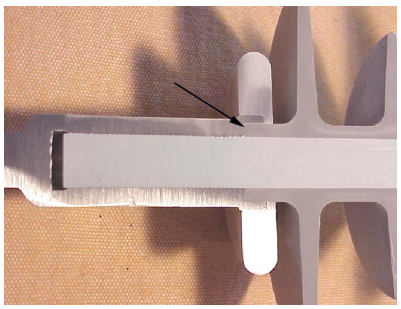
Research and service experience have shown that the electric field (E-field) within the rubber and rod material, as well as in the air close to the surface of a polymer insulator, needs to be controlled because it affects both the long- and short-term performance (Phillips et al. 1999a, 1999b; EPRI 2000a, 2002a, 2003a, 2004a). Reasons for this are discussed further in Section 4.4.3 on polymeric insulator aging and in the section on E-fields, Section 4.9.

The E-field needs to be controlled in the following regions (EPRI 1999):

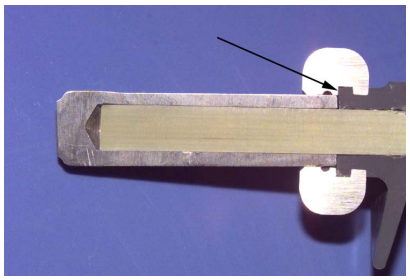


- Within the rubber and rod material
- On the surface of the metal end fittings, hardware, and corona rings
- On the surface of the polymer housing.

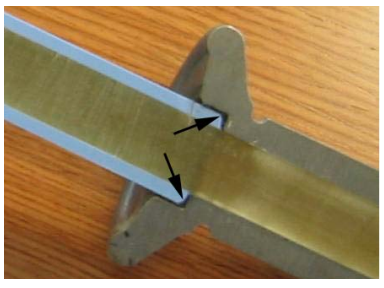
One or more of the following three methods may be used to achieve a proper E-field grading:



- The dimensioning and geometry design of the metal end fitting
- Attached E-field grading devices (often made of aluminum)
- Attachment of corona ring(s) at the high- and low-voltage ends (also called grading rings).



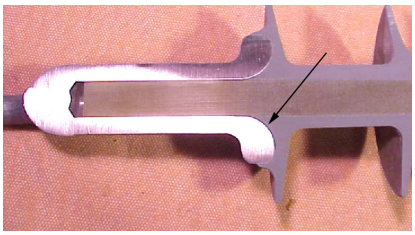
a) Direct Bonding of rubber onto metal end fitting



b) O-ring seal with outer sealant

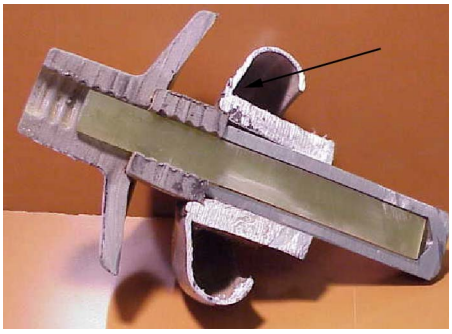
c) Compression end fitting seal

d) Intermediate Al ring forms part of end fitting seal. Sealant, compression, and internal gel all form part of end fitting seal.



e) Metastable sealant

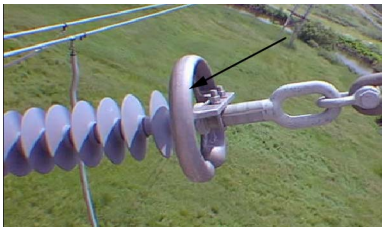
Figure 4.2-26 Examples of approaches to end fitting seals.



These methods are illustrated in Figure 4.2-27. Depending on the manufacturer and insulator application, one or all of the above may be utilized.

Corona rings need to be dimensioned by considering the system voltage, hardware geometry, structure dimensions, conductor bundle configuration, insulator parameters, and manufacturer recommendations. Depending on the system voltage level, corona rings may be necessary at the live end or/and at the grounded end of the insulator. Section 4.9 describes corona ring selection in more detail.

Other aspects that need to be considered when designing corona rings is their power arc withstand capability and attachment method.



a) Dimensions and geometry of end fitting used to grade E-field. Note large and curved end fitting. (Manufacturer-specific)

b) E-field grading devices permanently attached to end fitting. Note large dimensions and curved edges. (Manufacturer-specific)

c) Corona (grading) ring attached at energized end of insulator. (Not all applications – installed in incorrect location with respect to end fitting for test purposes)

d) Corona (grading) ring attached at grounded end of insulator. (Not all applications)

Figure 4.2-27 Examples of E-field grading devices.

4.3 THE MECHANISM OF CONTAMINATION FLASHOVER

4.3.1 Introduction

Contamination-related outages came to the fore soon after the introduction of high-voltage transmission in the 1930s, which prompted the development of many of the presently used insulator monitoring-techniques, such as leakage current measurement. (Note: In other parts of the world, the term insulator "pollution" is also used. The words "pollution" and "contamination" will be used interchangeably in this text.) Since then, the study of transmission-line performance under contaminated conditions has become increasingly important. Both the IEEE and CIGRE have active and long-standing working groups dealing with this subject. The work of these groups culminated in a series of important review publications (Lambeth 1971; IEEE 1979; CIGRE 2000b). Also, during this time, polymer insulators were developed, which proved to be effective in reducing the number of contamination-related outages, especially if the insulator housing material was hydrophobic. Polymer insulators are, however, more prone to the effects of aging—an issue that will be dealt with in Section 4.4.

Power frequency flashovers on transmission systems are normally the result of airborne contamination that is deposited on the insulators. These contaminants may originate from natural sources such as the sea or desert, or they may be generated by industrial, agricultural, or construction activities. One of the most common contaminants is sea-salt (sodium chloride), which may cause severe problems on transmission-line insulators in coastal areas. Other types of salt, such as magnesium chloride, may cause problems in inland areas, where it is increasingly used on highways to combat ice during the winter season. In industrial or agricultural areas, a great variety of substances, such as gypsum, sulfuric acid, fly ash and cement, may be present as contamination on the insulators. Generally these deposits do not decrease the insulation strength when dry; they only become a threat under wet conditions, when the salts contained in the deposit dissolve to form a conductive layer on the insulator. Often, however, the contamination may already be in the dissolved state when deposited onto the

insulator, as may happen when the insulators are exposed to a saltwater fog. Under certain extreme cases—for example, close to certain types of mining activity—the deposits themselves could be conductive (e.g., metallic or carbon deposits); wetting is not required to reduce the strength of the insulator.

The formation of a conductive layer on an energized insulator leads to the flow of leakage current and the formation of dry bands in the areas with a high current density. When this happens, the voltage distribution along the insulator becomes highly nonuniform, with most of the voltage stress concentrated over the dry bands. This concentration of voltage stress may cause the dry bands to spark over. If this happens, a partial arc is established in series with the resistance of the conductive layer on the insulator. Depending on the layer conductivity, this partial arc may grow to span the whole insulator, leading to flashover.

In summary, there are three aspects that play an important part in the contamination flashover process (CIGRE 1979b):

1. Buildup of contaminants on the insulator surfaces
2. Wetting of the insulator
3. Discharge activity and its development into flashover.

Each of these aspects may comprise several subprocesses, as highlighted in Table 4.3-1. Although these are listed as individual items in the table, they actually combine into one seamless process. Some of the listed items may occur simultaneously, while others may happen at different times.

In practical situations, two types of contamination are generally identified: in this chapter, the terms "solid" and "liquid" contamination will be used. In the revised edition of the IEC 60815 (IEC Forthcoming b), these types are identified as Types A and B, respectively. These two types can be described as follows (CIGRE Forthcoming):

- **Solid contamination, or predeposited contamination.** Contaminants are deposited. Flashover may occur in a separate phase when the insulator is critically wetted by rain, fog, or condensation.
- **Liquid contamination, or instantaneous contamination.** Contaminants and wetting are deposited on the insulator surface simultaneously, which may result in flashover.

Of these two, solid contamination occurs more frequently, and it may originate from industry, agriculture, mining, bird feces, road-salt, or the sea. Examples of liquid contamination are conductive fog (or salt-fog) conditions or liquid salt spray directly from the sea.

The deposition and wetting conditions associated with solid and liquid contamination are distinctly different, as will be highlighted in the sections that follow.

4.3.2 Buildup of Contaminants on Insulator Surfaces

Types of Contaminant

Solid Contaminant

The deposited dry contaminants can be described in terms of two distinct components (CIGRE 2000b):

1. *Soluble contaminant* that, when in dissolved in water, will form a conductive solution. Examples include ionic salt such as sea-salt (NaCl), gypsum, and $CaSO_4$, or other constituents such as fly ash and cement.
2. *Nonsoluble contaminant*, which reduces the insulator's flashover voltage due to retention of water and the resulting influence on the formation of the conductive layer. Nonsoluble pollution may also be hydrophobic, such as oily or greasy substances that may enhance the insulator flashover characteristics.

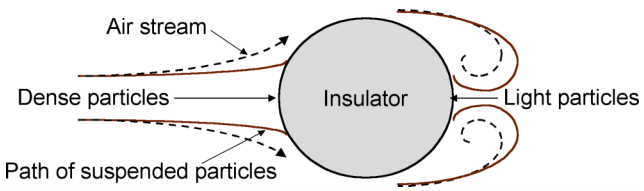
Liquid Contaminant

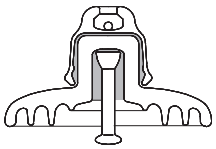
The active component of liquid contamination is already in the dissolved state when it is deposited on the insulator surface. Typical examples are: saltwater spray close to the coast or gases in solution, such as SO_2, H_2S, or NH_3 close to chemical plants. Liquid contamination generally contains little or no nonsoluble contaminants.

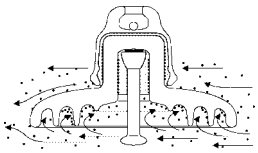
Mechanism of Contaminant Deposit

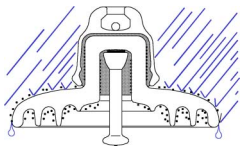
There are several mechanisms by which solid or liquid contaminants can be deposited onto the insulators.

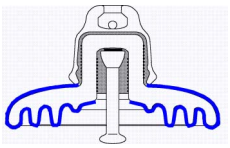
- **Aerodynamic action.** Contamination particles suspended in the air can be carried over great distances by wind (Fikke et al. 1993). When this contaminant-laden air encounters an insulator, the air is deflected around the insulator body. The particles suspended in the air are, however, not deflected to the same extent and are deposited on the insulator. Denser particles (e.g., sand) will be deposited on the windward side of the insulator since they are not sufficiently deflected by the airflow, as illustrated in Figure 4.3-1. Less dense particles will fol-

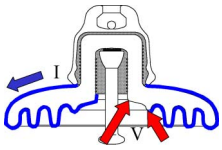


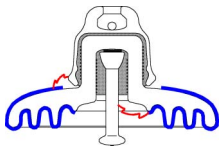


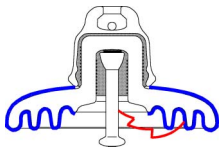












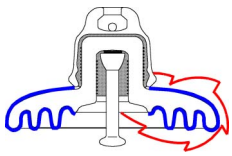


Figure 4.3-1 Pollution deposit by aerodynamic action (Looms 1988).

Table 4.3-1 Key Processes of the Contamination Flashover Process

	Description and Mechanisms	Influencing Factors	
	1.Clean Insulation surface	None	
Contaminant Build-up	2. Contamination Deposited a. Airborne particles b. Salt spray c. Under dry conditions, surface remains a good insulator	- Aerodynamic properties - Surface properties - Contamination type - Electric field (mainly dc)	
	3. Cleaning (removal of contamination) a. Rain b. Wind	- Insulator profile - String orientation - Precipitation type and intensity	
Wetting	4. Wetting of Contamination Layer a. Condensation b. Fog c. Rain d. Absorption e. Chemical Diffusion	- Contamination type (e.g., salt solubility) - Insulator profile - Surface properties - Wetting type	
Discharge Activity and Flashover	5. Formation of Dry Bands a. Leakage current flows on surface b. Increased heating in regions of high current density c. Dry bands form in regions of increased heating	Surface resistance • Humidity of air • Rate of rainfall • Level of contamination - Distribution of contamination - Insulator geometry	
	6. Dry Band Arcing a. Dry bands interrupt leakage current flow b. Full voltage across dry bands c. Air/surface cannot maintain potential difference d. Arcs form across dry bands e. Leakage currents surge when arcs form	- Surface properties - Degree of wetting - Level of contamination - Size of dry band	
	7. Growth/Quenching of Dry Band Arcs a. Dry band arcs sustained if surface resistance of entire string is low enough b. Increased heating at arc roots dries out contamination, increasing dry band size and hence arc length c. Surface resistance decreases with increases in arc lengths, resulting in increased leakage current magnitudes c. Arc grows and may self-extinguish as gap bridged becomes too large for arc to maintain itself. d. Arcs may be quenched by precipitation	-Surface Resistance • Rate of precipitation • Humidity • Amount and type of contamination • Surface properties - Insulator profile	
	8. Flashover a. If dry band arcs bridge a critical length of insulator, flashover occurs b. Multiple arcs may join (coalesce) c. Single arc may grow entire length	-Surface Resistance • Rate of precipitation • Humidity • Amount and type of contamination • Surface properties - Insulator profile	

low the airflow more closely and will only be deposited in areas where the airflow becomes turbulent (i.e., small curvature of the airflow), such as on the leeward side of the insulator or between the shed under-ribs (Looms 1988). Figure 4.3-2 shows the concentration of the contamination deposit in areas of turbulence, as indicated by the arrows. Aerodynamic action is, with a few exceptions, the dominant mechanism of contamination deposit (Taniguchi et al. 1979).

- **Precipitation by gravity.** Under low wind or still conditions, suspended particles in the air will precipitate and settle on horizontal surfaces under the influence of gravity. Precipitation by gravity may be the dominant mode of pollution deposition in areas close to a distinct contamination source, such as an industrial plant.
- **Heating effect of leakage current.** During conductive fog conditions, the heating effect of the current evaporates the water from the wet contaminant, leaving a salt residue behind. This residue is normally concentrated around the areas of the insulator with the highest current density. Heating by leakage current occurs on insulators installed close to the coast that are exposed to salt-fog.
- **Electric field.** Contamination may be deposited on the insulator surfaces due to the force exerted by the electric field on charged particles. This effect is, however, negligible under power-frequency energization, because of the alternating polarity of the field. It is more relevant for direct current energization, which falls outside the scope of this document.

Natural Cleaning of Surface Contaminant

Generally, two agents may remove contaminants from the insulator surface, thereby reducing the risk of flashover. These are:

1. **Precipitation.** High-intensity rain is very effective in removing contaminants from insulator surfaces. Exposed (i.e., top) surfaces that come in direct contact with the rain are most effectively cleaned. The more protected, or bottom, surfaces on the insulator may also undergo a significant amount of cleaning, but it is reduced as the amount of "protected" creepage increases (Kimoto et al. 1972).
2. **Wind.** In desert areas, strong winds may carry large sand particles that have a "sand blasting" effect, removing pollutants from the windward side of the insulator.

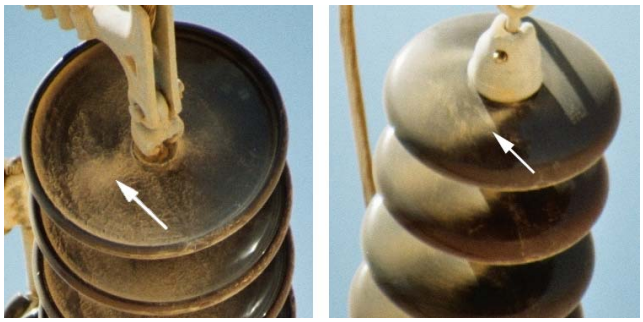

Figure 4.3-2 Photographs showing typical particle distribution on aerodynamically contaminated insulators. Note the concentration of the contaminants in areas of turbulence, as indicated by the arrows.

Accumulation of the Contaminants on the Insulator Surface

Solid Pollution

Contamination settles on the insulating surfaces in the form of dusty deposits. The contamination may be naturally removed from the insulators by the mechanisms indicated. The extent of this removal is related to the intensity and duration of the cleaning event. As a result, the level of contamination deposit varies over time, with the highest levels occurring at the start of cleaning events. Over time, equilibrium is reached when the rates of deposition and cleaning are in balance with random variations. Depending on the environment, it may take from weeks to years to reach this equilibrium (Looms 1988). In cold climates, where icing performance is a concern, the longest periods without rain tend to occur over the winter season. For example, climate norms for Minneapolis, Minnesota in the U.S. suggest that maximum temperature will be below freezing from December to March, a period of 120 days, well in excess of the days between rain events during the spring, summer, and fall.

Liquid Pollution

Wet pollution is characterized by the fast buildup of contaminants during events when the insulator is exposed to simultaneous pollution and wetting. In this case, the heating effect of the leakage current plays a major role in the deposition process, with the highest pollution deposit occurring in the areas with the highest current density on the insulator (IEEE 1979). The buildup of the deposit on the insulator may, in fact, be so fast that a clean insulator can build up sufficient contaminants to flash over during a single event. Thus natural cleaning has little influence on the flashover process in the case of liquid pollution.

Effect of Insulator Properties on the Accumulation of Contaminants

From the description above, it should be clear that the level and distribution of contamination are the result of a complex interaction between the insulator and the environment. This process is influenced by the profile of the insulator, its surface properties, and the orientation in which the insulator is installed. All these factors need to be taken account of when selecting insulators for a particular environment. Some guidelines are provided below:

Profile

- When insulators with convoluted profiles are exposed to wind-borne pollution, vortices are created by the underribs, which are conducive to the deposition of pollution, as illustrated in Figure 4.3-3 (Looms 1988). These regions are also sheltered, reducing natural cleaning and resulting in high contamination levels over time.
- Insulators shapes having large horizontal surfaces are at a disadvantage when contaminated by gravitational precipitation, as these surfaces present large areas on which the contaminants can settle.

Based on these principles, it can be concluded that: Open aerodynamic profiles tend to be beneficial in areas where there is a risk of a long-term buildup of airborne contaminants since these profiles collect generally less pollution and are accessible for natural or artificial cleaning. When there is a risk of a rapid buildup of contaminants, such as during storm conditions, profiles with a more convoluted design can be advantageous since large parts of the surface are "protected" from fast pollution accumulation. Likewise, profiles with large horizontal surfaces should be avoided when there is a significant gravitational precipitation.

Surface Properties

The insulator surface properties are also important in determining how much pollution attaches to the surface:

- Smooth surfaces accumulate less pollution than rough ones.
- Dry surfaces retain less pollution than damp ones.
- Studies have shown that silicone rubber insulators, due to the presence of the silicone oils, collect more contaminants than glass or ceramic surfaces (Naito et al. 1999); however, this is offset by the hydrophobicity encapsulation of the pollution layer (Kindersberger and Kuhl 1991). The surface hydrophobicity also influences the uniformity of the pollution deposit. The surface hydrophobicity causes the contaminated water drops to bead on the surface, leaving distinct spots of contamination behind when the water evaporates (Karady et al. 1995). On the other hand, solid pollution is not affected in the same way—due to absence of water—resulting in a more uniform deposit (Besztercey and Karady 2000; Engelbrecht et al. 2003).

Insulator String Orientation

Vertically orientated insulator strings (I-strings) collect more contamination than angled (V-strings) or horizontally (dead ends) installed units since there are large sheltered areas on the underside of the insulator where natural cleaning is less effective.

Horizontally orientated insulator strings pointing to, or from, a well-defined source may collect more contamination than strings pointing in other directions due to the larger windward and leeward regions where airborne deposition may occur (Houlgate et al. 1982).

4.3.3 Wetting Processes

Wetting Mechanisms

It is commonly recognized that flashovers caused by contamination generally occur during drizzle, fog, or high humidity conditions due to a reduction in the surface resistance. Four wetting processes are recognized (Karady 1975; Leclerc et al. 1982; Chrzan et al. 1989):

- **Collision of water droplets.** The insulator is wetted by the collision of free water droplets in the air (e.g., during rain, mist, or fog) with the insulator. The distribution of the wetting on the insulator is dependent on the insulator shape and the droplet size. Small droplets are more likely to wet the insulator underside since they are more influenced by air movement around the insulator.

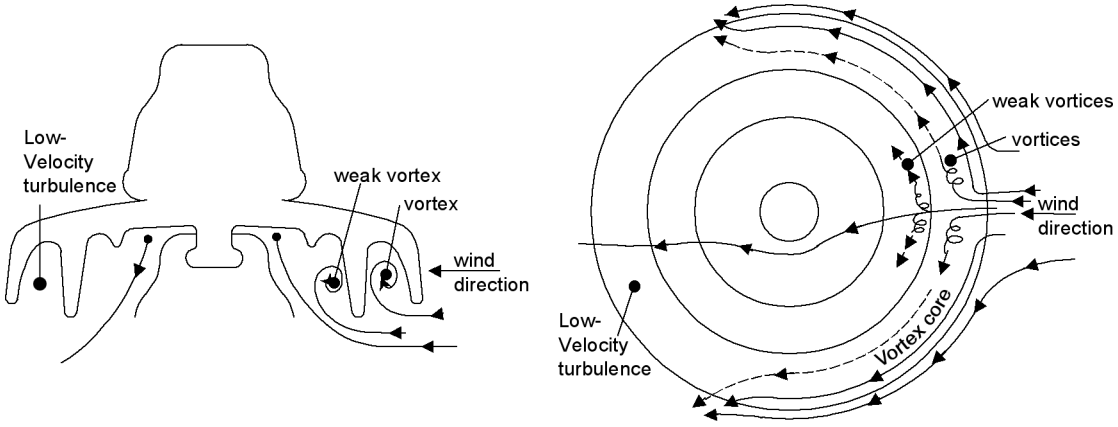

Figure 4.3-3 Airflow around a disc insulator (Looms 1988).

- **Hygroscopic behavior of surface deposits (absorption).** Surface contamination absorbs water molecules from the air by the process of deliquescence if it is salt, or absorption if it is a nonsoluble material. For typical contamination layers, this process occurs when the partial vapor pressure of the ambient is greater than the vapor pressure of the salt; for sodium chloride, this occurs approximately at a relative humidity of 75%. The type of salt and inert material present determines the distribution and amount of the wetting.
- **Condensation.** Condensation occurs when the insulator surfaces are colder than the ambient temperature and are below the dew point temperature. The temperature difference is due to thermal lag or radiation, and is therefore influenced by the thermal properties of the insulator. Polymer insulators, due to their low thermal conductivity and thermal mass, adjust quickly to the ambient temperature, resulting in small temperature differences, while a larger temperature difference would occur with glass and porcelain insulators during the same conditions. Hence polymer insulators have less condensation than glass or porcelain insulators (Engelbrecht et al. 2003).
- **Chemical diffusion.** The condensation rate is higher for solutions than for pure liquids due to the phenomenon of chemical diffusion. This is a contributing factor that results in a higher rate of condensation on moist contaminated surfaces than on clean surfaces.

These wetting processes combine during different ambient conditions to produce a characteristic wetting-pattern on the insulator surface. Some examples are:

- **Clear conditions.** Under clear air conditions, moisture can only be deposited on the insulator via condensation or moisture absorption. The whole insulator surface is likely to be wetted during these conditions. Typically this occurs during late night or early morning when the insulator may be cooler than the ambient air due to thermal radiation or thermal lag.
- **Fog or mist:** Fog occurs when the ambient air is cooled down sufficiently that condensation occurs in the air itself, resulting in suspended water droplets. The wetting of the insulator surface is mainly through collisions of fog droplets with the insulator surface, but condensation and absorption also make a significant contribution. The whole insulator surface is likely to be wetted during these conditions, unless there are deep shed under-ribs present that prevent effective droplet collision with the protected parts on the insulator.
- **Salt spray.** In areas close to the coast, wind can transport the salt-spray produced by the breaking waves. Wetting occurs due to the collision of the droplets with the insulator surface. The distribution of the wetting is mainly determined by the aerodynamic properties of the insulator and the size of the salt-water droplets. Logically, the exposed upper surfaces are wetted most effectively, but the insulator underside may also be wetted to some extent due to the turbulence created by the under-ribs, if present.
- **Rain.** Rain wets the insulator surface by the collision of the raindrops with the insulator surface. It is mostly the upper surfaces of the insulator that are wetted while the "protected creepage" remains relatively dry.

The rate by which the moisture impinges on a contaminated insulator may vary from light, during mist or fog, to heavy, during rain. It may further impinge on the insulator surface gently, as during a light drizzle, or violently as during a wind-driven downpour. As the rate of the wetting increases, so does its natural cleaning effect, as was discussed in the previous section. These are important factors that need to be considered when identifying when wetting conditions pose the greatest risk to the insulators.

Critical Wetting on Solid or Predeposited Contamination

In an area characterized by a predeposited contamination layer, the soluble electrolytes within the contamination coating gradually dissolve. A thin film of conducting liquid then forms on the insulator surface if it is hydrophilic, or droplets form if the surface is hydrophobic. As the wetting continues, a redistribution of the contamination may take place, and some of the contamination may even leach by run-off. Because of these processes taking place, the surface resistivity initially decreases due the salts that dissolve and increases after a while due to the leaching effect.

The minimum resistivity of the layer (i.e., highest conductivity) and the time at which it occurs are very dependent on solution characteristics of the predeposited contamination layer. Both the solubility and the speed by which it goes into solution play an important role (Williams et al. 1974; Ramos et al. 1993).

- The impact of the wetting rate on the flashover voltage is greater for low-solubility than for high-solubility salts. This was illustrated during laboratory tests that found a greater reduction in flashover voltage as a function of the steam input rate on insulators polluted with gypsum, as compared with insulators polluted with sea-salt (Campillo et al. 1995).
- The amount and type of nonsoluble contamination present also influence the wetting process. The nonsoluble contamination "binds" water to the insulator surface, which helps the formation of the low-resistance layer, resulting in a lowering of the flashover voltage.
- Different kinds of inert material influence the time it takes to reach the minimum resistivity and the value of

the minimum resistivity depending on its hygroscopic and hydrophobic properties (Matsuoka et al. 1996).

It can thus be seen that the surface conductivity of the insulator is the result of a complex process that depends not only on the amount of moisture and the chemical composition of the soluble and nonsoluble contaminants, but also on the material and shape of the insulator itself. On this basis, the critical wetting is defined as a wetting rate that is fast enough to wet the pollution sufficiently for the flashover process to take place and slow enough not to wash the pollutants from the insulator surface. In general, it can be stated that low wetting rates, such as during fog or mist, are critical for fast dissolving salts, and a heavy wetting rate is required to produce critical conditions for slow dissolving salts. For instance, in coastal areas where the main pollutant is sea-salt (NaCl), condensation or fog conditions generally provide sufficient wetting to dissolve the contamination layer, whereas in certain industrial areas, where gypsum is prevalent, a more severe wetting condition, such as rain, is needed to dissolve the contamination layer.

Wetting Aspects When Dealing with Liquid Contamination

Under conductive-fog conditions, the contaminants are deposited in the dissolved state. This is typical of sea storms when sea spray may be carried inland by wind, or close to industrial plants where the insulators may be exposed to a conductive rain or fog. The dissolving characteristics of the salts involved are in this case not important; what is important is the conductivity of the solution itself. A higher conductivity solution results in a greater risk of flashover. Leakage current flowing in the surface layer will cause a drying out in the areas of the insulator with the highest current density, and the initiation of dry-band activity (Lambeth et al. 1973). This electrical activity may also enhance the deposition of salt on the surface due to the heating effect of the current.

4.3.4 Discharge Activity and Development of Flashover

A critical part of the contamination flashover process is the formation of the conductive layer on the insulator's surface. The presence of such a layer invariably leads to a very nonuniform voltage distribution along the insulator and the inception of discharge activity. Depending on the conductivity of this layer, the wetting conditions, and the surface properties of the insulator, the discharge activity may develop into a flashover. The discharge development is basically the same for both solid and liquid pollution types, so no distinction will be made in the text that follows. However, the discharge development is markedly different on hydrophilic (e.g., ceramic and glass) and hydrophobic (e.g., silicone rubber) insulators. These two types of insulator will, therefore, be treated separately.

Hydrophilic Insulators

Contamination Flashover Process on Single-Unit Insulators

Development of electrical discharges on contaminated insulators will be discussed with reference to the simplified diagram presented in Figure 4.3-4.

The following description covers the flashover process from the formation of dry bands to the final arc in terms of the steps identified in Figure 4.3-4.

- **Condition A.** As wetting increases, the impedance of the insulator lowers and changes from mainly capacitive, at the start of the wetting, to mainly resistive. This is demonstrated by the change of surface impedance over time presented in Figure 4.3-5 (Kawai 1971; Standving 1934; John and Clark 1939), as measured during laboratory tests. The increase of the capacitance shown in the figure is a result of the increase in the conductive area on the insulator surface.
- **Condition B.** This drop in impedance leads to an increased level of leakage current across the insulator, which, in turn, leads to the formation of dry bands in the areas with the highest current density due to localized heating. On disc insulators, this is around the pin-and-cap area. The dry band blocks the flow of leakage current, which results in a concentration of the applied voltage over the dry bands. Figure 4.3-6 shows this voltage drop around the pin area of the disc insulator, as measured during laboratory tests. Corona and sparking activity ensues, which leads to a further drying out and an increase in the size of the dry band, until a stable con-

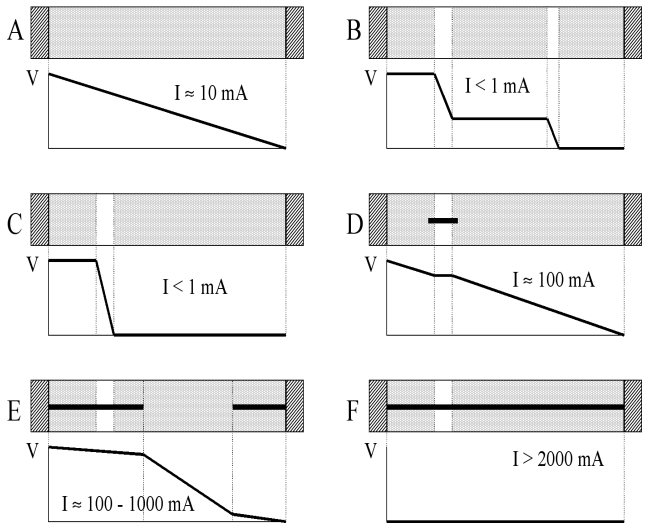

Figure 4.3-4 Typical steps and their associated voltage distribution, in the discharge development of contaminated insulators. (A - Wetting begins, B - Dry bands form, C - Consolidation of dry bands, D - Scintillation, E - Discharges extend, F - Flashover) (Lambeth 1971).

dition is reached where the dry band can withstand the applied voltage with occasional sparkovers (Lambeth 1971).

The degree to which dry bands form initially and the rate at which they reabsorb moisture depend on the intensity of the wetting process and the drying effect of the leakage current. In falling rain conditions, the wetting action may be so intense that dry band formation may not be possible until after the rain ceases.

- **Condition C.** When the dry band is established, the general level of leakage current over the insulator drops, which allows the wetting process to overcome the drying effect of the leakage current. On long-rod insulators, this may lead to the re-wetting of the smaller dry bands and the formation of only one dominant dry band, which is maintained by the heating effect of the discharge and corona activity (Chrzan 2003).
- **Condition D.** During the occasional sparkovers of the dry band, the voltage distribution over the insulator becomes more linear. This is supported by experimental findings, such as those presented in Figure 4.3-7, which shows the average measured voltage distributions along the insulator surface for different levels of leakage current. This linearization is more pronounced at higher levels of leakage current, and it is caused by the voltage drop associated with the current flow through the conductive surface layer (Lambeth 1971).
- **Condition E.** Exactly how the scintillation activity develops into flashover is not yet fully understood, as there are many factors that influence this process. Most theoretical studies have been based on a simplified model that assumes the contaminated insulator surface is already wetted and highly conductive (Rizk 1981; Hampton 1964; Nasser 1968; Woodson and McElroy; 1970). However, these models ignore the drying effect of the leakage current and partial arcs on the wet pollution layer, which in some cases can be so intense that it extinguishes the partial arc over the insulator, preventing flashover despite a high level of leakage current.

  However, on single-disc insulators, it is known that the arc develops from the high-voltage electrode, and that the complete flashover is the result of the growth of the partial discharges to span the whole insulator length.
- **Condition F.** At an advanced stage of discharge development, flashover is determined by the breakdown strength of the contamination layer, which holds most of the voltage (Lambeth 1971).

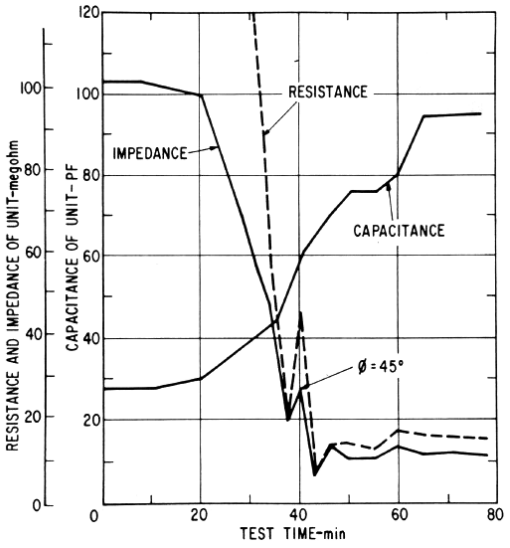

Figure 4.3-5 Example of dynamic surface impedance of standard insulators. (Salt-deposit density = 0.07 mg/cm^2; kaolin = 40 g/l.) Applied voltage per 5 $^3/_4$ in. (146 mm) disc = 6.3 kV.

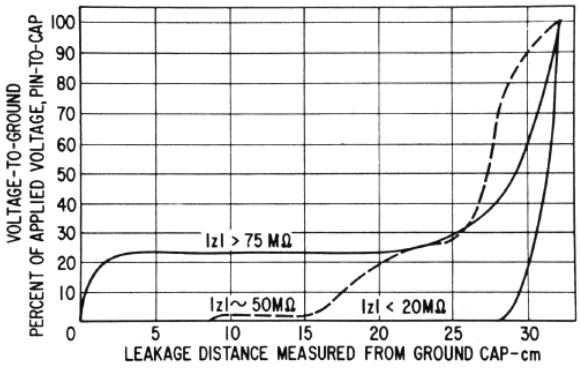

Figure 4.3-6 Voltage distribution measured from grounded cap before onset of scintillation for different values of surface impedance magnitude.

Flashover Mechanism of Long Insulator Strings under Light Wetting Conditions

During the contamination tests at Project UHV (EPRI 1982), which were performed under a relatively low degree

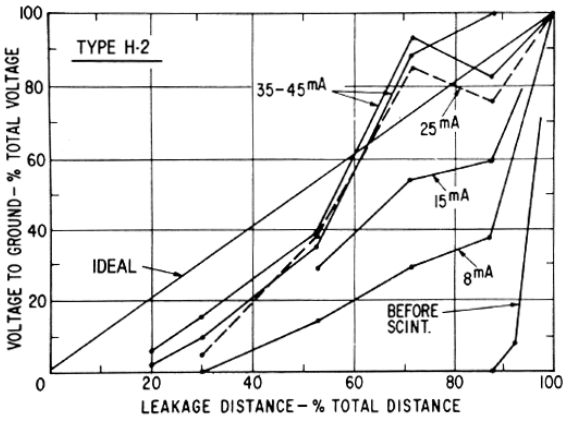

Figure 4.3-7 Typical measurement results of the dynamic voltage distribution on a disc type insulator under various levels of leakage current.

of wetting, it was found that a nonlinear voltage distribution on the insulator string might exist. This suggests that the contamination flashover of long insulator strings might be different from that of single insulator discs. From observations, the following phases in the flashover process were identified:

- Initially, the contaminated insulator surface is completely dry. Consequently, the voltage distribution on the string may be regarded as the same as that on a dry, clean insulator string (i.e., mainly capacitive). The equivalent circuit may be represented by a network of capacitances only, since the leakage resistance of the insulator surface may be ignored (see Figure 4.3-8). This distribution is usually nonuniform, with the highest voltage stress on the insulators closest to the high-voltage end.
- As the wetting progresses, the resistance of the insulator becomes more important. The value of this resistance is influenced by the drying effect created by leakage current and corona discharges, which are functions of the voltage across individual discs. Since the electric field distribution along the string is not uniform, the voltage across the units closest to the conductor is higher, and hence these units dry out first, forming a dry zone.

  The surface temperature of the discs in the dry zone is much higher than that of the insulators on the remaining section of the string. A wet zone is usually formed at the midsection of the string, where the voltage drop is the lowest. Thus the nonuniform voltage distribution can be held throughout the time of wetting. Surface leakage current in this period is about 100–600 mA (rms).
- As the dry zone dries out further and the wet zone becomes wetter, the voltage across the dry zones increases. Finally, the units on the bottom section can no longer withstand the voltage stress, and they flash over. This is observed when an arc bridges several units at the bottom of the string.
- The activity develops upward. The arcs bridging the bottom section result in an overvoltage over the rest of the string, producing heavier activity along the string. This activity appears as leakage current surges, usually having peak values ranging from 500 to 700 mA (rms).
- The leakage currents dry the insulator surfaces in the wet zone, linearizing the voltage distribution along the entire string and reducing the voltage drop across the initial dry zone, extinguishing the arc. However, this heavy activity does not make the insulator surfaces in the wet zone as dry as those of the dry zone of the string.
- After the activity has ceased, the insulator surfaces under low-voltage stress begin to absorb moisture, making the values of surface impedance lower. The units in the high field region do not absorb as much moisture due to their higher temperature. Therefore, the voltage distribution along the string again becomes nonuniform enough to produce another surge. This process is repeated either until a flashover develops or until the surge activity gradually disappears as the contaminants are leached from the insulator surface.

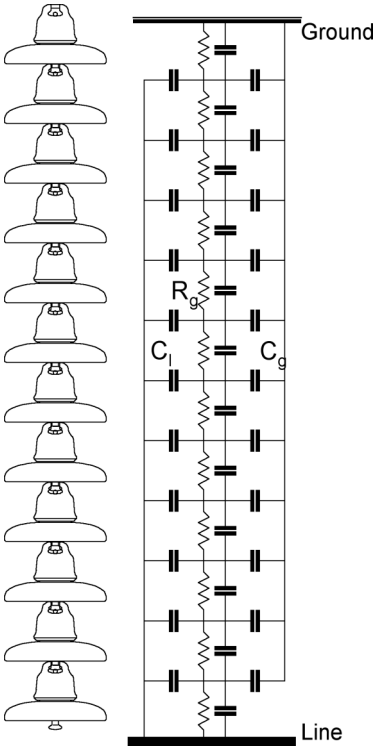

Figure 4.3-8 Equivalent circuit for voltage distribution along a contaminated insulator string.

Because it is a thermal process that causes the nonlinearity of the voltage distribution along the string (Boehne and Weiner 1966, 1967), it does not appear when the rate of surface wetting is fast enough to overwhelm the drying effect of the leakage current. Since the rate of wetting in natural conditions is often low, this nonlinear phenomenon has only been found for those tests in which the wetting condition was arranged to duplicate a natural wetting process. These nonlinear effects are reduced when the voltage distribution along the insulator string is made more uniform by the application of a grading/corona ring, an effect that has been illustrated in tests.

Influence of Pollution Level and Degree of Wetting on Flashover Development

Observations of artificially polluted insulators under natural wetting conditions have shown that the degree of discharge activity is a function of both the contamination severity and the degree of wetting (EPRI 2004f). These observations were performed during times when condensation and moisture absorption were the main wetting pro-

cesses. A schematic diagram, based on the observations, is presented in Figure 4.3-9, to illustrate this dependency. Images taken with a daylight ultraviolet camera during the different zones identified in Figure 4.3-9 are presented in Table 4.3-2.

The following distinct phases, or zones, were observed:

Zone I No discharges occur on dry insulators independent of the contamination level. Clean insulators also showed no discharges independent of the degree of wetting.

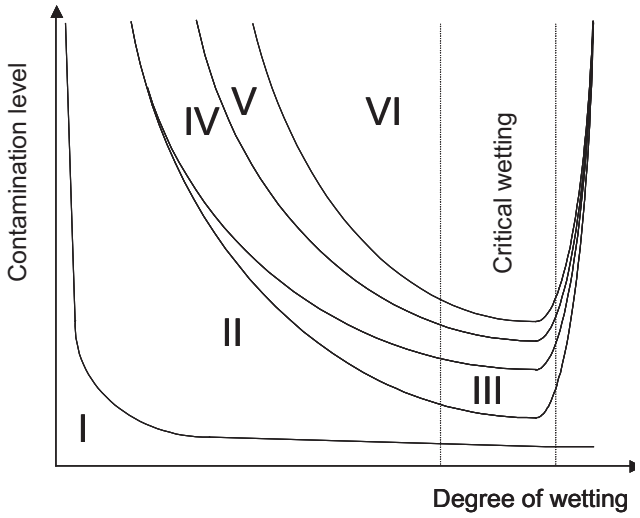

Figure 4.3-9 A schematic diagram of typical discharge activity on artificially polluted insulators, as observed during natural wetting conditions. Zone I: No activity, Zone II: Corona, Zone III: Scintillation, Zone IV: Quiet, Zone V: Intermittent sparking, Zone VI: Flashover. The different zones are described in more detail in the accompanying text.

Zone II In this zone, the insulator is partly wet, and corona discharges occur at the edges of the wet areas. These are generally concentrated in the high E-field stress areas of the insulator string.

Zone III A dry band is established, and sparking activity occurs—Condition B in Figure 4.3-4. This level of activity can be maintained for a relatively long time since the heating effect of leakage current is insufficient to increase the size of the dry band. Therefore this type of activity is mostly common on insulators with a critical to subcritical level of pollution.

Zone IV If the degree of wetting is balanced by the drying-out effect of the leakage current, a stable condition arises that is characterized by a low level of discharge activity—Condition C in Figure 4.3-4.

Zone V If the wetting rate is high enough to overcome the drying effect of the leakage current, occasional sparkovers of the dry band occur. This corresponds to Conditions D and E in Figure 4.3-4.

Natural cleaning and a quenching of the discharge activity take place if the degree of wetting is higher than the critical wetting rate.

Effect of the Insulator Properties

On convoluted insulator designs, scintillation discharges may take shortcuts between the shed protrusions, rendering a part of the leakage distance ineffective (Woodson and McElroy 1970; Baker and Kawai 1973). This is generally more apparent at lower contamination levels where the capacitive steering of the voltage across the insulator is still significant. A comparison of different insulator types

Table 4.3-2 Photos of the Typical Discharge Patterns That May Be Observed During the Zones Defined in Figure 4.3-9

Zone I: No activity	Zone II: Corona	Zone III: Scintillation	Zone IV: Quiet	Zone V: Intermittent sparking	Zone VI: Flashover
					

at low contamination severities shows that the flashover strength of insulators is not proportional to the leakage distance. At a higher degree of contamination, the conductivity of the surface layer is low enough so that the scintillation discharge follows the surface more closely, and the flashover strength is more proportional to the leakage distance.

On both single insulator discs and long insulator strings, the flashover process is driven by the nonuniform voltage distribution caused by thermal phenomena related to the leakage current. Recognizing this, some measures to improve the contamination performance may be proposed. For instance, employing insulators having high capacitance between cap-and-pin can reduce the nonuniformity of voltage distribution on long insulator strings, because the voltage distribution along the string would be greatly linearized. Also, a better contamination performance of single insulator units can be expected when the voltage concentration around the pin is greatly reduced (Akizuki et al. 2002).

Flashover Process on Hydrophobic Polymer Insulators

The flashover process on hydrophobic polymer insulators is markedly different from that of hydrophilic insulators such as porcelain and glass. Observations of the leakage current behavior of polymer insulators show a continuous low level of current that is interspersed with single high current spikes (Gorur et al. 1997). This is in contrast with the gradual buildup of current over ceramic and glass insulators and the densely spaced high current pulses. The main reason for the difference in behavior is the hydrophobicity that inhibits the formation of a continuous conducting layer of the polymeric insulator.

When a hydrophobic insulator is wetted—by condensation, fog, or rain—the water on the surface forms into droplets due to the hydrophobic properties. Through a process of diffusion, some of the salt on the insulator dissolves into the water, making the droplets conductive. The water from the drops also migrates into the dry pollution to form a damp layer with a high resistance. At this stage, a high resistive layer with conductive water drops scattered over it covers the insulator. The leakage current across the insulator reaches a stable, but low, value once equilibrium is reached between the evaporation caused by the heating effect and the reduction of the surface resistance by wetting (Karady 1999).

The scattered water drops on the insulator surface react to the presence of the oscillating electric field in two ways: first, the water drops elongate on the sheath sections and flatten under the oscillating force that the electric field exerts on the polar water molecules, and second, the electric field is enhanced at the edges in the wet areas as a result of the high permittivity of the water. If neighboring droplets are close enough, these may coalesce to form runnels, leading to a further strengthening of the electric field at the edges. The electric field may be increased sufficiently to cause corona discharges (Phillips et al. 1999b; Karady 1999). The discharge activity may reduce the surface hydrophobicity locally, which may help the formation of longer runnels.

On short insulators with a relatively uniform E-field distribution, the leakage current across the insulator may increase sufficiently over time to cause the formation of a dry band on the shank (or sheath) of the insulator, which is the area of the highest current density (Vosloo and Holzhausen 2003). As the hydrophobicity breaks down further in the high-stress zones, the dry-band activity extends to the sheds. The discharges extend as the water runnels extend further, resulting in sparking that bridges the wet areas. Depending on the conductivity of the water, the sparking may eventually extend to reach a flashover.

On long insulators (transmission voltages), the electric field along the insulator is very nonuniform, and the initial corona and sparking activity occurs in the area of the highest electric field close to the high voltage end. This causes the highly stressed section of the insulator to dry out more than the rest of the insulator, forming a high resistance area compared with the rest of the insulator (Gorur et al. 1997). This effectively blocks the leakage current from flowing. The highly nonuniform field concentrations at the ends of this high-resistance area may initiate a streamer breakdown process. If the streamer discharge spans the high resistance section, and the width of this region is large enough, a condition will arise whereby the wet section of the insulator is overstressed. The streamer can then quickly develop into a flashover. This flashover process is characterized by a general absence of leakage current, until the breakdown of the high resistance section, leading to single high current pulses or flashover.

4.4 LONG-TERM PERFORMANCE OF INSULATORS

4.4.1 Causes of Degradation and Damage

Degradation and damage to insulators can be divided into the following categories:

- **Manufacturing defects.** Manufacturing defects can be any flaw that results from an improper manufacturing and assembly process, or a lack of quality control (EPRI 2002a).
- **Damage from handling.** The insulator may be damaged during installation due to improper handling, such as improper storage, dropping, or using incorrect hoisting techniques. There is also the possibility that insulators

may be damaged during maintenance due to improper cleaning procedures (EPRI 2001a, c).

- **Service-induced damage or deterioration.** Service-induced damage may result if the insulator is not dimensioned correctly for the particular environment in question. This may result in damaging discharge activity or mechanical overload conditions. Degradation of correctly dimensioned insulators may also occur due to normal aging as a result of environmental and electrical stresses (EPRI 2004c).
- **Vandalism.** Vandalism is damage inflicted on the insulator by human activity other than that related to installation or maintenance. Gunshot damage or damage from projectiles are examples (Burnham and Waidelich 1997; EPRI 2004c).
- **Damage caused by animals.** Rodents and birds may damage polymer insulator housings through pecking or gnawing (EPRI 2004c).

In this section the discussion will focus exclusively on service-induced damage and deterioration since this should be taken account of when dimensioning the insulators.

4.4.2 Porcelain and Glass Insulators

Deterioration of Ceramic and Glass Insulators

High-quality porcelain and glass insulators can be kept in service for more than 30 years with little to no change in their electrical and mechanical properties. For example, there are records of porcelain insulators with more than 70 years of service life. Accelerated degradation does occur, but only when insulators are electrically or environmentally overstressed. A typical example is surface erosion of the glass or porcelain on insulators that are subjected frequently to elevated levels of leakage current (see Figure 4.4-1). These units may also exhibit corrosion of the pin and, in severe cases, the cap as well (Parraud and Dumora 2001).

Failure Modes of Glass Disc Insulators

Glass insulators may experience infant mortality to some degree—that is, it is not unusual to have a very small number of units shatter within a short time of installation.

Electrical Puncture

Glass insulators are highly resistant to electrical puncturing. However, in the event that they do puncture, the residual tensile stress in the glass, due to the toughening process, will cause the glass shell to shatter. Therefore, no hidden punctures can exist within a glass insulator (Looms 1988).

Punctures and subsequent shattering of the glass shell can be caused by:

- Concentrated electrical discharges under thick pollution layers may cause localized heating, leading to a thermal puncture.
- Thermal punctures due to heating caused by dielectric losses in the glass.
- Punctures or thermal shock due to lightning or high-energy power frequency power arc flashover.

Mechanical Failure

There are reasons other than electrical puncture that may also cause the glass shell to break. Internal mechanical stresses can build up in the glass shell and can lead to its eventual breaking. These stresses include:

- Erosion due to leakage currents, or in desert conditions due to "sand blasting," may lead to a disturbance of the internal mechanical forces, causing the glass shell to shatter.
- Vandalism is also a major contributor to insulator breakages. Gunshot and rocks thrown at insulator strings are common types of vandalism.
- Under dc energization, the migration of ions in sodium-rich glass cause the sodium to aggregate or deplete under the insulator cap. This may lead to a redistribution of mechanical forces inside the shell that can eventually shatter it (CIGRE 1994b).

Hardware corrosion (i.e., corrosion of the metal end fittings) may also lead to deterioration of the mechanical strength of the insulators.

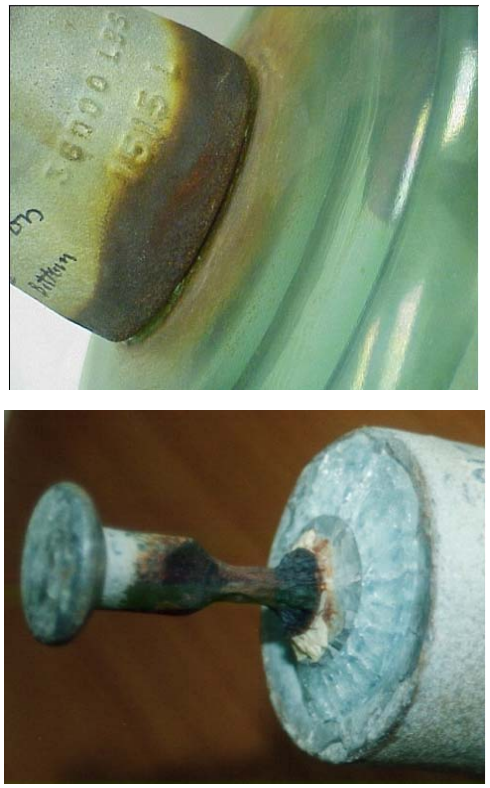

Figure 4.4-1 Examples of glass disc erosion and corrosion of the metal end fittings.

Failure Modes of Porcelain Disc Insulators

Electrical Puncture

An electrical failure on porcelain disc insulators normally manifests itself as a pinhole through the porcelain shell between the cap and pin (see Figure 4.4-2). The causes for puncture are varied, and some causes include (Looms 1988):

- Steep electrical impulse normally caused by lightning.
- Thermal runaway as a result of the heat generated by dielectric losses.
- Long-term high electric field stressing.

Mechanical Failure

A porcelain disc may be considered to have mechanically failed when it can no longer hold mechanical load or when there is significant damage to the porcelain shell. Examples of mechanical failures are as follows: (also see Figures 4.4-3 and 4.4-4):

- A radial crack of porcelain shell.
- A donut crack of porcelain shell
- A crack in the porcelain under the metal cap or in the porcelain head.
- Mechanical separation of the cap or pin hardware
- Mechanical failure of the porcelain shell

Figure 4.4-2 Examples of electrically induced failures.

These cracks may be formed due to one or a combination of the following:

- Stresses generated by ion movement within the porcelain under dc energization.
- Material erosion due to corona activity and/or high E-fields.
- Localized stresses induced by corrosion of metallic parts of the insulator.
- Mechanical stresses or forces created by the swelling of some of the components in the cement such as gypsum (Looms 1988; Gorur et al. 1999).
- Stresses created by unequal thermal expansion and contraction of the various insulator components (porcelain, metals, glazing, sand band, and bituminous material between the metal and cement, etc.).
- Mechanical overload conditions, such as those occurring during severe conductor icing conditions.
- Cracks and shell breakage caused by an impact and/or vandalism.
- Mechanical stresses in the disc that are induced by the electrical puncture of the porcelain.

Failure Modes of Porcelain Longrod Insulators

Electrical Puncture

Since porcelain longrod insulators fall under IEC Class A (see Figure 4.2-4), they are regarded as puncture proof.

Figure 4.4-3 Examples of mechanical failures.

Figure 4.4-4 Erosion of the cement around the pin caused by electrical discharges.

Mechanical Failure
Mechanical breakage on longrod insulators is normally associated with a failure of the end-caps or the cement or lead-antimony filling material that fixes the cap to the porcelain body. Breakages of the porcelain body may also occur when its dynamic or static mechanical strength has been exceeded.

4.4.3 Polymer Insulators

Degradation Mechanisms
Stresses that result in degradation of polymer insulators may be categorized into the following broad areas:

1. Environmental stresses
2. Mechanical stresses
3. Electrical stresses

Environmental stresses include temperature cycling, precipitation, solar radiation, and contamination, while *mechanical stresses* include static and dynamic loading (e.g., compression and tension loads, vibration, bending, twisting, and torque loads). If applied within the manufacturer-specified ranges, today's designs of polymer insulators are designed and tested to withstand these *individual* stresses without significant degradation. Hence environmental and mechanical stresses alone may be considered secondary as regards long-term degradation. However, some of the above stresses in combination with electrical stresses may result in significant degradation.

Electrical stresses may result in degradation of polymer insulators either alone or when combined with environmental stresses, such as precipitation and contamination (EPRI 1999; Maxwell et al. 2002; EPRI 1998; Maxwell and Hartings 2000). The electrical stresses considered are:

- Electric field distribution along the insulator
- Voltage applied across the insulator

These electrical stresses may result in discharge activity and leakage currents that, in turn, may degrade the rod, polymer weathershed material, interfaces, end-fittings, and end fitting seals. The ability of the insulator to withstand these stresses is a function of the insulator design, manufacturing process, and application. It should be noted that polymer insulator designs and manufacturing processes vary considerably from manufacturer to manufacturer and, hence, so does the ability to withstand these stresses.

Degrading discharge activity and leakage currents may be classified into distinct categories that are described in detail in the following sections:

- Discharges internal to the FRP rod and polymer weathershed material or, at the interface between the rod and housing
- Corona activity from metallic end-fittings or corona rings under dry conditions
- Discharges due to nonuniform wetting of the polymer rubber material
- Dry band arcing under contaminated conditions
- Damage due to external power arcs

The following sections provide an overview of each of these.

Discharges Internal to the Fiberglass Rod and Polymer Weathershed Material
If a critical E-field magnitude is exceeded, internal defects—such as voids, inclusions, or poor bonding between the rod and rubber sheath—may result in internal discharge activity (Cherney 1991). This internal discharge activity may have one or more of the following results:

- Destruction of the fiberglass rod resulting in a mechanical failure.
- Damage of rubber weathershed material, exposing the fiberglass rod to the environment and precipitating an electrical or mechanical failure. Possible failure modes are described in detail in a later section.
- Tracking along or through the fiberglass rod. This tracking may propagate axially along the length of an insulator, resulting in a larger conductive defect. If the conductive defect becomes a critical length, a flashunder electrical failure may occur. Figure 4.4-5 is an example of tracking along the interface between the fiberglass rod and rubber sheath.

Degradation due to internal discharges may be avoided by reducing the occurrence of internal defects in the manufacturing process and controlling the E-field internal to the insulator by the correct application of corona rings.

Internal discharge activity may also be initiated by moisture and/or contaminants that have penetrated the weather-

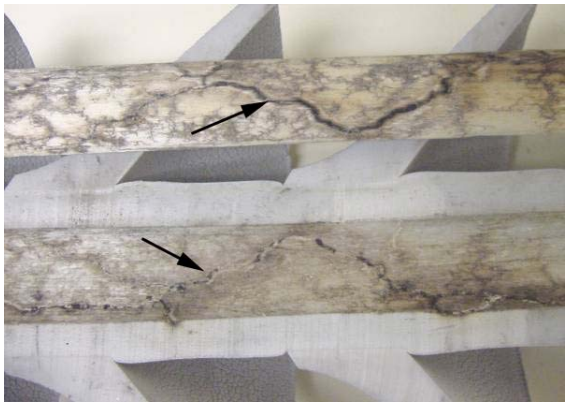

Figure 4.4-5 Tracking along the interface between the fiberglass rod and rubber sheath.

shed system. It is not feasible to control the internal E-field to prevent discharge activity caused by moisture present due to ingress.

Corona Activity from Metallic End-fittings or Corona Rings under Dry Conditions

High E-field magnitudes on the surface of, and surrounding, the metallic end fittings and corona rings can result in corona activity under dry conditions. These discharges result in radio interference and audible noise that, in turn, may result in complaints. If this discharge activity is in contact with the rubber weathershed system, or end fitting seal, degradation may occur. Figure 4.4-6 shows such activity and resulting degradation.

Sustained corona activity from galvanized end fittings has been shown to result in localized loss of galvanization from the steel end fitting and resulting localized corrosion.

Correct design and application of corona rings will ensure that the surface E-field magnitudes are below the threshold values required for dry corona activity. Tests are specified in most standards to ensure that corona activity under dry conditions does not occur (ANSI 2002a, 2002c; IEC 1992). It should be noted that these tests are usually only applicable to a single configuration type (usually an I-suspension string with minimal hardware), and testing may be necessary for other configurations.

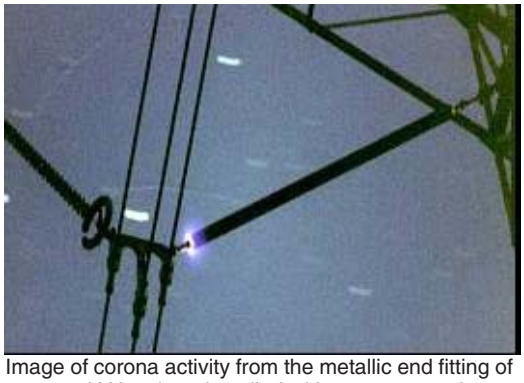
Discharges due to Nonuniform Wetting of the Polymer Rubber Material

Discharge activity may occur on the surface of polymer insulators due to the presence of moisture. Moisture may be in the form of discrete droplets or water patches, depending on the surface properties of the rubber and the type of wetting. This type of discharge activity occurs due to the high dielectric constant of water and hence is not dependent on contamination being present—i.e., it occurs under low, or even clean, conditions (Phillips et al. 1999a, 1999b; Lopez et al. 2002; Lopez et al. 2001).

The discharge activity takes on different forms on hydrophobic and hydrophilic insulators.

Hydrophobic Insulators (e.g., Silicone Rubber)

Water drops and patches on the rubber surface enhance the electric field due to the high permittivity of water ($\varepsilon_r = 80$). If the electric field (E-field) is enhanced above a critical value, corona activity will result from the edge of the water. Figure 4.4-7 shows how a water drop enhances an electric field.



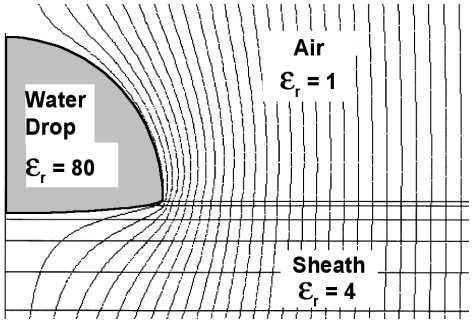


Image of corona activity from the metallic end fitting of a 500-kV insulator installed without a corona ring.

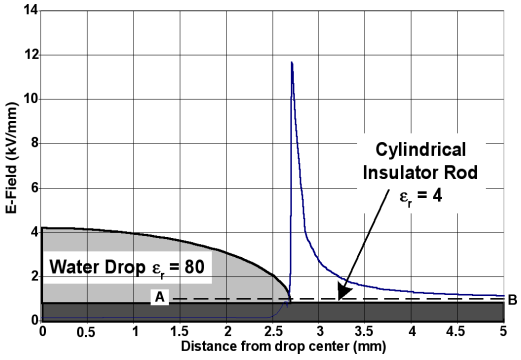

Erosions on the rubber weathershed material as a result of corona activity.

Figure 4.4-6 Corona activity from energized end fittings and the resulting damage.

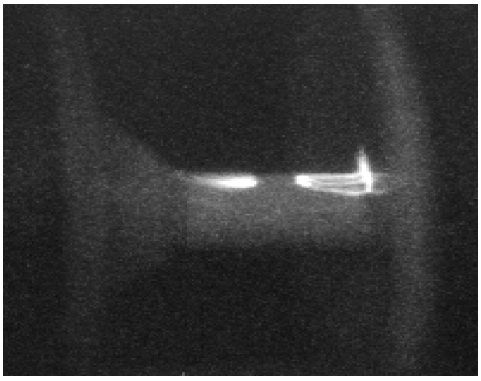
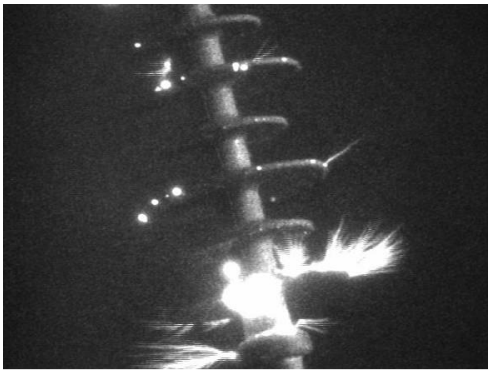
(b) Graph showing the increase in the E-field magnitude surrounding a water drop.

Figure 4.4-7 Results of finite elements modeling, showing enhancement of the E-field surrounding a water drop on the surface of a polymer insulator (Phillips et al. 1999a).



As can be seen from Figure 4.4-8, the E-field is significantly enhanced at the water/air/rubber interface. The enhanced E-field, in turn, results in corona discharge activity from the tip of the drop, as shown in the figure. This discharge, in turn, may degrade the polymer material.

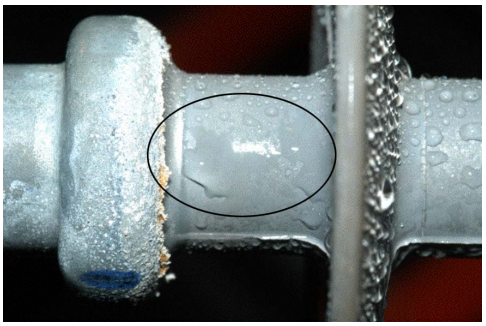
The unperturbed, or dry, E-field magnitude necessary to result in corona activity from water drops is primarily a function of drop size and hydrophobicity. The larger the drop and lower the hydrophobicity, the lower the E-field magnitudes required. The E-field magnitudes for water drop corona on the sheath and shed are different due to the orientation of the E-field. Single drop experiments have shown that drops on the sheath have an onset field of greater than 4 kV/cm, depending on the hydrophobicity, while drops on the shed surfaces require an E-field of 8.5 kV/cm.



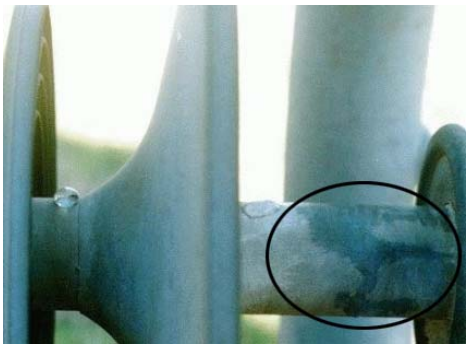
EPRI research has verified the occurrence of water drop corona and has shown that it may result in localized loss of hydrophobicity on silicone rubber insulators, as shown in Figure 4.4-9 (Phillips et al. 1999a, 1999b; EPRI 2000a, 2002a, 2003a, 2004a). This loss can be attributed to either the chemical by-products of the corona together with the moisture present or thermal increases due to the localized ionization (Goldman et al. 1989). Research indicates that the effect of the temperature increases due to corona is minimal, while the effects of chemical by-products, together with moisture, are more significant. It is unlikely, however, that water drop corona alone will result in significant degradation of the polymer weathershed system (Moreno and Gorur 2001, 2003).

Recent findings have indicated that water drop corona may just be the initial phase of the following, more severe, degradation mechanism that affects the long-term performance of the insulator:

1. Water drop corona in the high electric field regions results in localized loss of hydrophobicity. Regions affected have E-field magnitudes above the water drop corona onset threshold.
2. Under wetting conditions, patches of water form in the regions of lower hydrophobicity. These surface water patches are separated by dry regions or bands.
3. Localized arcs form, bridging the gaps between the water patches (EPRI 2003a).



(a). Corona activity from a single water drop.



(b). Wetting corona activity at the live end of a polymer insulator.

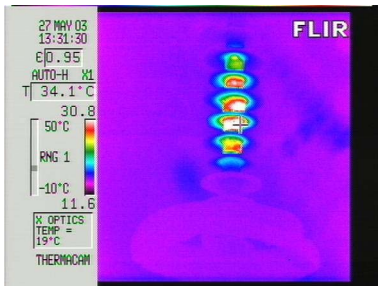
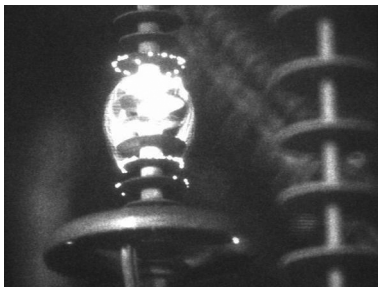
Aging chamber



Insulator removed from service

Figure 4.4-9 Photos illustrating localized loss of hydrophobicity in the aging chamber and its effects on an insulator removed from service.



4. The energy and temperature of these localized arcs are significantly higher than that of water drop corona, stressing the rubber weathershed surface further (Gubanski 2003).
5. Over time, as the affected regions lose hydrophobicity, and completely wet out, the E-field in the adjacent regions is enhanced above the water drop corona onset threshold under wetting conditions.
6. The aging mechanism is then initiated in the previously unaffected regions. In this manner, the region affected is increased.

The activity described above is initially localized to the high electric field region of the insulator—i.e., the energized or grounded ends. The rest of the insulator remains hydrophobic and in good condition, hence there will be no significant increase in the leakage currents measured at the grounded end. Observations from the EPRI accelerated aging tests have indicated that, after 30 years of simulated aging, the loss of hydrophobicity can encompass as much as one-quarter of the insulator length (EPRI 2003a, 2004a).

Figure 4.4-10 shows an example of arcing activity observed in the high electric field region of a silicone rubber insulator.

Infrared image

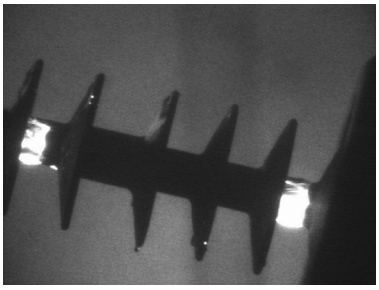
Ultraviolet image

Figure 4.4-10 Localized arcing activity observed on a 230-kV silicone rubber insulator. The observed activity was correlated with localized loss of hydrophobicity in the high field region. Apart from the region showing activity, the rest of the insulator had a high level of hydrophobicity, and no leakage currents were measured at the grounded end.

Hydrophilic Insulators (e.g., EPDM)

During wetting conditions, the rubber surfaces of hydrophilic polymer insulators are covered with distinct droplets and patches of water. Dry regions separate these patches, and due to E-field enhancement, sparking may occur between patches. These discharges may degrade the rubber material. Figure 4.4-11 shows an example of this arcing activity.

Observations have shown that this activity may occur away from the high electric field region; however, casual observation in aging tests indicates that it is more prevalent in the high electric field regions.



Dry Band Arcing under Contaminated Conditions

Contaminated insulators may have surface leakage currents and dry band arcing on the polymer weathershed system surfaces. For most types of contaminants, these phenomena occur only under wetting conditions due to the increased conductivity of the contamination layer.

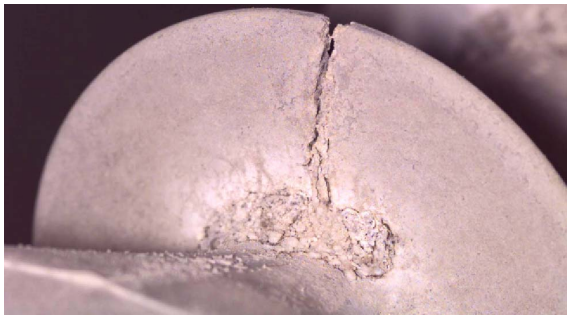
As explained in Section 4.3.4, the dry band arcing on long polymer insulators is usually concentrated around the end fittings of the insulator, resulting in increased degradation in these areas. This discharge activity may result in degradation of the rubber housing as well as the end fitting seal. This degradation may include erosion, tracking, and localized loss of hydrophobicity. Loss of hydrophobicity is a

Infrared image

Ultraviolet image

Figure 4.4-11 Infrared and ultraviolet images of dry-band arcing activity on a polymer insulator (EPRI 2003a).

concern with silicone rubber insulators only. Severe examples of erosion and tracking are presented in Figure 4.4-12.



Damage due to External Power Arcs

Insulators may flash over due to lightning, switching, bird contact, or other activity, resulting in a power arc that terminates on the insulator or associated components. Termination points include end fittings, either energized or grounded, or the corona rings.

If the arc terminates on the end fittings, the intense arc root temperatures and energy dissipation may result in:

- Damage to end fitting seals.
- Loss of the galvanization.
- Localized heating that may damage the fiberglass rod or rubber weathershed system.
- Short-term loss in mechanical strength (Matsuoka 1998).

Damage to the end fitting seals is the largest concern. This concern is accentuated when aluminum components are integral to the seal mechanism since the melting temperature of aluminum is often lower than the arc root temperatures. Figure 4.8-9 shows an example of an end fitting seal damaged by power arcs.

Severe erosion along a mould line

Tracking on a polymer insulator

Figure 4.4-12 Examples of erosion *(top)* and tracking *(bottom)* along mould lines.

Testing has shown that a 60% reduction can occur in the ultimate strength of units during a power arc event (corresponding to 80% of specified mechanical load). A long-term loss of 10 to 20% in ultimate strength was recorded, but the units were still able to hold the specified mechanical load (Matsuoka et al. 1998).

Localized damage to galvanization will result in corrosion. In most cases, damage to the weathershed system is secondary.

Failure Modes

A failure may be defined when a polymer insulator is unable to fulfill either of its principal roles (EPRI 2003b, 2004c):

- Unable to insulate under power frequency conditions.
- Unable to hold everyday mechanical load.

The inability of an insulator to withstand transient overvoltages or temporary mechanical overloads within rating may also be considered a failure. However, in most cases, it is almost impossible to know the magnitude of these events for in-service units.

Mechanical failure modes include:

- Brittle fracture (stress corrosion cracking of fiberglass rod)
- Destruction of rod by discharge activity
- Mechanical failure due to end fitting pullout or mechanical failure of the rod

Electrical failure modes include:

- Flashunder (tracking along or through the fiberglass rod and the resulting flashover)
- Flashover due to contamination

The first four failure modes listed above relate to failure of the fiberglass rod, or the interface between the rod and rubber. Hence one of the most common reasons for failure is exposure of the fiberglass rod to the environment. This may occur through the functional failure of either the rubber weathershed system or the end fitting seal.

The following sections provide more detail on each of the failure modes.

Brittle Fracture (Stress Corrosion Cracking of Fiberglass Rod)

A brittle fracture is a mechanical failure of the fiberglass rod—i.e., a complete separation of fiberglass rod, as shown in Figure 4.4-13 (Burnham et al. 2002; CIGRE 1992b; Chandler et al. 1983; Chandler and Reynders 1984).

Features of a brittle fracture are:

- One or more smooth, clean planar surfaces, mainly perpendicular to the axis of the fiberglass rod giving the appearance of the rod being cut.
- Several planar fracture planes separated by axial delaminations.
- Residual mechanical fracture surfaces—i.e., broomstick.

Brittle fractures are caused by chemical attack of the FRP rod when nonsiliceous ions are leached from the fibers, and the surrounding thermoset resin matrix is hydrolyzed. This chemical attack, together with the mechanical load, results in transverse cracking. The cracking will progress until the remaining cross section of the rod can no longer support the applied load, and total separation occurs. Brittle fracture is more accurately defined as stress corrosion cracking. In many instances, failures may be misdiagnosed as being due to brittle fracture through simple visual examination. To properly identify a brittle fracture failure, it is helpful to utilize SEM and chemical analyses techniques.

Research indicates that brittle fracture occurs due to the presence of acids in proximity of the rod. There are a number of competing theories on how these acids are formed (Montesinos et al. 2003; Kumosa et al. 2004; de Tourreil et al. 2000).

Flashunder (Tracking Along or Through the Fiberglass Rod and the Resulting Flashover)

This is an electrical failure mode. This failure mode occurs when internal discharge activity results in carbonization within or on the surface of the fiberglass rod. Internal discharge activity may occur due to moisture ingress or internal defects—e.g., voids, poor bonding, or conductive defects. Internal tracking grows in or on the rod until a critical distance along the insulator is reached and the applied voltage can no longer be withstood and a flashunder occurs.

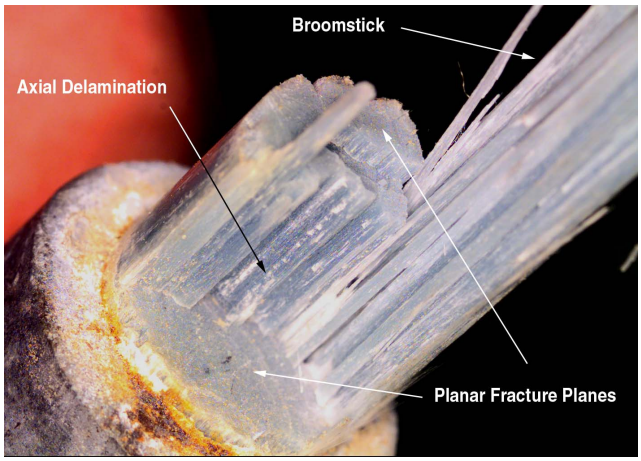


Figure 4.4-13 Brittle fracture. Note the several separate flat transverse fracture planes and the "broomstick."

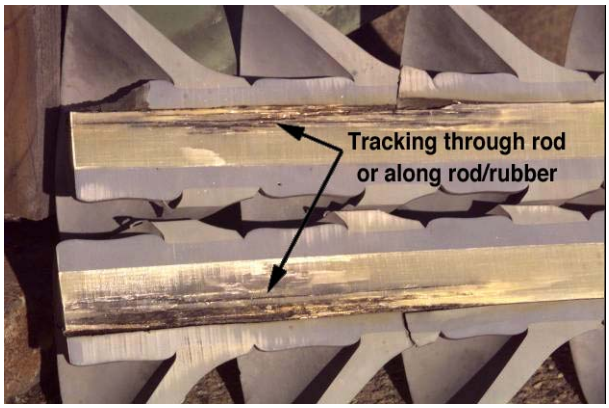
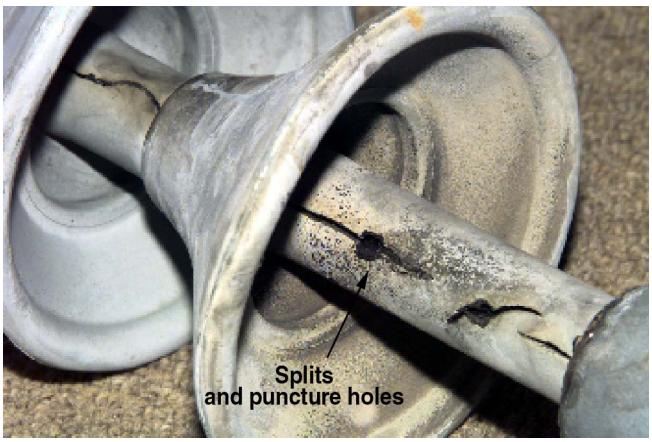
Features of a flashunder include:



- Tracking through the rod or along the rod/rubber interface.
- Puncture holes and splits along the length of insulator due to internal discharge activity and a power arc during failure.

Figure 4.4-14 shows images of a flashunder and the associated features.



In a number of cases, after a flashunder occurred, and the line was re-energized, the insulator has been able to provide insulation adequate to prevent an immediate outage. This is due to the resulting power arc drying out the insulator and improving the insulation ability of the unit. However, with time or renewed wetting, the unit may precipitate further outages, leading to further damage that eventually results in complete electrical or mechanical failure.

Destruction of Rod by Discharge Activity

Destruction of the rod by discharge activity is a mechanical failure mode. Internal defects or moisture or contaminant ingress may result in internal discharge activity. If the rod

Two halves of a dissected polymer insulator that has failed due to a flashunder.

External photograph of the live end of an insulator that has failed due to a flashunder.

Figure 4.4-14 A flashunder and associated features.

becomes carbonized, a larger conductive defect is formed. These discharges degrade the rod until the unit is unable to hold the applied mechanical load and the rod separates. Figure 4.4-15 shows images of a rod damaged by discharge activity.

Mechanical Failure due to End Fitting Pullout or Mechanical Failure of the Rod

These are mechanical failure modes where either the insulator mechanically fails when the rod separates from the end fitting or the rod itself mechanically fails. These failures may occur due to mishandling, errors in the manufacturing process, and/or degradation—e.g., overheating of the fiberglass rod during manufacturing, or decomposition of the epoxy in an epoxy-cone-type end fitting, etc.

Figure 4.4-16 shows an example of a fiberglass rod that failed mechanically in-service. The reason for failure was traced back to a manufacturing defect.

Figure 4.4-17 shows an example of a unit that has failed due to the rod pulling out of the end fitting due to decomposition of the epoxy cone.

Dissected rod and end fitting of failed unit.

End fitting and rod of failed unit.

Figure 4.4-15 Unit that failed due to destruction of the rod by discharge activity.

Figure 4.4-16 Mechanically failed rod due to manufacturing defect.

Flashover due to Contamination

As explained in Section 4.3, the two main modes of insulator contamination flashover are solid and liquid contamination flashover. Flashovers occur mainly due to power frequency stress. Switching impulses may result in contamination-related flashovers, but this is rare. Contamination flashovers are not included in the EPRI failure database, as flashovers are mainly attributed to inadequate design, exceptionally harsh environments, or extraordinary contamination events.

Summary of Failures

In 1997, EPRI started a database recording failures of transmission polymer insulators in the field. Information and images, where possible, were obtained on each individual failure and stored in an electronic database, which may be queried at a later date. Information on failures as far back at the 1970s was obtained. The database continues to track failures on an ongoing basis, and the data presented in the following section was current as of September 2004 (EPRI 2003b).

Information is obtained from the relevant utility using a questionnaire containing a range of standard questions. Often the utility is unable to answer all of the questions in the questionnaire. This is often the case when utilities provide information on failures that did not occur recently.

For purposes of the database, a failure was defined as either of two conditions:

- Electrical: The insulator was unable to electrically insulate the energized conductor and hardware from the grounded structure. This may occur internally or externally along the surface of the polymer insulator.
- Mechanical: The insulator loses its ability to hold its everyday mechanical load and, consequently, the mechanical load that it is holding is released.

Dissected end fitting of failed unit.

Rod from failed unit.

Figure 4.4-17 Unit that has failed due to decomposition of the epoxy cone.

Precluded from this survey are three types of failures:

- Flashover due to external contamination—e.g., due to marine pollution.
- Failure due to extreme mishandling—e.g., the unit is broken during installation.
- Failure due to extreme mechanical loads—e.g., icing or hurricanes.

Although the database contains a comprehensive number of failures in North America, no attempt was made to collect information on a significant number of failures internationally due to the logistics involved. As of June 2003, EPRI has collected 189 failures from 53 different utilities. With four exceptions, all of the failures were collected from North American utilities. Of the 189 failures, 159 occurred in North America. Figure 4.4-18 shows the distribution of the failures between the different failure modes (EPRI 2003b).

A review of a recent paper, *IEEE Task Force Report: Brittle Fracture in Nonceramic Insulators* (Burnham et al. 2002), indicates that there are an additional 46 international brittle fracture failures that are not included in the EPRI failure database. The Task Force report only reported brittle fracture failures, and hence the total number of failures worldwide may be larger. The total number of recorded failures worldwide, therefore, exceeds 220.

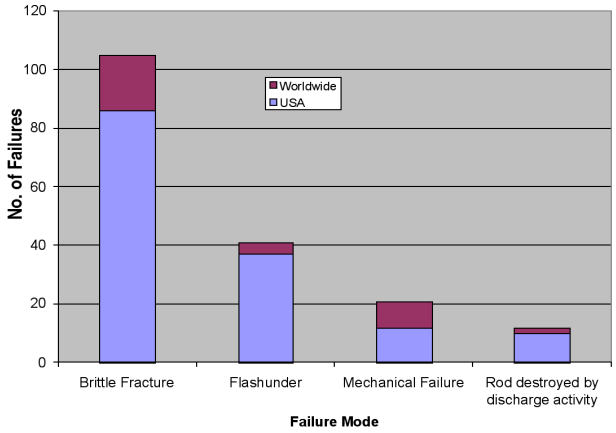


Figure 4.4-18 Failure mode distribution from EPRI failure database. Failures within and outside of the USA are indicated (EPRI 2003b).

It should further be noted that the failure database has by no means captured all of the failures that have occurred. In reality, it is the authors' opinion that a large percentage have not been captured in the EPRI failure database. EPRI is continuing to obtain failure information to increase the accuracy of the database and results.

Failure Rates

Of the 188 failures reported in North America, 89 related to the manufacturers that provided information to EPRI on the number of units sold. Based on this information, the average failure rate for all the manufacturers that provided sales information was 1 in every 45,000 units sold. Apart from one manufacturer for which there are no recorded failures, the individual manufacturer failure rates varied from 1 in every 65,000 to 1 in every 31,000 units sold (EPRI 2003b).

Utilizing the average failure rate data indicated above may be misleading, as 100 of the failures recorded in the database were from manufacturers that did not provide data or are no longer selling product and hence did not provide sales information.

Occurrence of Failures

An analysis of the data captured in the database has shown that 40% of failures occur within three years of installation (see Figure 4.4-19). This may be attributed to the weeding out of defective units or minor damage during installation. Although the number of units installed has increased over the years, the number of failures has not, indicating improved manufacturing techniques and materials have resolved early issues.

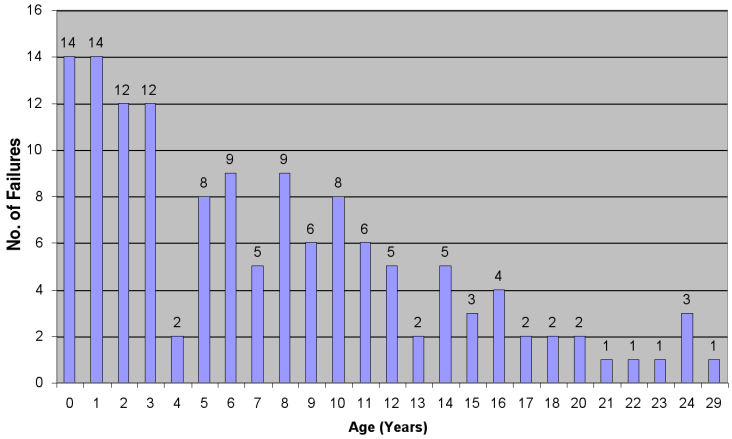

Figure 4.4-19 Age of failures (the age of failure for 57 failures could not be determined). Note: Installation year is used rather than year of manufacture, as the data is more readily available (EPRI 2003b).

4.5 LABORATORY TESTING

4.5.1 Introduction

Laboratory testing of insulators aims to verify by relatively short-term testing in a controlled environment, that the insulator is capable of withstanding the highest level of service voltage and the expected environmental stress without flashover or irreversible degradation (CIGRE 1999a). In this respect the validity of a laboratory test method can be measured in terms of the following concepts:

- **Representativity.** A test method must represent actual service conditions. Because it is impossible to simulate completely all of the many conditions in nature, only those conditions essential to determining insulator performance should be considered. A test method can be considered representative if the ranking order of different types of insulator produced by the test corresponds to that obtained in the service environment.
- **Repeatability.** If the test method gives consistent results from test to test performed in the same laboratory, then the test method can be considered repeatable. This requires that all test parameters be controlled as well as possible to eliminate excess dispersion in test results.
- **Practicality.** Insulator tests can be time consuming especially if the method is complicated. From the utility engineer's point of view, the insulator tests must be accomplished within a limited time and cost due to construction schedules and budgets. This obviously requires simplified test procedures.
- **Reproducibility.** If consistent results are obtained when different laboratories perform the test, then the test method can be considered reproducible. This aspect requires that all the test parameters are well defined and an unambiguous description of the method itself. Insulator manufacturers particularly emphasize the need for the development of reproducible test methods.

All laboratory test methods represent a compromise between the above requirements. Any particular method can, therefore, be criticized because of the necessary simplifications to achieve a practical method. On the other hand, research-oriented methods involve more complicated procedures, possibly with an increased dispersion in the results, and longer, time-consuming test durations. These problems are inevitable when trying to duplicate natural conditions.

There are two aspects that need to be considered when selecting tests to verify the performance of insulators. These are test methods that verify:

1. **Long-term performance of the insulator.** The exposure of the insulator to the environmental stresses may cause deterioration. This is mainly a concern for polymer insulators that may be influenced by electrical discharges and environmental factors.
2. **Electric flashover performance.** It is expected that the insulator, in the aged condition, will withstand the highest level of service voltage and the level of contamination to which it will be exposed with an acceptable Risk of flashover.

The first aspect is normally addressed by so-called "aging" tests, while the latter is verified by contamination tests.

4.5.2 Test Methods to Determine the Long-Term Performance of Insulators (Aging Tests)

Since the required life expectancy for polymer insulators is often 30 years or greater, a number of accelerated aging tests have been used worldwide to evaluate the long-term performance of polymer insulators. These tests are intended to simulate specific environments around which an aging cycle is developed. The design of the aging cycle is dependent on the primary aging mechanism under consideration. For example, if a highly contaminated environment is being considered, a higher number of pollution events may be included in the cycle. In the case of an aging test simulating a low-contamination environment, the number, or duration, of wetting events may be increased.

When considering the results of an existing test, or implementing a new aging test, care should be taken to consider the environment in which units will be installed and what the primary and secondary degradation modes are. The aging cycle should be designed to simulate the degradation phenomena that will occur in the field as accurately as possible. If a degradation mode is introduced that does not occur in the field, the test results may not be relevant.

Acceleration rates quoted for the individual tests are only approximate and are specific to the environment being simulated. Determining the acceleration rate requires a thorough understanding of the aging mechanisms, and in some cases, research performed at a later date may require the readjustment of initial acceleration rates. For example, at the time of development of the EPRI "Deserts with a Distinctly Cold Season" aging test, the assumption was made that the elevated temperature present in the desert was the primary aging process. Later research indicated, however, that wetting time was instead the primary aging factor; hence the initially calculated acceleration factor of between 12 and 20 was revised at the end of the test to a value between 7 and 14 (EPRI 2000a).

Also important when designing an aging cycle is to include rest periods where silicone rubber-based insulators are able to recover their hydrophobicity. These rest periods were not always included in the early versions of accelerated aging tests, leading to pessimistic and unrepresentative test results. The required conditions and duration of rest peri-

ods remain undefined and a topic of ongoing research via comparisons with service experience and natural testing sites where relevant and available.

It is, furthermore, essential to compare the results from accelerated aging tests against field-aged units to confirm that the aging mechanisms simulated in the tests are relevant to actual service conditions. In a number of cases, the accelerated aging results have compared favorably with both field-aged and outdoor test station units (EPRI 2000a, 2002a, 2003a, 2004a; Maxwell et al. 2002).

A number of accelerated aging tests have also been performed to assess the performance of one or possibly two components of an insulator but not the entire insulator (e.g., end fitting seal, mechanical performance, or rubber insulator housing). Examples include the incline plane test, the CEA tracking wheel test, EPRI's end fitting seal test, and EPRI's long-term dynamic and mechanical loading tests. These tests do not provide an indication of life expectancy; rather they provide a performance comparison between different designs, or highlight design weaknesses in the component being evaluated.

Some, but not all, of the accelerated aging tests are described in a document produced by a CIGRE Working Group (CIGRE 1999a). A summary of these tests, together with tests that have subsequently been implemented, is provided in this section.

IEC 601109 5000-h Test (CIGRE, Electricité de France Specification)

This 5000-h test, which was developed by Electricité de France (EDF) and subsequently adopted by the IEC, introduces multiple stresses in 24-h cycles while energized to the highest system voltage $V_m/\sqrt{3}$ kV (IEC 1992; Riquel 1993; CIGRE 1986). One cycle consists of different periods during which the insulator is exposed to demineralized rain, heating, humidification, fog generated from saltwater, and ultraviolet (UV) radiation, as shown in Figure 4.5-1. The representativity of the test was confirmed by comparing the damage sustained during the test with that occurring at an outdoor test station. Based on this comparison, an acceleration factor of 10 was determined for this test. Due to practical and cost limitations, the 5000-h test is normally performed in a small test chamber with a test voltage of between 14 and 20 kV. However, an aging chamber with a test voltage of $245/\sqrt{3}$ kV has been installed in France for full-scale testing at higher voltage levels.

ENEL 5000-h Test

This test is based on the same types of stresses as the IEC/CIGRE test, but it comprises a seven-day cycle (Fini et al.1993), of which details are presented in Figure 4.5-2. Other differences between the ENEL and IEC/CIGRE tests concern the salinity of the saltwater used for the pollution

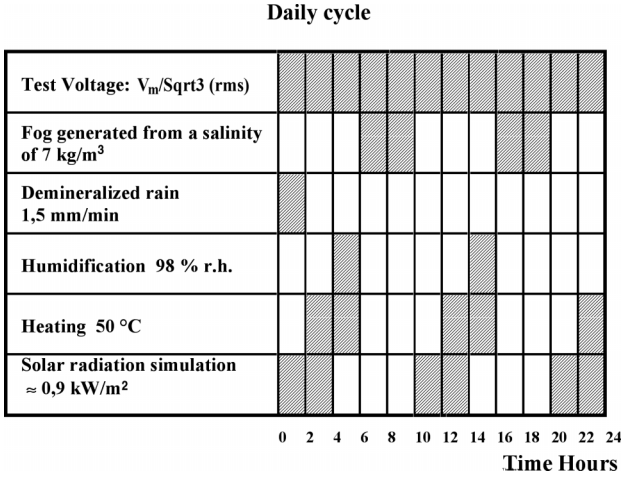

Figure 4.5-1 The aging cycle for the IEC/CIGRE 5000-h test.

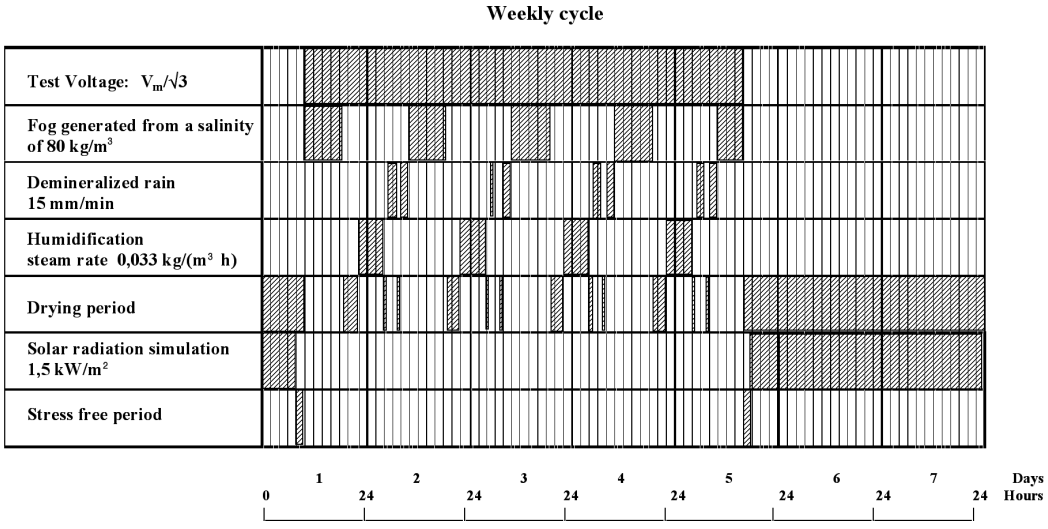

Figure 4.5-2 The aging cycle of the ENEL 5000-h test.

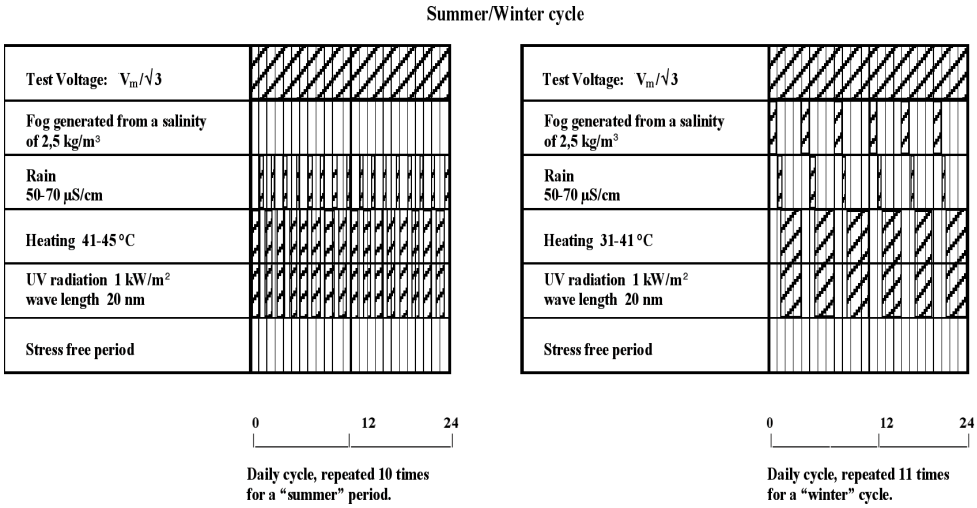

Figure 4.5-3 Aging cycle for the EPRI summer/winter cycle test.

period (i.e., ENEL uses 80 g/m^3 instead of 7 g/m^3) and the intensity of the solar radiation (i.e., ENEL uses 1.5 kW/m^2 instead of 0.9 kW/m^2). The test was devised for the selection of polymer insulators based on Italian conditions. It can be performed on full-scale insulators for system voltages of up to 540 kV.

EPRI Summer/Winter Cycle Test

This test was devised to simulate the weather conditions of the Florida seacoast area. There are two different 24-hour cycles, one for the summer and one for the winter. One year of service is represented by 10 summer cycles, which is followed by 11 winter cycles. The schematic of the cycles is shown in Figure 4.5-3. By this definition of the test cycles, the acceleration factor is about 17. The test has been performed on full-scale insulators at 138 and 15 kV (EPRI 1992; Schneider et al. 1992).

EPRI Test to Simulate "Deserts with a Distinctly Cold Season"

This test has been devised to simulate the weather conditions of the western part of the United States, where there is light rainfall, extensive UV duration, and elevated temperatures with relatively little contamination, which can be described as "deserts with a distinctly cold season." The aging cycle of this test is shown in Figure 4.5-4. One year of service is represented by 30 daily cycles. By this definition, the acceleration factor lies between 7 and 14. The test duration depends on the number of years that have to be simulated.

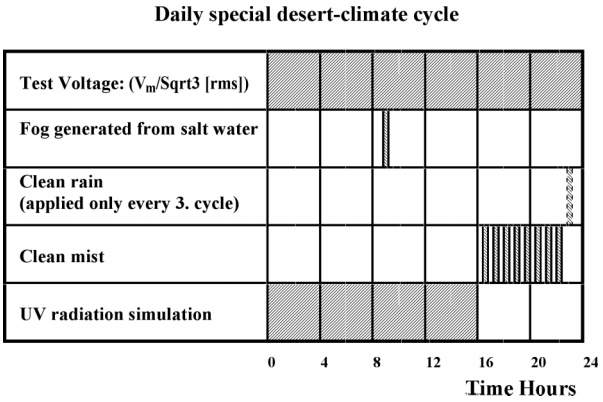

Figure 4.5-4 Aging cycle for EPRI Test to Simulate "Deserts with a Distinctly Cold Season."

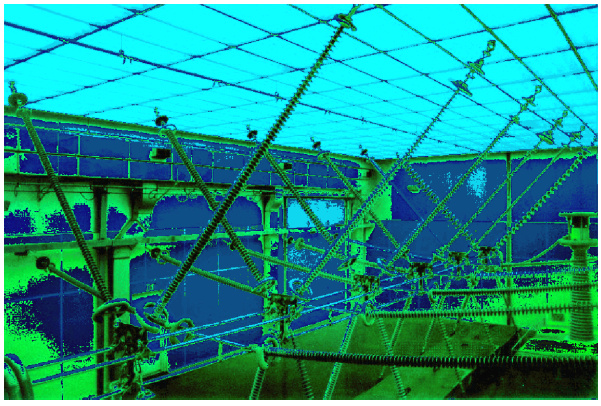

Figure 4.5-5 EPRI 500-kV accelerated aging test.

This test was performed on full-scale 500-kV insulators in both a horizontal and V-string setup. The V-suspension insulators were placed under a static mechanical load of 27 kN each. The horizontal insulators were not mechanically loaded. Figure 4.5-5 shows a general view of the 500-kV test set-up. The test was completed after six years on 22 insulators from five different manufacturers. The results of the test and comparison between the performance of different designs may be reviewed in the appropriate EPRI reports (EPRI 2000a; Schneider 1993).

EPRI Test to Simulate a "Warm Temperate" Climate

This full-scale multi-stress test was designed to simulate the climate of the southeastern United States, although the results may be translated to regions with similar climates. The aging cycle is presented in Figure 4.5-6, and the stresses applied to the insulator include voltage, UV, light fog, rainstorms, salt fog, mechanical loading, and temperature cycling. The level of contamination applied in this test is relatively low. One year of experience is simulated by 36 days of aging. Units are assessed biannually using a detailed visual inspection, as well as infrared and discharge inspection tools under energized conditions. The test is currently under way simulating a system voltage of 230 kV with 43 I-string, V-String, dead-end, post, and braced post units under test. This test also includes transmission-line surge arresters, fiberglass cross-arms, and fiber optic polymer insulators. Suspension units are mechanically loaded to their routine test load (RTL) and post units to their maximum design cantilever loads. The current test is expected to end in December 2004 after four years of aging. Figure 4.5-7 is an image of the 230-kV aging test chamber (EPRI 2002a, 2003a, 2004a).

FGH 5000-h Test

This test produces accelerated aging on polymer insulators under 100-kV dc test voltage at a specific leakage distance of 20 mm/kV_{DC}. A simple 14-day cycle is used, including a stress-free period of five days. The test duration is 5000 h (see Figure 4.5-8).

Inclined Plane Test

Flat rubber samples are placed at a predefined angle with two electrodes touching the surface at a predefined distance. A saline solution is then dripped onto the rubber surface between the electrodes, which results in leakage currents and arcing activity. The test is intended to evaluate the ability of the rubber formulation with withstand tracking and erosion (ASTM D2303).

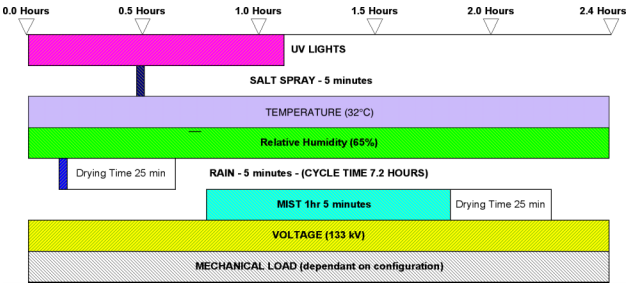

Figure 4.5-6 Aging cycle for EPRI test to simulate a warm temperate climate.

Figure 4.5-7 Some of the insulators installed in 230-kV accelerated aging chamber.

CEA Tracking Wheel Tests

There are two tracking wheel test methods commonly utilized as tests for polymer insulators. The tests are not accelerated aging tests with a fixed acceleration factor. The intent of the tests is more as a material and design screening test. During the tests the insulators are subjected to surface arcing generated through wetting with a saline solution and applied voltage. The properties of the insulator examined are material suitability, design (shed spacing and thickness, housing thickness), and the sealing system.

EPRI End Fitting Evaluation Tests

The end fitting regions of suspension polymer insulators are subjected to electrical and environmental stresses, while the entire insulator is subjected to both a static and vibration mechanical load. The test apparatus used to apply these stresses to the insulators is shown in Figure 4.5-9.

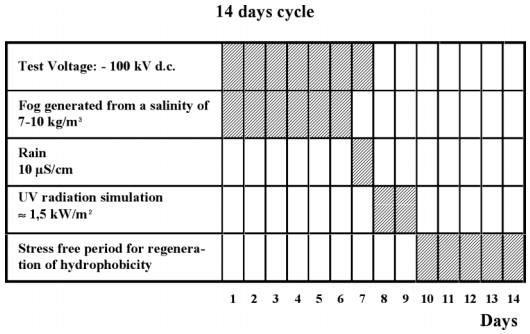

Figure 4.5-8 Aging cycle for FGH 500-h test.

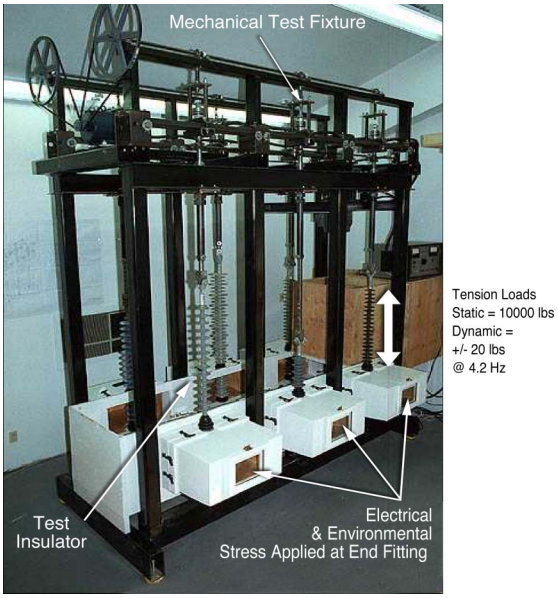

Figure 4.5-9 Overall view of test rig used for evaluating the end fitting seal and the mechanical performance of the insulator.

An electrical stress is applied to insulator end fitting regions using a remote electrode. The electrode geometry is designed to ensure that the peak magnitude of the E-field surrounding the end fitting is 0.7 kV/mm. Wetting is applied at regular intervals together with temperature cycling.

A static tension load is applied to each insulator with two leaf springs. Each insulator is loaded to 10,000 lb (4,535 Kg). In addition, large pulleys apply a 4.2-Hz dynamic tension load (an oscillating load of +/- 20 lb [9 Kg]).

After 365 days of testing, the failure load of the insulators is obtained and compared against reference units. Dye penetration, together with dissection, is used to evaluate the effectiveness of the end fitting seals (EPRI 2002b).

EPRI Mechanical Loading Tests

Suspension polymer insulators are subjected to the following simultaneous mechanical stresses using the apparatus shown in Figure 4.5-10:

- 50% of SML (specific mechanical load)
- 4.2-Hz dynamic tension load (an oscillating load of +/-20 lb [9Kg]).
- A twisting of $\pm 25^{o}$ is applied at 0.1 Hz

After 365 days of testing the units, the failure load of the insulators is obtained and compared against reference units (EPRI 2002b).

4.5.3 Contamination Flashover Tests

The aim of performing laboratory contamination flashover tests is to obtain a reliable and quick estimation of the contamination-withstand characteristics of insulators. This information can then be used to dimension insulators with respect to actual contamination conditions at their proposed installation site. It has been shown through results from natural test sites that the flashover voltages of insulators in service exhibit a larger standard deviation than those tested under artificial conditions. This can be ascribed to the greater nonuniformity of the pollution deposit and wide range in natural wetting intensity that occurs under natural conditions. A laboratory test, by contrast, aims to reduce the standard deviation of the flashover strength—without a change in its withstand value—by eliminating the factors that contribute to the large standard deviation observed in service. Laboratory contamination testing should still emulate the service environment of the insulator in a realistic manner to ensure that the withstand level obtained under artificial conditions corresponds to that under natural conditions.

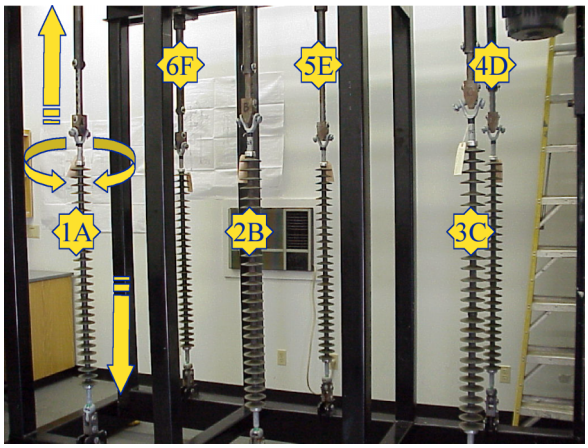

Figure 4.5-10 Test to evaluate mechanical performance (arrows indicate the static and dynamic loading applied).

The most often used laboratory contamination tests are those standardized by the IEC—namely, the Salt-Fog and the Solid-Layer methods (IEC 1991). These methods proved to be unsuitable for polymer insulators, since the hydrophobic nature of the insulator surface and its transfer to the contamination layer, as well as the dynamic nature of the surface conditions, adversely affect the uniformity of the pollution deposit and the repeatability of the test results (CIGRE 1999a; Gorur et al. 1989; Kindersberger and Kuhl 1993). This has prompted the development of alternative techniques for the artificial deposition of contaminants and new nonstandardized simulated environment tests such as the "Dust-Cycle" and the "Dry-Salt-Layer" methods (Marrone et al. 1987; Engelbrecht et al. 2003). However, to date, there is no formal agreement on a contamination test regimen for polymer insulators.

In the standards, the procedure for performing withstand tests is described. This type of testing aims to verify that the insulator can withstand (i.e., has a less than 10% probability for flashover) a specific voltage and contamination stress. The applied test voltage remains at a constant level for the duration of the withstand test. Although this test strategy has its advantages—that is, the insulator is subjected to a low number of flashovers and the test result is a clear pass / no pass verdict—little information is obtained about the flashover characteristics of the tested insulators. Variable voltage tests, or quick flashover tests, have, therefore, been devised to obtain statistical information (e.g., 50% flashover voltage and standard deviation) on the insulator flashover characteristics at a specific contamination severity level. During these tests the applied voltage is increased in a stepwise fashion until flashover occurs (Lambeth 1988). These voltage "ramps" are repeated throughout the test to obtain the required statistical information.

Conditioning

Conditioning is a precursory treatment of the insulator before the contamination test is performed to get the test insulator in a state that is representative of an aged insulator in service and to ensure consistent test results (CIGRE 1999a).

The conditioning on glass and ceramic insulators aims to clean the insulator from grease and dirt so that a completely hydrophilic insulating surface is obtained. For the Salt-Fog Test, this entails washing the insulator, as well as a series of eight conditioning flashovers across the insulator prior to testing. For the Solid Layer methods, the insulator surface can be made hydrophilic by repeated applications of the pollution layer after the insulator has been washed.

For polymer insulators, it is not so easy to define an appropriate method for conditioning, since the aged surface condition is not easily defined. Some polymer insulators, notably silicone rubber ones, may retain a high degree of hydrophobicity throughout their service life. There may be instances, however, when the hydrophobic properties of these insulators may temporarily be suppressed, after which they may recover fully. Other insulator types, such as EPDM insulators, lose their initial hydrophobic properties completely after some time in service. A third group of insulator types may retain some intermediate level of hydrophobicity. Also the level of surface roughness will be different for the various makes of insulator; some maintain the same level of surface roughness as new units, while others exhibit an increasing level of surface roughness with increasing service aging.

The choice of representative surface condition for polymer insulators is very important since it has been shown that the hydrophobic properties greatly affect recorded flashover voltages. An additional complication is that the hydrophobicity of the insulators may change during the testing procedure, due to the electric discharge activity that the insulator is subjected to during the test (Kindersberger and Kuhl 1993). This will lead to inconsistent results during repetitive testing.

Various treatments of the polymeric surface have been proposed. Nearly all of them are aimed at suppressing any hydrophobicity for the duration of the test. This approach has the advantage of ensuring consistent results and making the application of the pollution layer easier, but at the risk of obtaining pessimistic results in the case of insulators with good long-term hydrophobic properties. Some of these treatments put forward are:

- Application of inert materials, such as kaolin or tonoko, to mask the surface's hydrophobicity.
- Abrasive techniques such as scrubbing or sandblasting the insulator to roughen up the surface and to remove any hydrophobicity.
- Chemical treatments with wetting agents or detergents to remove the surface's hydrophobicity.
- Exposure to electrical discharge activity for prolonged times.
- Combinations of the above.

These methods can be criticized as unrealistic since they all aim to suppress the insulator's hydrophobicity completely, which may not be representative of actual service conditions. However, several laboratories seem to prefer the use of inert materials to temporarily mask the hydrophobic properties of the insulator, as this may actually occur in service (De La O et al. 1994; Matsuoka et al. 1996; Xidong et al. 1999; Gutman et al. 2001).

Contamination Test Methods

Before standardization there were a host of different contamination test methods in use. These were compared and reviewed by CIGRE (CIGRE 1979a), and a few were subsequently standardized (IEC 1991) for use on ceramic and glass insulators. Developments are now focused to obtain a suitable contamination test method for polymeric insulators (CIGRE 1999a). These developments are further highlighted at the end of this section.

The most often used contamination test methods can be grouped as follows:

1. Salt-Fog test
2. Solid Layer tests
3. Simulated environment tests

There are significant differences among these test methods since each simulates a different aspect that may occur in service. This has led to disagreement in test results: an insulator rated high by one test method may receive a lower rating with other test methods. It is, therefore, important to select the test method that will best represents the environment for which the insulators are intended.

The Salt-Fog Test

This method, first derived in 1960-1964 in Great Britain, was given its final form as the result of a collaboration between the Central Electricity Generating Board (CEGB) in Britain, EDF in France, and Ente Nazionale per L'Energia Elettrica (ENEL) in Italy (Lambeth et al. 1973). In this method, the insulator is energized at the service voltage, which is held constant through the test, and subjected to a salt fog. The salt-fog salinity, expressed in kilograms of salt per cubic meter of the solution, defines the severity of the contamination condition. The salinity values used are chosen from values increasing in a geometric progression, usually from 2.5 to 224 kg/m^3. The fog is produced by arrays of nozzles on opposite sides of the insulator, directing a fog of droplets at the insulator by means of compressed air. The highest salinity at which there is a withstand, in at least three out of four one-hour tests, is called the withstand salinity and is regarded as the criterion of performance (IEC 1991).

In a variation of the Salt-Fog test, named the quick flashover method, a variable voltage is applied to obtain statistical information on the flashover voltage at a given salinity

(Lambeth 1988). This method is regarded as more cost and time efficient than the standardized method. After an initial stabilization period, the voltage is raised in a step-wise fashion until flashover. The process is repeated with a starting voltage that is 90% of the previous flashover voltage. Each step comprises a rise in voltage of between 2.5 and 3.5% and a duration of 5 min. It has been shown that there is a good relationship between the withstand salinity and the average flashover voltage obtained from the quick flashover method.

The validity of the Salt-Fog test was evaluated by natural contamination tests. First, a set of various types of insulators was selected to serve as a test sample in different laboratories. The relative performance of the insulators was determined with natural contamination tests by recording surge leakage currents. Then, the same set of insulators was tested with the Salt-Fog method, and the order of merit was determined by withstand salinity. In the Salt-Fog test, there is a relationship between maximum leakage current and fog salinity; thus the comparison of insulator performance is made in terms of leakage current. Good correlation in order of merit between both tests was reported (Lambeth et al. 1973). For polymer insulators, however, it was found that the Salt-Fog test produced inconsistent results that did not correlate well with flashover results from natural testing stations (Houlgate and Swift 1989). This method is, therefore, not generally recommended for the contamination testing of polymer insulators.

Solid Layer Tests

The IEC describes two variants of the Solid-Layer test (IEC 1991):

- Wetting before and after energization
- Wetting after energization

In both methods the insulators are contaminated by spraying or flow-coating the contaminant mixture—comprising a mixture of saltwater and an inert material such as Kaolin, Tonoko, or Kieselguhr—onto the insulator surface. The applied layer of pollution is allowed to dry on the insulator before the actual test starts.

Wetting before and after energization (Wet Contaminant Test). In this test, the insulator is placed in its test position, and the fog generation is started. During this time, surface conductance measurements are performed at regular intervals, and the test voltage is applied when the measurements indicate that the surface conductance has reached its maximum value. The constant amplitude test voltage is applied instantaneously and only for a period of 10 min while the fog generation continues. This process is repeated a maximum of four times, and the insulator is only recontaminated if the conductance measurements have deteriorated by more than 10% from the target value. The insulator has passed the test if no more than one flashover has occurred during four tests. This test method simulates wet contaminant conditions such as cold switch-on. The test severity is normally expressed in terms of the layer conductance. Steam fog is the preferred wetting method for this type of test, but other types of fog may also be used.

Wetting after energization (Clean Fog Test). In this second variant the dry test object is placed in its test position and energized to the test voltage. The steam-fog generation is then started, and the test ends on flashover or if the insulator withstands the voltage and fog for 100 min. Again, this procedure is repeated a maximum of four times, and the insulator has passed the test if it has not flashed over more than once. The Clean-Fog test is regarded as an approximation of inland conditions where condensation is the main mechanism of wetting. Wetting of the insulators is established by a steam-fog of a specific fog density. The severity of this test is normally expressed in the Salt Deposit Density of the contamination on the insulator.

Both these methods are normally performed with constant applied voltage to determine whether an insulator will withstand the applied contamination and voltage stress. Variable voltage tests have also been used in conjunction with the latter method to obtain statistical information about the flashover voltage of an insulator at a specific contamination severity (Lambeth 1988). The application of variable voltage testing is, in this case, more complicated than with the Salt-Fog test, since the flashover voltage changes during the test. It decreases initially due to the wetting of the pollution layer and then increases because the contaminants are leached from the insulator surface.

Experience with the solid layer methods indicates that it cannot be used to test polymer insulators unless changes are made to the test. The main difficulty is to obtain a uniform contamination layer on the insulator. In service, the insulator surface is mostly exposed to dry or humid contamination particles that are not influenced by the insulator's surface hydrophobicity. This leads to a fairly uniform distribution of contamination on the insulator surface. When a contamination layer is artificially applied, as described above, the contamination does not stick to the hydrophobic surface, leading to an irregular distribution of the contamination (Matsuoka et al. 1996).

Various methods have been suggested; the most common variant is to mask insulator's hydrophobicity by the application to the insulator surface of a light dusting of dry Kaolin or Kieselguhr. The contamination solution can then be applied with the normal methods, as described in the standards (De La O et al. 1994; Xidong et al. 1999). It was found that Kieselguhr has an advantage over Kaolin as a masking agent since it resulted in a faster and more predictable hydrophobicity recovery rate (Gutman et al.

2001). This method has subsequently been adopted by a CIGRE Task Force (CIGRE Forthcoming). In order to compare the performance of insulators with different hydrophobicity characteristics, the Task Force suggests that a range of Solid Layer tests (wetting after energization variant) be performed at specified time intervals after the pollution application. In this way, the flashover performance under the best and worst hydrophobicity can be quantified, irrespective of the insulator type. In addition to using a masking agent, the Task Force also suggests that a wetting agent can be used to suppress the hydrophobicity (Swift et al. 2001). NGK has developed a similar method to contaminate polymer insulators. Dry Tonoko powder is applied to the wet insulator surface; after a drying and washing process, the insulator can be contaminated with a slurry of Tonoko and saltwater (Matsuoka et al. 1996).

As was mentioned in Section 4.3, polymer insulators have different wetting characteristics than glass and ceramic insulators due to their low thermal capacity. The insulator adjusts quickly to the ambient conditions, which poses a problem when using a steam-fog wetting that relies on condensation to wet the insulator. Experimental results have shown that a high fog density is an important parameter that has a strong influence on the flashover values obtained on silicone rubber insulators, as shown in Figure 4.5-11. On the strength of these results, it is suggested that polymer insulators be tested with a steam-fog density of 13-15 g/m^3 (Matsuoka et al. 1996).

Another method that has been devised to contaminate hydrophobic polymer insulators uses a so-called Dry-Mixing contamination method (Besztercey and Karady 2000). A special dry mixing nozzle has been developed to produce a mixture of solid contaminant particles and an atomized salt solution in a turbulent jet of air. This nozzle can be used to produce a predictable, uniform, dry contamination layer on hydrophobic or hydrophilic insulators. The coated insulators can subsequently be tested using the standard Clean-Fog method described above.

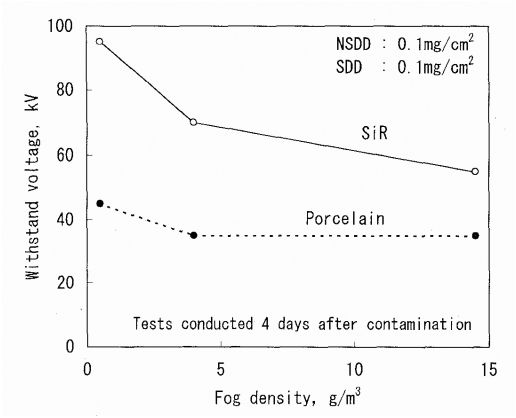

Figure 4.5-11 The relationship between fog density and the contamination withstand voltage of porcelain and silicone rubber insulators (Matusuoka et al. 1996).

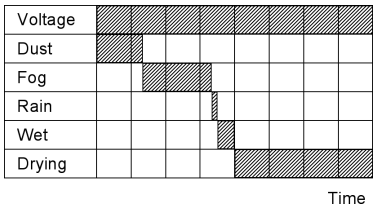


Simulated Environmental Flashover Tests

Simulated environment tests have been developed in order to improve on the aspects where the standardized laboratory tests were perceived to be weak. Two aspects were seen as important:

1. Testing of polymer insulators without the need for surface conditioning before the test
2. Evaluation of the insulator profile and its effect on the "pollution catch" of the insulator.

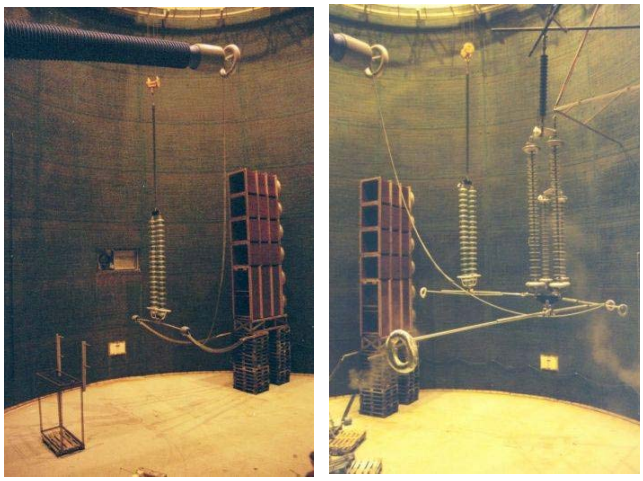
Two variants of simulated environment tests have so far been developed. These are the Dust-Cycle method (Eklund et al. 1994; Suzuki et al. 1999) and the Dry-Salt-Layer method (Engelbrecht et al. 2003). Both these methods expose the tested insulators to airborne contaminants.

In the case of the Dust-Cycle method, a "wind tunnel" is used to blow a mixture of salt and inert material toward the insulator under humid conditions. With this method, a predetermined stress cycle is repeatedly applied to accumulate contamination on the insulator until the insulator flashes over. This stress cycle simulates the pollution deposition by windborne contaminants, "natural" cleaning by rain, and a dry period where the polymer insulators get a chance to recover some of their hydrophobicity. The cycle is shown schematically in Figure 4.5-12, together with a view of a typical test chamber. It is also possible to adjust the cycle to fit specific types of environment. For example, a special

Stress cycle

General view of the test chamber

Figure 4.5-12 The Dust-Cycle method: the test cycle *(top)* and test chamber *(bottom).*



cycle, that included a period of wind cleaning, has been devised to simulate desert conditions (Engelbrecht et al. 2000). It was found that this type of testing produced the same flashover ranking of insulators as was found at field test stations (Znaidi 2001).

For the Dry-Salt-Layer method, a set of fans are used to circulate salt-laden air in the test laboratory and toward the test object under energized conditions, as shown in Figure 4.5-13. As with the Dust-Cycle method, this method also includes separate deposition and wetting phases. During the deposit phase, the insulators are exposed for a predetermined time to the salt-laden air to obtain a target Salt-Deposit Density while energized. After a short rest period, when the contamination layer is allowed to dry on the insulator, the wetting phase begins. A modified steam-fog wetting is utilized, where the steam is gently blown toward the test objects to obtain optimal wetting on polymer insulators. The wetting phase lasts 100 min or until the insulator flashes over. No conditioning of the insulators is necessary because they are exposed to dry, or nearly dry, contaminants so the hydrophobic properties do not influence the formation of a realistic pollution layer in a negative way.

Comparison of Flashover Test Methods

It is important to understand how contamination test methods differ from each other. Each test method presented above essentially simulates a different phenomenon. A factor that is important for one method may not be significant for other methods.

All the wet contaminant tests (e.g., Salt-Fog test) have been established on the assumption that the surface of the contaminated insulator is already wet when voltage is applied. A different approach is taken for the Clean-Fog test, in which a wetting condition, usually fog, is applied to the energized dry insulators. Different assumptions are also made regarding the manner in which the contaminant is deposited onto the insulator surface. For instance, the Dust-Cycle and Dry-Salt-Layer methods use an artificially generated wind to transport and deposit the contamination nonuniformly onto the insulator. This is in contrast to the Solid Layer methods, where the contaminants are applied uniformly to the insulator surface, or the Salt-Fog test, where a significant amount of contamination is accumulated on the insulator surface through the heating effect of the leakage current.

Deposit phase Wetting Phase

Figure 4.5-13 A view of the test set-up during the Dry-Salt-Layer method. Note the cabinet with fans on the right-hand side that blow the salt-laden air toward the test object, at center.

Aspects that should be considered when choosing a representative laboratory test method are:

- The way the insulator is conditioned to obtain a surface condition representative of an aged insulator.
- The type of contamination that the insulator is exposed to during the test: The contaminant can either be in liquid form, as in the Salt-Fog test, or as a dry contaminant layer, as in the Solid Layer tests.
- The way that the insulator is polluted: This can be either an artificially applied pollution layer, as in the Solid Layer tests, or some sort of environmental simulation that brings the pollution onto the insulator by a natural contamination process, such as during the Salt-Fog test.
- Voltage application: Contamination tests are either performed as constant voltage tests (i.e., withstand tests) or with a variable voltage (e.g., quick flashover method).

There is no direct relationship between the results of the Salt-Fog, Clean-Fog, and Wet-Contaminant methods, and one single method cannot simulate the breakdown phenomena created by the others. Thus, it is unreasonable to discuss the order of merit for several types of insulators by employing different test methods. For practical design, it is very important to choose the test method that will simulate the particular natural condition found in service. This means that nature is the ultimate standard to be used in contamination studies.

Clean-Fog tests are normally regarded as the most representative of contamination flashovers in the United States, which are commonly caused by contaminant deposition followed by a wet-weather condition. This test method closely simulates the slow wetting condition regarded as an essential component of almost any natural fog- or dew-initiated flashover. The high wetting rate present in Salt-Fog tests is more representative of coastal conductive fog conditions, and wet contaminant tests are more relevant to cold

switch-on conditions, which is when a completely wetted insulator string on a de-energized line is switched on.

4.6 ELECTRICAL PERFORMANCE OF INSULATORS AND AIR GAPS UNDER AC VOLTAGE

4.6.1 Introduction

An insulator needs to withstand all the electrical stresses that it is exposed to for the whole of its expected life. These stresses include transient overvoltages, such as switching and lightning, as well as more long-term voltage stresses, such as ac temporary overvoltage and the continuous ac supply voltage.

This section will concentrate on the insulation strength under ac voltages. Information can be obtained on the switching and lightning performance in Chapter 5 (Section 5.6.3) and Chapter 6 (Section 6.5), respectively.

4.6.2 Dry and Wet AC Flashover Strength of Air Gaps and Insulators

When insulators are dry, they have an ac flashover characteristic that is between that of a rod-rod and rod-plane gap, unless special field grading is employed, as shown in Figure 4.6-1 (Aleksandrov et al. 1962). This figure presents the flashover strength of a group of basic insulation configurations. The flashover stress of smaller gaps is presented in Figure 4.6-2 (IEEE 1974). Since the dry ac flashover strength of insulators is not a determinant in the insulation design, this data is used in the most cases to set the minimum clearances for power-frequency voltages in tower configurations during the initial design stages. For tower configurations for which the gap factor, "K", is known (see Chapter 5 [Section 5.2.4]), the ac 50% flashover strength can be estimated from (IEC 1996):

$$V_{a.c.50} = 750(1.35K - 0.35K^2)Ln(1 + 0.55L^{1.2}) \qquad 4.6\text{-}1$$

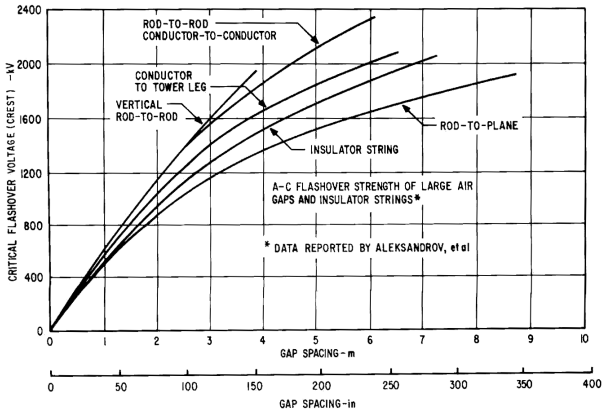


Figure 4.6-1 AC flashover strength of large air gaps *(*Aleksandrov et al. 1962*).*

This equation is valid for gap spacings greater than or equal to 2 m. A standard deviation of 2% may be assumed for the ac flashover strengths of air gaps. If the withstand voltage is assumed to be at the 3-σ level, its voltage would be 94% of the 50% flashover voltage (CFO).

Fires under transmission lines have proven to be a major cause of transmission-line outages. For example, in South Africa, 15.6% of transmission-line faults were classified as due to fires under the lines (Vosloo and Van Rooyen 2001). Investigations have shown that fires under lines cause a dramatic reduction in the withstand strength of the air between phases and between phase and ground (Fonseca et al. 1990; Sadurski and Reynders 1989; CIGRE 1992a; Swift and Naidoo 1993; Hoch and Sukhnandan 2003; Deno and Zaffanella 1987).

The heat in the flame associated with a fire reduces the air density according to the well-known expression:

$$\delta = p\frac{293}{273 + t} \qquad 4.6\text{-}2$$

Where:

δ = the air density relative to a pressure of 1.0 bar and a temperature of 20°C.

p = the pressure in bar.

t = the air temperature in °C.

Bearing in mind that temperatures as high as 900 °C are found in the flames of a large fire, the equation shows that the air density can be reduced to 25% of its value at 20 °C. Since breakdown strength is directly proportional to air density, the heat of the fire can reduce the strength of the air to 25% of its value at 20 °C (CIGRE 1992a). However, elevated temperature is not the only mechanism present in a fire that causes a reduction in the breakdown strength. Wilderness (bush) and agricultural-land fires produce conducting particles in the air gap, which increase the conductance of the gap. The carbonized particles in the gap

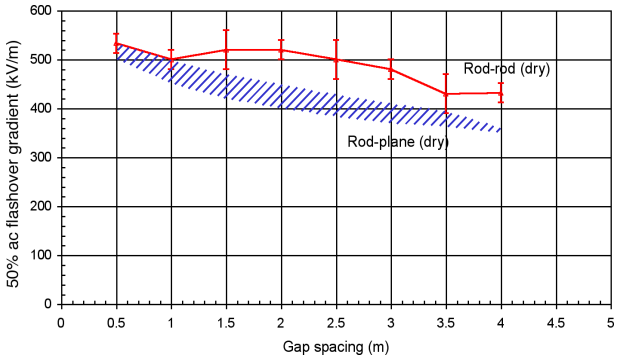

Figure 4.6-2 AC flashover gradient of small rod-rod and rod plane gaps under dry conditions. Note that the rod-plane data is represented by a band (IEEE 1974).

shorten the electrical length of the gap, and they are also sources of electrons, contributing in two ways to increasing the conductivity of the air (Hoch and Sukhnandan 2003). Long carbon particles, like those produced by sugarcane fires, lead to the greatest reduction in breakdown strength (Fonseca et al. 1990; Swift and Naidoo 1993). Measurements have shown that the resistivity of an air gap in a fire ranges between 5 MΩ-m and 25 MΩ-m (ESKOM 2003). As a consequence of the combined effect of these mechanisms, the withstand gradient, in the presence of a fire, can be reduced to as little as 10% of that without the fire. Flashovers are most common at mid-span, since that is where the clearance to ground is the least (ESKOM 2003; Fonseca et al. 1990; Deno and Zaffanella 1987).

Fires also lead to deposits on the surface of the line insulation. However, it has been found that the conductivity of the deposits is very small compared with other environmental deposits and does not make a significant contribution to insulator flashover (Fonseca et al. 1990).

When considering the impact of fires on line design, investigations have shown that it is necessary to achieve an average gradient between conductors and between conductors and ground of not more that 11 kV/m if fire flashovers are to be eliminated (Sadurski and Reynders 1989). Table 4.6-1 gives representative values for the average field associated with modern transmission lines (taken from data in ESKOM 2003).

Table 4.6-1 Average Gradient to Ground, at Mid-span, as a Function of Transmission-Line Voltage

Max System voltage, kV (rms)	145	245	300	420	800
Average gradient, kV (rms)/m	13	20	23	30	31

From the table, it is obvious that the gradients of transmission lines of 200 kV and above are too high to prevent flashover to ground in the event of a bush fire. The cost of increasing the clearances to values where the probability of flashover is negligible is so significant that it is not done. The strategy is to manage the right-of-way by regular clearing of the vegetation under the line and controlling the nature of farming activity in the right-of-way.

Bird excrement may also lead to flashover directly across the air gap by forming a continuous streamer of up to 2.5 m (for large birds). This may span enough of the air gap in the tower window to cause flashover under steady-state ac conditions. This proved to be the explanation of many "unknown" flashovers in the U.S. (Burnham 1995), Germany (Kaiser 1970) and South Africa (Vosloo and Van Rooyen 2001). The only solution is to install bird guards to prevent the birds from sitting above critical gaps in the tower—e.g., as shown in Figure 4.2-5 for the I-suspension string configuration (IEEE 2004a, 2004b). This aspect is further discussed in Chapter 12 (Section 12.16).

Rain may substantially reduce the ac strength of insulator strings, depending on the rate of rainfall, conductivity of the rainwater, and the insulator configuration considered. Typical flashover stress levels on glass and porcelain cap-and-pin insulators are between 250 and 300 kV per meter of section length during standard wet tests, with a low conductivity artificial rain (Sediver Catalog). Figure 4.6-3 shows the wet ac flashover strength of a selection of typical disc insulator strings. The main insulator parameters that influence the flashover voltage are the spacing of the individual discs and their diameter. The results in Figure 4.6-4 show the wet ac flashover voltage of a typical silicone rubber insulator. This curve has been based on catalog data (Lapp catalog). A comparison of these curves shows that there is not much difference between the wet flashover strength of ceramic and glass disc and hydrophobic composite insulators. Hydrophilic polymer insulators may have a wet ac flashover voltage that is 10–20% lower than that of the hydrophobic ones (Shaowu et al. 2000).

The rainfall rate mainly influences the flashover strength by the amount of water that cascades down from one unit to the next. The effect is greatest on vertically orientated

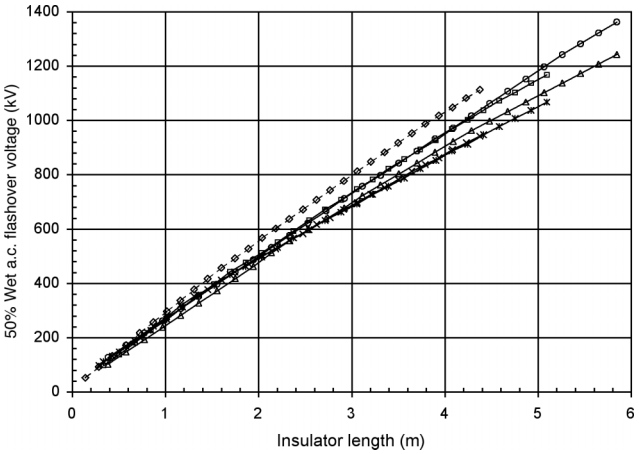

Figure 4.6-3 Wet ac flashover voltage of various shapes of cap-and-pin insulator strings (Sediver Catalog).

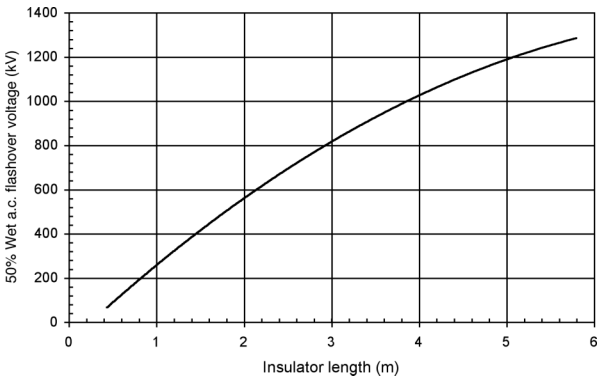

Figure 4.6-4 Wet ac flashover voltage of a silicone rubber insulator (Lapp Catalog).

strings (I-strings). For testing purposes, ANSI Standard C-29.1-1961 has specified a rain rate of 5 mm/min. This is equivalent to an extremely heavy rain, which rarely occurs in nature, and it causes a reduction in strength on long insulator strings of about 30% from the clean, dry critical flashover voltage (Locke Insulator Catalogue and Engineering Handbook; AIEE 1958; Standring et al. 1963). While this heavy rain rate was used historically, current wet tests on power apparatus are performed at a more realistic rain rate of 1 mm/min and a resistivity of 100 ohm-meters (IEEE 1995; IEC Forthcoming a). Figure 4.6-5 shows the correction factor curve used at Project UHV for rain rate. The critical flashover voltage for clean, dry conditions is defined as 1 p.u. To find the critical flashover voltage at any rain rate, one multiplies the reference value by the corresponding correction factor.

Critical ac flashover voltage also depends on water resistivity. The resistivity of rain is affected by pollution of the air, salt particles near seacoasts, and different kinds of contaminants near industrial areas. As rain begins, the rainwater resistivity is lowest, thereafter increasing with time. Figure 4.6-6 shows the correction factor curves used at Project UHV for rain resistivity on glass and ceramic insulators. The curve corrects the per-unit critical flashover voltage versus water resistivity for the case of a rain rate of 5 mm/min. As a reference value, Figure 4.6-6 uses a resistivity of 17.8 kΩ/cm. The slope of this curve is less for a lower rain rate.

Increasing levels of rainwater resistivity also adversely affect the ac flashover voltage of polymer insulators. Hydrophilic insulators are more affected than hydrophobic insulators, as shown in Figure 4.6-7. However, even hydrophobic insulators are strongly affected for rainwater conductivities above 10 mS/cm.

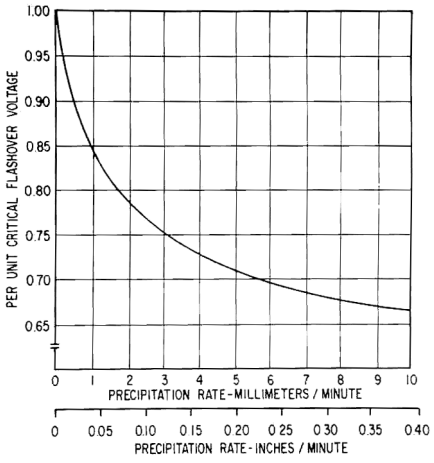

Figure 4.6-5 Correction factor for rate-of-rain on the a.c. flashover strength of I-strings (EPRI 1982).

4.6.3 Contamination Flashover Performance of Insulators

Over the years, many reports have been published on the performance of insulators under contaminated conditions. It is generally difficult to extrapolate results from one particular insulator to another, since small changes in the profile may lead to quite big differences in performance. On the other hand, most transmission lines are installed with very similar, or in many cases, the same type of insulator. In this section, some general conclusions are presented regarding transmission-line insulators, based on the assumption that most are installed with disc insulators or polymer longrod insulators. Some information is also provided regarding porcelain post insulators.

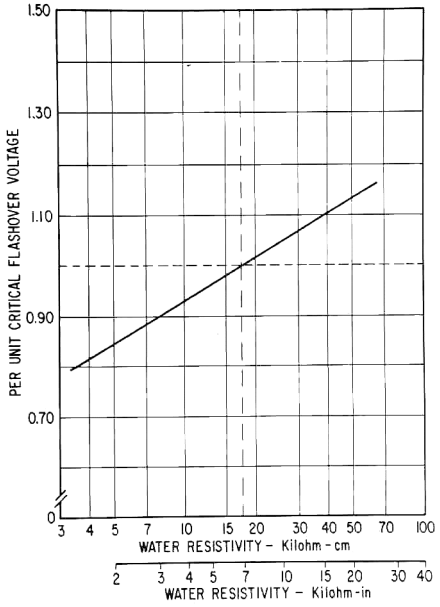

Figure 4.6-6 Correction factor for rainfall resistivity on the ac flashover strength of insulators (EPRI 1982).

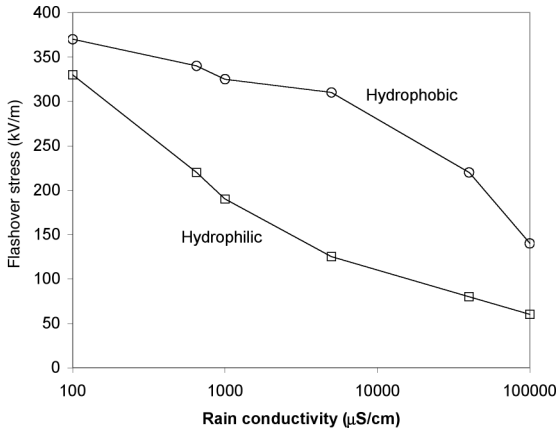

Figure 4.6-7 The relationship between ac wet flashover and rain conductivity for hydrophobic and hydrophilic polymer insulators (Shaowu et al. 2000).

Results are presented for both glass-and-porcelain insulators and polymer insulators separately since their characteristics differ considerably. It is, however, difficult to draw general conclusions for polymer insulators, since there is still no general agreement on a standardized method to determine the contamination performance of these insulators. Consequently, the results from different laboratories cannot be compared directly.

4.6.4 Glass and Porcelain Insulators

Flashover Voltage as a Function of Contamination Severity

Figure 4.6-8 shows withstand specific creepage distance as a function of contamination severity, based on a compilation of published results for standard-shape disc insulators (CIGRE 2000b). This relationship can be adequately described by:

$$\text{Flashover Gradient} = \frac{V}{L} = A \cdot \gamma^{-\alpha} \text{ or} \qquad 4.6\text{-}3$$

$$\text{Unified Specific Creepage Distance} = \frac{CD}{V} = B \cdot \gamma^{\alpha} \qquad 4.6\text{-}4$$

V = flashover voltage.
L = section length of the insulator.
CD = leakage distance of the insulator.
γ = contamination severity level.
A, B, and α are constants.

The value of α, which determines the "slope" of the curve, can be considered as a weighted average of the value for an electrolyte (α = 0.33) and that of air (α = 0). For line insulators, a value of α =0.2 can be considered typical (Looms 1988).

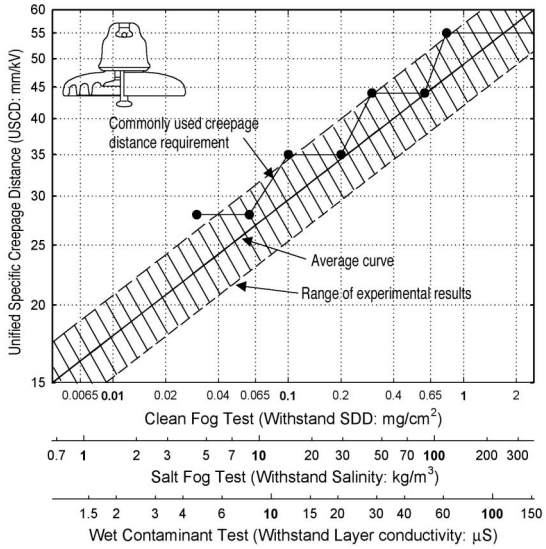

Figure 4.6-8 The withstand ac contamination performance of standard types of disc insulator based on the results from Salt-Fog and the Solid-Layer tests (CIGRE 2000b).

Table 4.6-2 presents the constants of the above equations associated with the curves in Figure 4.6-8. These values are based on the assumption that the flashover gradient is expressed in kV/m and the Unified Specific Creepage Distance (USCD) in mm/kV. (*Note: the unified creepage distance is the creepage, or leakage, distance of the insulator divided by the maximum operating voltage across the insulator, not the phase-to-phase system voltage as previously defined for the creepage distance, as used in the first version of IEC 60815.*) The values for *A* were derived from *B* by assuming a creepage distance to section length ratio of 2.21, which is typical for a standard-shape disc insulator.

Insulators with a long leakage distance, the so-called antifog insulators, have generally higher flashover strengths per unit length as compared with standard units, as shown in Figure 4.6-9. These results have shown:

- The performance of antifog insulators is not always proportional to leakage distance. The flashover values approach that of standard insulators at low contamination severity levels, while at high contamination levels, the performance becomes more proportional to the leakage distance.

Table 4.6-2 Experimental Parameters for the Withstand Curves Presented in Figure 4.6-8

Type of Laboratory Test (Severity Parameter)	Lower Limit			Average			Upper Limit		
	A	B	α	A	B	α	A	B	α
Salt – Fog (kg/m³)	115.7	19.1	0.22	134.8	16.4	0.22	156.7	14.1	0.22
Clean – Fog (mg/cm²)	38.8	56.9	0.22	45.1	49.0	0.22	52.6	42.0	0.22
Wet contaminant (μS)	126.3	17.5	0.28	148.3	14.9	0.28	175.4	12.6	0.28

- The spacing of the insulator discs is an important parameter at low pollution levels (i.e., SDD < 0.1). A greater spacing leads to a higher flashover voltage, even if the leakage distance is kept the same.
- Larger discs, with a diameter greater than 280 mm, have higher flashover strengths than regular disc insulators with a diameter of 254 mm.

Longrod and post insulators have approximately the same flashover performance as standard-shape insulators, as illustrated in Figure 4.6-10.

In Section 4.3.2, the importance of the nonsoluble components in the contamination layer was highlighted. Standardized solid layer tests utilize a nonsoluble deposit density (NSDD) of 0.1 mg per cm^2 of surface area of the insulator. In desert areas the NSDD may be much higher, which may severely affect the flashover voltage. As Figure 4.6-11 shows, longrod insulators are more affected by NSDD than disc insulators, and the reduction in flashover strength can be by as much as 40% in extreme cases (Matsuoka et al. 1996). These results show the importance of taking account of the nonsoluble deposit density when dimensioning insulators. It may even be prudent to confirm the insulator performance with testing at appropriate NSDD levels.

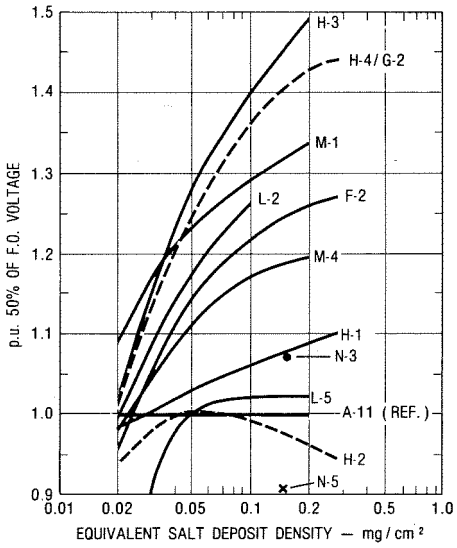

Figure 4.6-9 The flashover voltage of antifog insulators in relation to that of a standard-shape disc. (Labels on the graph refer to insulator types listed in Appendix 4.1) (EPRI 1982)

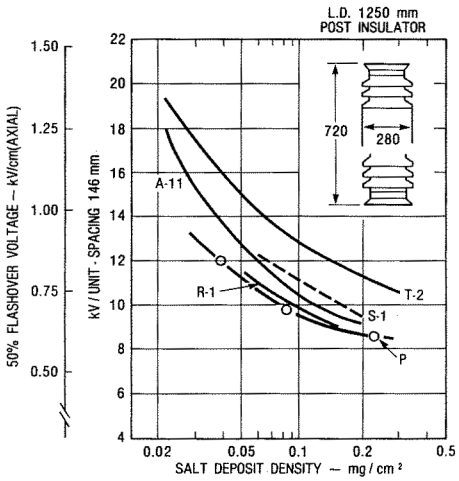

Figure 4.6-10 Performance of post insulators. (Standard disc A-11 is shown as a reference.) (EPRI 1982)

The type of soluble contaminants on the insulator may also affect the flashover under fog conditions (Ramos et al. 1993; Fujimura et al. 1979). Results from comparative Clean-Fog tests with different kinds of contamination salts are shown in Figure 4.6-12. These results show that low-solubility salts have a higher fog withstand voltage than high-solubility salts such as sodium-chloride.

Leakage Path Length

In most international standards the leakage path length is used as the main parameter for the dimensioning of

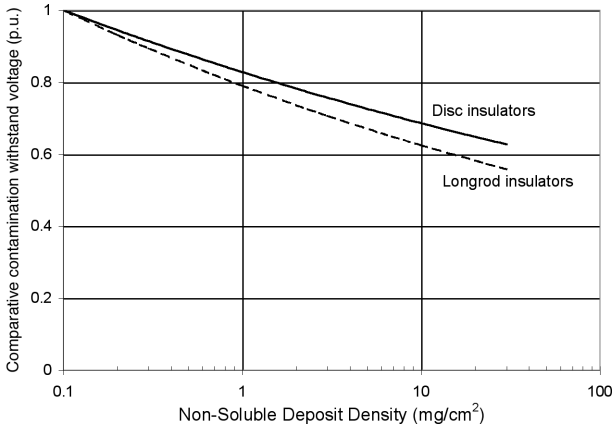

Figure 4.6-11 The influence of the amount of nonsoluble material on the contamination withstand voltage of disc and longrod insulators (CIGRE 2000b).

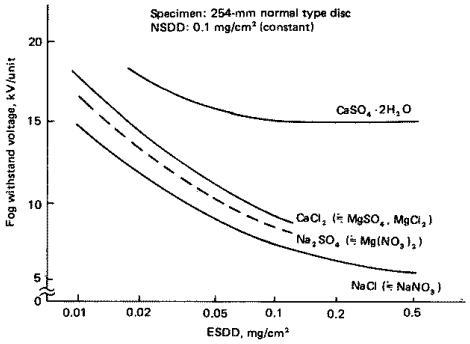

Figure 4.6-12 Influence of various salts in the contamination layer on the insulator fog withstand voltage (Fujimura et al. 1979).

insulators with respect to contamination. The guidelines commonly used are presented in Table 4.6-3. A comparison of this table with Figure 4.6-8 shows that the creepage distance guidelines agree well with the performance of standard-shape disc-type insulators. This agreement is probably due to the fact that the recommendations were based on the performance of standard-shape disc insulators in the first place.

The reasons for the differences in the classifications of the IEC and IEEE are not clear. It could be speculated that the differences may be due to differences in the NSDD levels of the typical environment on which each of these recommendations was based.

There is, however, a growing body of evidence to suggest that neither the leakage distance nor the section length can be used as a sole parameter for dimensioning (Swift 1996). This fact is also demonstrated in Figure 4.6-9, which shows that:

- At low pollution levels, the antifog and reference insulator have a similar flashover stress, despite the large differences in the leakage path length.
- At high pollution levels, the flashover voltage per unit length of the antifog units is much higher than that of the reference insulator.

Observations during low-pollution-level tests have shown that the growth of the dry-band arcing takes place through air, whereas at a high pollution severity, the breakdown takes place along the surface. The greater amount of inter-skirt breakdown at low pollution levels, therefore, reduces the leakage distance effectiveness of antifog insulators (Swift 1996). This is illustrated graphically in Figure 4.6-13.

There may also be other conditions when the leakage path may be rendered less effective. Field observations of longrod insulators with a close shed spacing have shown that the dry-band arcing often develops from the shed tips, as can be seen in Figure 4.6-14. This is in contrast to laboratory tests, with a higher degree of wetting, where the dry-band arcing follows the surface much closer.

In conclusion it can be said that the creepage distance concept seems to work well for those cases where the insulator profile has been selected to suit the environment. The concept breaks down, however, for inefficient profiles where nonlinear effects, such as inter-shed or inter-skirt breakdown, become important.

Natural Versus Artificial Contamination Tests

In Figure 4.6-15, the ac flashover voltage data obtained at three different natural test stations (situated in coastal areas) is compared against those of artificially polluted insulators under a Clean-Fog test (Naito et al. 1990). It shows that:

- The withstand voltage is about the same for the natural and artificial tests.
- The dispersion in the test results of natural tests is greater than that of artificial tests.

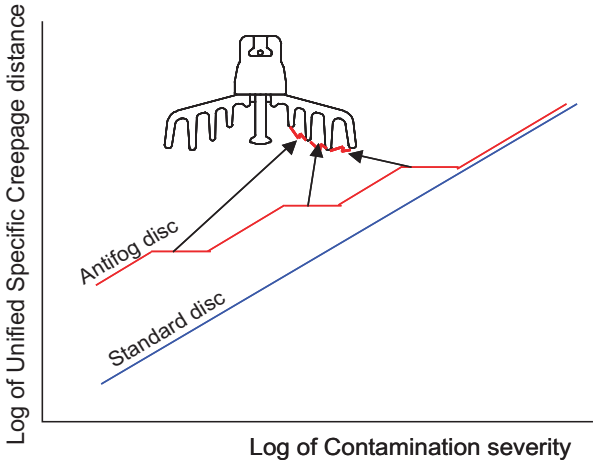

Figure 4.6-13 General effect of inter-skirt breakdown on the creepage distance requirement of antifog insulators.

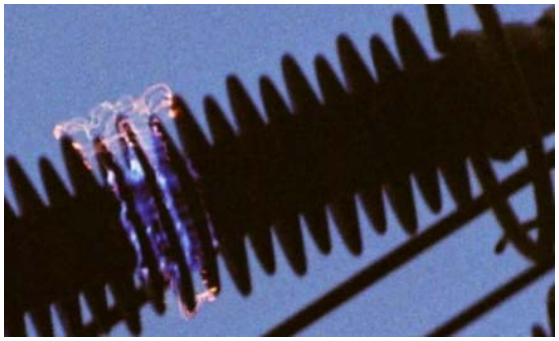

Figure 4.6-14 Discharge development on a porcelain longrod insulator under natural wetting conditions.

Table 4.6-3 Commonly Used Guidelines for the Selection of Creepage Distance Based on ESDD Measurements

Pollution Class	From IEC ESDD (mg/cm^2)	IEEE ESDD (mg/cm^2)	Unified Specific Creepage Distance (mm/kV_{p-g})
		< 0.03	21 (IEEE only)
1. Light	0.03 – 0.06	0.03 - 0.06	28
2. Medium	0.10 – 0.20	0.06 – 0.1	35
3. Heavy	0.30 – 0.60	>0.1	44
4. Very heavy	> 0.80		55

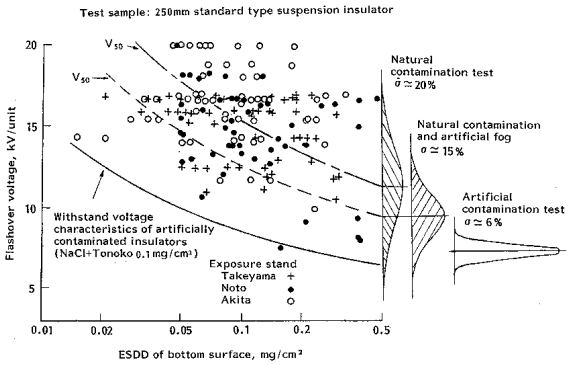

Figure 4.6-15 Results of ac natural contamination tests compared with Clean-Fog tests (Naito et al. 1990).

The larger dispersion of the natural test results is mainly due to variations in the wetting conditions, as well as the greater nonuniformity of the contamination deposit during the natural tests.

For inland areas, the agreement between artificial and natural contamination tests is not always as good. In most cases, this is due to the effects of higher levels of nonsoluble contaminants and the presence of low-solubility salts (Lin et al. 1992).

Linearity of Flashover Voltage as a Function of Insulator Length

In the preceding sections, the results were presented based on the assumption of a linear relationship between insulator length and flashover voltage. There seems to be general agreement, based on results from both natural and artificial contamination tests, that this is in fact correct (Fujimura et al. 1979; Houlgate et al. 1982; Looms 1988). There has been, however, some evidence from laboratory tests performed at Project UHV (EPRI 1982) to suggest a nonlinear relationship for insulator strings of over 3 m in length and low contamination levels (i.e., a Salt Deposit Density of below 0.02 mg/cm^2) (EPRI 1982). The results suggest further that this nonlinearity is accentuated by natural wetting conditions (i.e., noncritical wetting). Based on these tests, the concept of the long-string efficiency, λ, has been defined, which is expressed as:

$$\lambda = \frac{L_{EHV} \cdot V_{UHV}}{L_{UHV} \cdot V_{EHV}} \qquad 4.6\text{-}5$$

Where:

L_{UHV} = string length required at a UHV voltage level.
L_{EHV} = string length determined at a lower voltage level.
V_{UHV} = UHV voltage level.
V_{EHV} = lower voltage level.
λ = long-string efficiency.

The dependence of long-string efficiency on the line-to-earth voltage is shown in Figure 4.6-16, which applies to standard vertical insulator strings up to 11.5 m connection length (CIGRE 2000b). The equivalent salt deposit density (ESDD) is in the range of 0.01-0.04 mg/cm^2. For antifog insulators, the results for long-string efficiency are shown in Figure 4.6-17 for string connection lengths up to 8 m. In this case, the range of ESDD is 0.02–0.04 mg/cm^2 (CIGRE 2000b).

There is still no general agreement on how the long-string efficiency should be taken into account when dimensioning insulators, since this mainly occurs under light wetting and low contamination severities. This reduction in strength, which is only on the order of 5–10%, needs to be weighed against the greater uncertainty with which the site contamination severity is known.

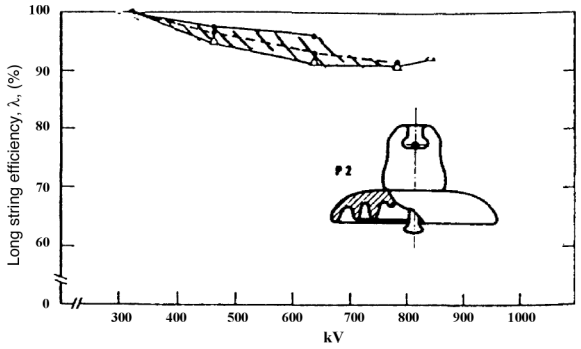

Figure 4.6-16 Long-string efficiency for ac energization as a function of line-to-earth voltage. Range of ESDD 0.01-0.04 mg/cm^2 (CIGRE 2000b). IEEE insulators (146 mm spacing, 254 mm diameter, and ratio leakage to spacing 2.1).

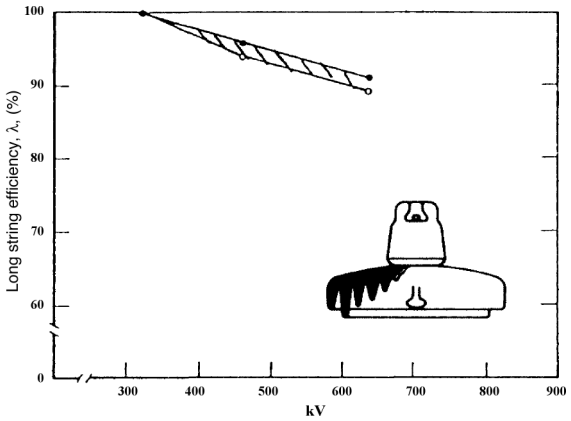

Figure 4.6-17 Long-string efficiency for ac energization as a function of line-to-earth voltage. Range of ESDD 0.02-0.04 mg/cm^2 (CIGRE 2000b). Antifog insulators (220 mm spacing, 420 mm diameter, and ratio leakage to spacing 3.3).

Effect of Insulator Orientation on Contamination Flashover Performance

It is generally agreed that inclined and horizontal line insulators have a better contamination performance than vertical insulators. The most important orientation effect is the accumulation of pollution, where inclined and horizontally installed insulators are more accessible for natural cleaning.

Also, during artificial testing, inclined and horizontally installed insulators may have significantly higher flashover voltages, as illustrated in Table 4.6-4, which presents the 50% flashover strength for the horizontal and V-string configurations as compared to equivalent flashover strength for I-strings. All tests were conducted on identical-length standard-shape insulators (Type A-11) at a Salt Deposit Density of 0.02 mg/cm^2 (average). Table 4.6-4 also gives a comparison of long-string efficiency (λ). From these results, it may be seen that the strength of horizontal configurations falls between the I- and V-configurations, and that they are somewhat more linear (higher λ). It would appear that these results, together with the available data on I- and V-strings, provide a sufficient guide for horizontal string usage.

The Flashover Performance of Closely Spaced Insulator Strings

Insulator assemblies consist sometimes of multiple insulator strings to fulfill mechanical or security requirements. Experimental results have shown that there is a reduction in flashover strength over and above that expected from statistical considerations. The following trends were observed (Sklenicka and Vokalek 1999; Petruch 1990):

- The flashover strength of closely spaced stings may be up to 30% lower than that of an identical single string. From purely statistical considerations, a reduction of only 7% is expected.
- The reduction in strength is caused by partial arcs bridging the gap between the parallel insulator strings.
- The proximity effect was independent of the laboratory test method used.
- Proximity effects have been observed on disc, longrod, and post insulator types.

Table 4.6-4 Comparison of 50% Flashover Strength and Long-String Efficiency for Different String Configurations (ESDD = 0.02 mg/cm^2)

Applied Voltage (kV l-g)	Relative Strength Using I-String as Reference		
	Horizontal	I-String (Ref)	V-String
370	1.22	1.0	1.60
740	1.29	1.0	1.63
	λ = 95%	λ = 90%	λ = 92%

- The proximity effect is independent of the orientation (i.e., vertical, inclined, or horizontal) of the parallel insulator set. Horizontal insulators are subjected to more frequent instances of natural cleaning, which may counter the proximity effect in practical situations.
- The reduction of strength increases with a decrease in the spacing between the parallel insulator sets.
- The reduction in strength was higher for longer insulator sets.

Based on the test results, an inter-string spacing of between 400 and 500 mm is recommended. Tapered insulator installations with a closer string spacing at the live end than at the grounded end may also offer a significant improvement in the flashover voltage of the double string.

4.6.5 Polymer Insulators

Overview of Contamination Flashover Performance

Hydrophobic polymer insulators generally have a superior contamination flashover performance when compared to that of glass and porcelain. Tests at Brighton insulator testing station showed that hydrophobic (i.e., silicone rubber) insulators exhibited a 60% higher flashover voltage than ceramic or glass insulators of the same axial length, and hydrophilic polymer insulators (i.e., EPDM) showed a 20% better flashover performance (Houlgate and Swift 1990). Most transmission-line owners who have changed the line insulation from glass or porcelain to polymer insulators have reported a major improvement in line contamination outage performance (Ravera et al. 1996; Fierro-Chavez and Ramirez-Vazquez 1999). The reasons for this are:

- **Surface hydrophobicity**. Good hydrophobicity is very efficient in preventing the formation of a uniform wet surface that is so fundamentally important to the contamination flashover process (Xidong et al. 1999). A part of the contamination deposit may also be "neutralized" by the hydrophobicity transfer phenomenon (Kindersberger and Kuhl 1989).
- **Thermal characteristics**. Polymer insulators adjust quickly to the ambient temperature. The wetting is, therefore, less efficient than on ceramic and glass insulators under critical wetting conditions.
- **The slender shape of the insulators**. For a given surface conductance, insulators with a slender shape will have a higher overall resistance than insulators with a larger diameter.
- **Longer leakage distances**. Polymer insulators are often installed with a longer leakage distance than ceramic and glass insulators (Maxwell and Hartings 2000). This is often done to avoid material deterioration due to leakage currents.

The above discussion does not account for differences between the contamination collection on polymer and ceramic or glass insulators (e.g., aerodynamic profile and surface roughness).

There are certain exceptions where the implementation of polymer insulators was not successful. In areas prone to bird streamer outages, an increased line outage rate was reported after the installation of polymer insulators. This was ascribed to presence of corona rings and the resulting shorter strike distance to the tower on replacement units (Burnham 1995). In extreme contamination conditions, polymer insulators may suffer from erosion and eventual electrical or mechanical failures due to the long-term exposure to damaging levels of leakage current (Fierro-Chavez and Ramirez-Vazquez, 1999).

Effect of Hydrophobic Properties on Insulator Flashover Performance

The level of surface hydrophobicity has a great influence on the surface conductivity of contaminated insulators during wetting conditions. Surface hydrophobicity measurements have shown that the surface layer becomes increasingly conductive for a level of hydrophobicity of above HC 4 (see Figure 4.2-16) (Eklund et al. 1995). This corresponds to the level of hydrophobicity when water runnels form on the surface. This behavior is reflected in the flashover gradient, as shown in Figure 4.6-18 (Xidong et al. 1999). (A runnel is defined as a narrow channel of water.)

Results from field inspections of hydrophobicity concluded that silicone rubber insulators showed good long-term hydrophobic properties (HC 1-4) in most environments, except close to the coast where hydrophobicity may regularly be suppressed. It was also noted that the loss of hydrophobicity is often very localized and concentrated around the end fittings, especially around the high-voltage end where the electric field is the highest (Xidong et al. 2001; Phillips et al. 1999a, 1999b). EPDM insulators do not have significant long-term hydrophobic properties (i.e., typically in the range of HC 5-7) (Maxwell and Hartings 2000; Montesinos et al. 2000).

Flashover Voltage as a Function of Contamination Severity

Laboratory tests on polymer insulators suggest that the performance of polymer insulators as a function of contamination severity can be expressed by the same power function as that used for ceramic and glass insulators. An example of typical results (NGK test method) is presented in Figure 4.6-19, which shows that silicone rubber insulators offer a significant improvement in insulator flashover stress as compared with standard disc insulators (Matsuoka et al. 1996). Tests indicated that this improvement may be between 20 and 70%, depending on the condition of the insulator's hydrophobicity when tested (Xidong et al. 1999).

The level of nonsoluble deposits in the contamination layer, as expressed by the NSDD, affects the flashover voltage of polymer insulators to the same extent as the ceramic longrod insulators (see Figure 4.6-11) (Matsuoka et al. 1996).

Laboratory test results suggest strongly that the contamination performance of hydrophobic polymer insulators should be evaluated under heavy wetting conditions (De la O and Gorur 1998; Matsuoka et al. 2002; Shaowu et al. 2000). Not only should the steam fog input rate used in Clean-Fog tests be much higher than specified in the standards, but also simulated rain tests on contaminated insulators are important to evaluate the shed profile and spacing in terms of water-cascading effects.

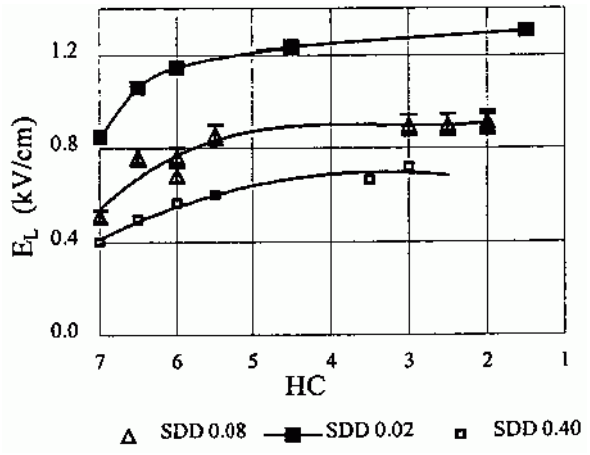

Figure 4.6-18 The flashover voltage over the leakage distance, as a function of the hydrophobicity class, as determined by modified Clean-Fog tests (Xidong et al. 1999).

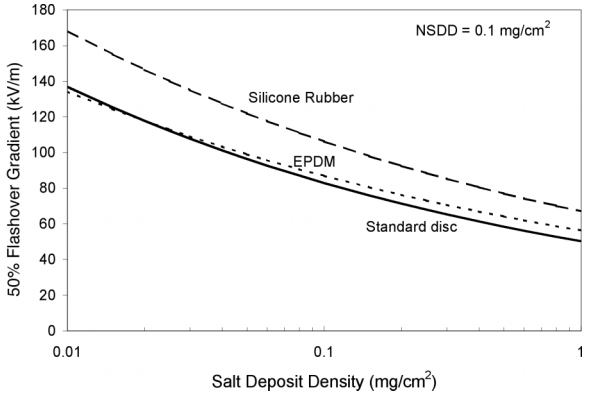

Figure 4.6-19 Comparison of the flashover stress of a hydrophobic silicone rubber insulator (Matsuoka et al. 1996) to that of a standard-shape disc insulator (derived from Figure 4.6-8 and based on a standard deviation of 8%).

4.6.6 Resistive Glaze Insulators

Insulators with semiconducting glaze have been available for some time. The use of these resistive coatings has been found effective both in suspension- and post-type insulators for EHV applications as a solution for insulation design in heavily contaminated areas. The presence of a resistive coating on the insulator surface results in two phenomena that lead to superior contamination performance. First, the continuous current flow of approximately 1 mA through the resistive layer provides enough heat on the surface of the insulators to keep them dry in dew or fog. Second, the resistive grading results in a significantly more uniform electrical stress along the insulator length. There have been some difficulties with the fabrication and field life of these insulators in the past. However, significant technological improvements have been made, and substantial service experience exists. Consequently, their use should be considered in the contamination design of UHV transmission lines.

Unfortunately, an operating stress of 10-12 kV/unit, suggested by several manufacturers for EHV applications, would impose a severe penalty on UHV line design. On an 1100-kV system, for example, 58 units would be required if the nominal rating were 11-kV/unit. The use of such long insulator strings raises performance- and cost-related questions. First, there is some concern as to the voltage distribution on these long strings, even if they are semiconducting. Second, the issue of thermal stability, with even a slightly nonuniform voltage distribution, should be considered. Finally, there is the economic consideration of the acceptability of a constant power loss due to resistive heating.

The voltage distribution on a long string of semiconducting glaze insulators will be more uniform than on a conventional string because of the resistance of each unit (Fukui et al. 1974). The thermal stability of a long string should also be better than that of a short string because changes in the impedance of one unit have a small effect on the total string impedance. Consequently, the total series current also does not change very much. Therefore, it is reasonable to expect that the test results obtained with short strings in fog tests at constant voltage will also apply to the long strings required for UHV because the primary mechanism involves the heating of the surfaces of each insulator.

To verify that the performance of semiconducting glaze insulators would exceed that of conventional insulators in the type of artificial contamination tests used at Project UHV, tests were conducted on suspension units with a predeposited contaminant and a clean fog. The insulators were the standard shape (146 mm by 254 mm) and were intended for energization at 11 kV per unit and a nominal resistive current of 1 mA. Short strings containing five units of these insulators were contaminated with a 40/100 mixture of Kaolin and NaCI (g/l) corresponding to a Salt Deposit Density of about 0.25 mg/cm^2, which represents a heavy level of contamination severity. The insulators were energized at a constant voltage of 11 kV/unit and exposed to the clean fog. The heat dissipation of 11 W/insulator kept the surfaces dry, and no flashovers occurred. Thus, it was verified that this type of insulator is effective for heavy contamination in areas where wetting usually occurs by fog.

The possibility of reducing string lengths with semiconducting glaze insulators was investigated with units designed for nominal 15-kV, 1-mA operation. Such insulators would be attractive for UHV line design. For example, on an 1100-kV system, 42 of these insulators would be required. This would mean a shorter overall string length than that possible with the number of conventional units (Massey 1972) necessary for even light contamination. (This assumes the semiconducting glaze units have the same spacing as the conventional ones.) Although the use of such semiconducting glaze units will aid in the power-frequency design of UHV lines, the resulting increased stress per unit in this case requires that attention be focused on the insulation strength during the energization of strings that are contaminated and wet, a condition known as cold switch-on. This situation occurs on lines that have been unenergized for a period of time long enough to render the heating, which results from the semiconducting glaze while the units are energized, ineffective in preventing the accumulation of moisture on the insulator surface.

Some data on the cold switch-on strength of semiconducting glaze insulators are available (Moran 1974). However, these data were obtained with relatively short strings, containing ten units (1.5 m) or less. The purpose of the tests reported here was to extend the data to strings that would be suitable for UHV transmission systems and to make a direct comparison with the cold switch-on strength of conventional insulators, which have a similar shape.

The cold switch-on test voltage was not applied to the insulator strings until they were thoroughly wet from the clean fog. To determine the time at which this condition was achieved, impedance measurements were made either on the strings to be tested or on an auxiliary monitor string that was prepared in an identical manner to the test strings. The impedance was found by applying a maximum voltage of 1 kV/unit to the insulators every five minutes for a duration that was only long enough to measure the current, generally 0.5 s or less. When the resistance reached its minimum value and was stabilized, the test series was begun.

In the test, two I-strings (one conventional and the other semiconducting glaze) were always tested in parallel by applying the full test voltage alternately to the conventional string for a maximum duration of 30 s and to the semicon-

ducting glaze units for 5 s, with another application of voltage on each string every 10 min. The 50% flashover voltage was determined by an up-and-down technique, in which the voltage for consecutive shots was raised or lowered by ~10% depending on whether a withstand, or a flashover, occurred. The total time of the test series was about 2-3 h. Consequently, the results of 10-15 voltage applications on each string were used to determine the 50% flashover voltage for a given string length and contaminant.

The preceding test procedure was devised after performing enough tests to verify that the short time durations, intervals, and total test time did not influence the performance. The data on cold switch-on strength are presented in Table 4.6-5 for the two types of insulators and two different contaminants. The results showing 50% flashover strength as a function of string length are given in Figure 4.6-20.

The issue of constant heat-energy dissipation and its economic penalty should be considered in any widespread application of the semiconducting glaze insulators. As an example, consider the possible use of these units for 1100-kV transmission. With 1 mA resistive current, each leg of a semiconducting glaze string would dissipate 581 W. Assuming a double V-string for each phase, the dissipation per tower would be 7.0 kW. With four towers per mile, the constant loss due to these insulators would be 28 kW per mile. For a typical 1100-kV design, the expected total average yearly I^2R and corona loss would amount to 110 kW/mile. This implies that the insulator losses are 30% of these other losses and are thus a factor that would contribute significantly to operating costs. These costs, however, must be balanced against the costs of over-insulation, greasing, or live-line washing, which might be required for conventional insulators. In cases of heavy contamination, the cost of power lost due to scintillation and dry band arcing of conventional insulators may also be worth considering.

4.7 PERFORMANCE OF INSULATORS IN FREEZING CONDITIONS

4.7.1 Introduction

Pollution accumulation, during or followed by ice or freezing fog accretion, has proved to create particularly severe conditions for insulators in power systems to withstand. In many areas, improvements in switching surge control led to the adoption of reduced insulation levels—for example, 1550-kV BIL for 500-kV systems, where many utilities had used 900-kV BIL for 230-kV systems. This insulation level has proved to be inadequate in cases where moderate pollution (often caused by road salting in the winter) can be exposed to freezing conditions that include fog or freezing rain.

In the years 1993-2001 (excluding 1997), the National Electric Reliability Council (www.nerc.com) reported 307 severe disturbance events. Of this total, six involved ice storms, and three of these were mainly mechanical problems, such as the collapse of 1300 hydro towers on January 4-9, 2003. Notable problems traced to the combined effects of pollution accumulation and winter precipitation are:

- **March 10, 1986**. Ontario Hydro nearly lost the operational use of its 500-kV network through a rare combination of contamination buildup (16 days without rain) and relatively mild winter icing conditions, leading to 57 flashovers on 500-kV lines and stations within a 2-h period. Nearby 230-kV and 115-kV lines were not affected.
- **December 14, 1994.** NERC Report on Western Systems Coordinating Council (WSCC) system disturbance affecting 1.7 million customers: "The three-terminal 345 kV (Idaho Power) Midpoint-Borah-Adelaide No.1 line protection scheme correctly detected a single line-to-ground fault when a contaminated insulator bell

flashed over to ground. These insulator strings are located in an agricultural area and are prone to collect dust and fertilizer contamination. The insulators had been washed the previous month."

- **December 20, 2000.** NERC Report on New Brunswick Power (NBP) Salt Contamination / Freezing Rain Related Loss of Transmission: NBP experienced a series of transmission system outages as a result of salt contamination on insulators combined with precipitation in the form of snow and freezing rain. The insulator contamination monitoring stations in the Saint John area recorded their highest level ever of contamination the day before the short circuits occurred. The contamination occurred following two days of strong southwesterly onshore winds (70 mph) off the Bay of Fundy, which deposited salt spray from high waves over a wide area in the south of the province. Light snow and freezing rain on the contaminated insulators caused five 345-kV flashovers and many lower-voltage flashovers in a 2-h period on December 20, 2000. As the precipitation turned to rain, the salt spray contamination on the insulators began to wash off, and the insulators regained their voltage withstand capability.

Most troubles have occurred on transmission lines and stations that are located near sources of salt, such as the ocean or urban expressways. With typical road salting levels of 16 tons per lane mile in the winter season for most provinces and states that perform winter maintenance, a location near an expressway is equivalent to a location 1 km from the seacoast.

A "Smart Washing" insulator monitoring and maintenance program using deionized water in freezing conditions has allowed one utility (IEEE 2000) to maintain adequate 500-kV network reliability without reinsulating a large number of stations and lines. With the relatively rare problem occurrence, this choice can be valid in many areas of limited exposure.

4.7.2 Clean- and Cold-Fog Test Results

Cold-Fog tests (Chisholm et al. 1996) on a variety of pre-contaminated insulators are summarized in Figure 4.7-1. Results are all expressed in terms of critical flashover strength (50%) for 30 min of exposure of line-to-ground voltage under cold fog conditions, including fog of moderate visibility (< 4 km) and temperatures rising from below to above 0°C. Results from conventional fog tests on strings of suspension insulators are plotted as circles to compare with the Cold-Fog test data.

According to IEC Standard 60815 (IEC 1986), and multiplying units of ESDD in mg/cm^2 by 1000, the four pollution levels shown in Table 4.7-1 are suggested for selection of insulator leakage distance.

Generally, the cold-fog requirements for leakage distance on transmission-line insulators are satisfied by IEC Standard 60815 recommendations, except for very heavy contamination levels above 300 µg/cm^2. The use of extended-leakage (fog-type) disc insulators is often needed to achieve the required specific leakage distance for EHV transmission lines. For example, with 500-kV system voltage and 25 disc insulators, the Level-III requirement of 11 m gives 440 mm per disc, while most standard-profile disks offer about 300 mm per disc. This leakage distance requirement for a single insulator string leaves no margin for system overvoltage or for exposure of several insulators in parallel.

4.7.3 Icing Test Results

Under conditions of moderate icing, it is common for icicles to form on insulator strings. These icicles tend to grow in length, bridging the air gaps between insulator caps or sheds and shorting out the leakage distance. Figure 4.7-2

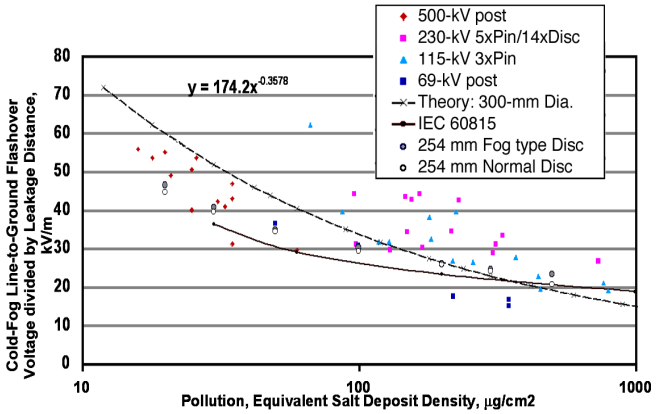

Figure 4.7-1 Cold-Fog and Clean-Fog flashover strength, kV of line-to-ground voltage per meter of leakage distance, decreases nonlinearly with increasing pollution level (Chisholm et al. 1996, Chisholm 1998).

Table 4.7-1 Specific Leakage Distance for Clean Fog and Cold Fog Conditions

Pollution Level	Unified Specific Leakage Distance for 20°C Fog	Unified Specific Leakage Distance for Cold Fog*
Level I (Light) – 2 to 30 µg/cm^2	28 mm per kV	19 mm per kV
Level II (Medium) – 30 to 60 µg/cm^2	35 mm per kV	24 mm per kV
Level III (Heavy) – 60 to 200 µg/cm^2	43 mm per kV	38 mm per kV
Level IV (Very Heavy) - > 200 µg/cm^2	54 mm per kV	68 mm per kV
* For transmission-line disc insulators.		

shows typical ice accretion levels on exposed 500-kV transmission disc insulators and on 230kV polymer insulators under conditions that led to line-voltage flashovers, at three orientations.

The electrical strength of the fully bridged insulator has been studied extensively, notably by Farzaneh et al. 1997; Farzaneh and Drapeau 1995; Farzaneh and Kiernicki 1997; Farzaneh et al. 2003; Farzaneh et al. 2004. Detailed modeling of the flashover process can be carried out using the Obenaus concept (Obenaus 1958), as adapted by Rizk (Rizk 1981) for ac flashover. On iced surfaces, the modeling uses different expressions for the voltage-current relation of the arc and the arc root voltage, compared to modeling of flashover on polluted surfaces (Farzaneh et al. 1997; Farzaneh et al. 2004). It is further complicated by several nonlinear factors, including the sensitivity of ice conductivity to temperature in the narrow range of –2 to 0°C and the nonlinear voltage distribution for EHV insulators, compared to HV systems.

One intermediate step in modeling the flashover process for engineering use was suggested in the CIGRE Task Force paper on Icing Test Methods (CIGRE 1999b). An "Icing Stress Product (ISP)," formed by the product of the ice conductivity and its weight per meter of dry arc distance, is proposed for evaluating performance. This product essentially defines the resistance of the deposit per unit length used in the Obenaus model.

$$ISP = \sigma \cdot \frac{\text{Deposit weight}}{\text{Dry arc distance}} \qquad 4.7\text{-}1$$

σ = the electrical conductivity of the ice deposit at 20°C in µS/cm.

Deposit weight = the weight of ice deposited on the whole insulator string in g.

Dry arc distance = the dry arc distance of the insulator string in cm.

The use of melted-water weight in the icing stress product automatically corrects for variations in ice or snow density. Figure 4.7-3 shows that the relations between electrical strength under melting conditions and icing stress product is well correlated over a wide range of conditions, including not just ice but also snow and cold-fog deposits.

The use of the icing stress product for evaluating dry-arc distance requirements is simple in experimental tests, using the recommended procedures as described in (Farzaneh et al. 2003; Farzaneh et al. 2004). This approach calls for the evaluation of insulator withstand performance using a fixed freezing-rain water conductivity of 100 µS/cm, corrected to 20°C. Ice accretion is measured, ideally both on the insulator surface and on a rotating reference cylinder of 25 to 29 mm diameter, similar to transmission-line conductors. The relationship between ice accretion thickness on the reference cylinder and ice weight on the insulator is

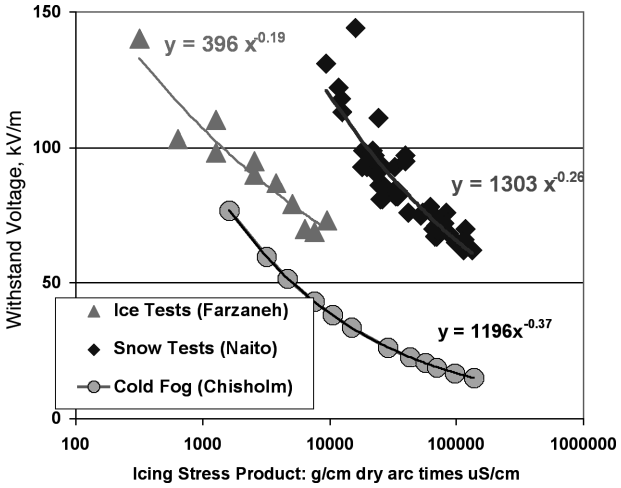

Figure 4.7-3 Relation between withstand voltage (line to ground) and icing stress product for ice, snow, and cold fog accretion.

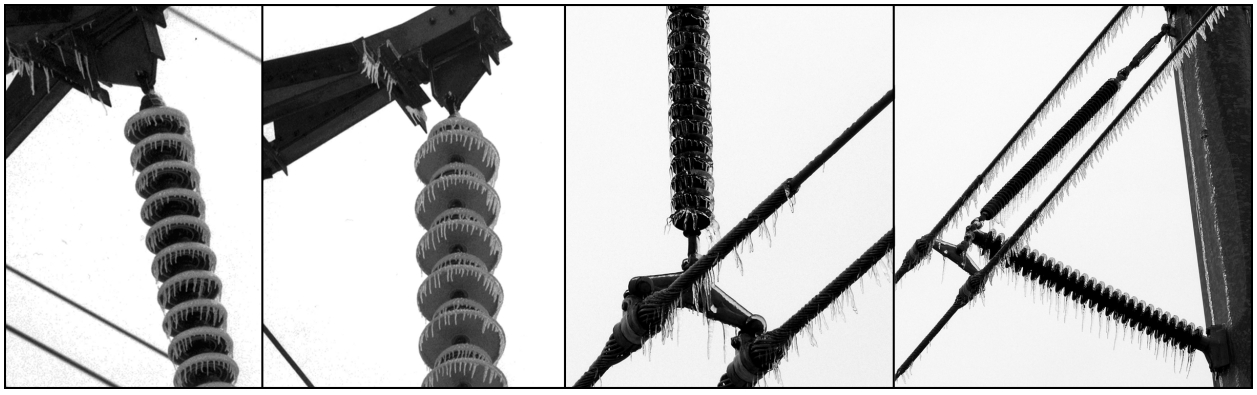

Figure 4.7-2 Examples of natural ice accretion on various types of transmission line insulator.

established by the insulator shape and size. Ice tends to accumulate only on one side of the insulator, and only the top surface of exposed disc insulators contributes any additional contamination to the native electrical conductivity of the freezing rainwater. Farzaneh and Kiernicki give the relation between ice accretion on a 25-mm reference cylinder and weight of wet-grown ice on IEEE standard disc insulators (Farzaneh and Kiernicki 1997):

$$Weight_{g/cm\,dry\,arc} = 3.2 \cdot Thickness_{mm} \qquad 4.7\text{-}2$$

Most tests suggest that the median electrical conductivity of snow, freezing rain, and rain samples at a particular site are roughly the same. There are large day-to-day variations in conductivity, often inversely correlated with daily precipitation amount, because the initial precipitation tends to capture most of the airborne pollution. At critical locations, site selection should probably rely on multiple measurements of snow conductivity to establish the probable values of freezing rain, which tends to have fewer opportunities for sampling without melting.

The process of freeze-thaw purification causes important gradients in the electrical conductivity of the ice deposit. Impurities from the ice itself and from surface pollution tend to migrate away from the ice caps and into the icicles, and also produce a radial gradient with highly conductive ice near the insulator surface.

The total icing stress product of an insulator string under natural conditions comprises the sum of two components:

1. A fixed contribution from the ice-coated area on the precontaminated top surface of the insulator
2. A variable contribution of the precipitation conductivity times the accumulation weight.

For example: The overall icing stress product of a disc insulator string can be evaluated as follows:

Insulator and ice characteristics:
Dry arc distance per insulator . . . . . 146 mm
Diameter of the insulator disc. . . . . 254 mm
Total top surface area . . . . . 647 cm² per disc
Surface area per insulator in contact with ice . . . . . .647 cm² / 4 = 162 cm²
Equivalent Salt Deposit Density . . . . . 100 µg/cm²
Salt from surface deposit in ice . . . . . 16,200 µg
Ice accumulation thickness on reference cylinder . . . . . 20 mm
Median freezing rain conductivity . . . . . .33 µS/cm

From Equation 4.7-2, the weight of wet grown ice per unit dry arc distance of the insulator can be estimated as 64 g/cm.

The contribution of the surface deposit can be calculated by evaluating the electrical conductivity of the melted ice deposit, corrected to 20°C:

$$\sigma = \left[\frac{ESDD \cdot Area}{0.42 \cdot Volume}\right]^{0.962} \qquad 4.7\text{-}3$$

ESDD is in µg/cm².
Area is in cm².
Volume is in ml.
Conductivity σ is in µS/cm at 20° C.

For each insulator, with a deposit weight of 64 g/cm, the ice weight per insulator is 64 g/cm × 14.6 cm = 934 g, corresponding to a water volume of 934 ml. Using Equation 4.7-3 and an ESDD of 100 µg/cm², the contribution of ESDD to the conductivity of the ice deposit is calculated as 35.8 µS/cm. The icing stress product of the predeposited contamination layer can then be evaluated from Equation 4.7-1 and is calculated as 2295 µS/cm x g/cm.

The surface deposit contributes a constant amount to the icing stress product, relatively independent of the amount of ice. For half the ice thickness, the concentration of the salt is doubled, giving no significant change in the series resistance of the ice deposit. For an ice deposit weight of 32 g/cm, the ice weight per insulator is 467 g, corresponding to a volume 467 ml. The electrical conductivity of the ice deposit at 20°C is 70 µS/cm, which translates as an icing stress product contribution of 2235 µS/cm x g/cm. Likewise, if the ice thickness is tripled to a deposit weight of 96 g/cm of dry arc distance (for the same insulator cross section), the ice volume per 146-mm insulator disc is 1402 ml, the conductivity is 24.3 µS/cm, and the icing stress product is nearly the same at 2329 µS/cm x g/cm.

The contribution from precipitation conductivity to icing stress product is evaluated directly from Equation 4.7-1. For an accumulation of 20 mm of ice, with a median freezing rain conductivity value of 33 µS/cm, the icing stress product on clean insulators would be 64 g/cm x 33 µS/cm, or 2112 µS/cm x g/cm.

The overall icing stress product of the precontaminated insulator exposed to the natural precipitation of 65 g/cm is the sum of the individual contributions, with (2295 + 2112), giving a total of 4407 µS/cm x g/cm.

Figure 4.7-4 gives an empirical expression for the electrical strength of the fully bridged iced insulator, in line-to-ground flashover voltage per meter of dry arc distance, as:

$$Ice\ Flashover_{kV_{l-g}/m\,dry\,arc} = 396 \cdot ISP^{-0.19}_{g/cm.\mu S/cm} \qquad 4.7\text{-}4$$

For the moderate accumulation on clean insulators, the ice flashover stress will be 92.5 kV/m, and a dry arc distance

of 3.28 m would be needed to withstand 500 kV ac system voltage using 5% above nominal or 303 $kV_{l\text{-}g}$. For the same accumulation on an insulator with ESDD of 100 μg/cm², the flashover stress is 80.4 kV/m, and a dry arc distance of 3.77 m (26 standard units) would be appropriate for a single insulator string.

4.7.4 Snow Test Results

Accumulation of snow on parallel strings of tangent (dead-end) insulator strings is a specific concern for EHV transmission lines. From Figure 4.7-3 it can be seen that snow becomes an electrical concern at an icing stress product of 30,000 g/cm x μS/cm for a typical voltage gradient of 100 kV/m. This value is valid for a dense snow accumulation (25% water equivalent density) of more than 50 cm on a pair of horizontal insulator strings spaced at 50 cm, with a typical snow conductivity of about 30 μS/cm. CIGRE (CIGRE 2000a) provides a detailed summary of test results for these special cases.

4.8 INSULATION DESIGN

4.8.1 Introduction

As with switching surge and lightning design of line insulation, the selection and dimensioning of insulators with respect to contamination and ice conditions involve the selection of the insulation strength relative to the stresses that it will experience during its service life to obtain a required performance. For both contamination and ice conditions, it is sufficient to assume that a voltage of constant magnitude will stress the insulator. In this case, it is the environment that presents itself as a statistical variable(s).

In many cases, the environmental stresses can be sufficiently characterized with a single stress parameter. The installation is then designed to withstand a single contingency—adverse weather stresses. Examples of this design philosophy for overhead lines include:

- The use of towers with adequate strength to withstand the static weight of accumulated ice.
- The use of overhead groundwires and grounding electrodes to protect against 95-99% of overvoltages resulting from direct lightning flashes.
- The use of insulators with adequate wet flashover performance under normal ac operating voltage for rain rates of 1-2 mm per min (both horizontal and vertical) with a rain resistivity of 100 Ω-m.

In other cases, a single-contingency approach is not sufficient since some composite adverse weather stresses are common enough that they should be included in transmission-line design analysis. Examples of two-contingency stresses include:

- The use of adequate parallel capacity (limited-time thermal rating) to carry summer peak load after loss of a double-circuit line from a severe lightning flash.
- The use of towers with adequate strength to withstand the static force of wind pressure on accumulated ice on conductors and overhead groundwires.
- The use of adequate clearance or galloping control devices (torsional dampers or inter-phase spacers) to limit the coupling of high-speed steady wind energy into lightly iced conductors.
- The use of adequate insulator dimensions to withstand the line voltage stress when insulator surfaces are coated (over a long time of exposure) with electrically conductive pollution, then wetted by fog.

Industry experience has shown that combinations of two or three moderate contingencies at the same time can be more damaging than single, extreme events. A good example is the series of three sequential ice storms that occurred from January 4 to 9, 1998, leading to 1300 toppled towers in Quebec, Ontario and the northeast U.S., and more than two million customers without power. No single storm was extreme, but the combined accumulation of ice onto previously iced conductors added more than 80 mm of radial ice and 1000 kg to each transmission span in some locations.

As a two-contingency design is significantly more complex to perform, assumptions are often made to simplify the problem to allow a single-contingency analysis. This will be explained by considering the design of insulation with respect to contamination.

When considering contamination on insulators, three statistical variables need to be considered:

1. Applied voltage
2. Level of contaminants and their distribution on the insulator surface
3. Degree of wetting

A worst-case design would dictate that insulation needs to be designed to withstand the:

1. Highest temporary overvoltage that may occur in the network
2. Highest level of contaminants that are distributed evenly over the insulator surface
3. Critical (or worst) wetting conditions that occur

By doing this, it is implicitly assumed that all three variables reach their maximum level at the same time. While often overly pessimistic, this assumption makes it very simple to specify a design requirement for the insulators.

A fully statistical design will consider the density functions of the applied voltage, the pollution level and its distribution, and the intensity of the wetting to obtain a distribution of the total stress on the insulator. This approach demands a lot of input information since sufficient data should be available to characterize the probability density function of each stress parameter.

A middle-of-the-road approach would be to simplify to a single-contingency stress by identifying which variables are correlated. One simplification is to assume that critical wetting occurs at the peak level of the pollution deposit. In many cases, this is a reasonable assumption, since after a critical wetting event, the contamination level is less due to the leaching of contaminants from the insulator surface. Another assumption that could be made is to say that there is no correlation between the level of temporary overvoltage (TOV) in the network and the occurrence of a critical wetting event when the insulator has its highest probability for flashover, which means that the design can be based on the maximum continuous operating voltage. By making these assumptions, the multiple contingency is reduced to a single-contingency problem that can be solved relatively easily.

Another aspect that should be considered when designing insulators is whether to design for an average or maximum failure rate. This is decided by the consequences of a failure. If the consequences of a failure are severe—for example, in the case of non-self-restoring insulation—then the statistical variables are quantified so that the maximum possible failure rate is evaluated. For self-restoring insulation, it is generally sufficient to consider average failure rates, since these types of faults are of transient nature, and a line can be auto-reclosed.

Contamination flashovers lie somewhere between the self-restoring and non-self-restoring cases, since it often proves difficult to restore the line in service after this type of outage. This manifests either as unsuccessful reclose operations or as subsequent flashovers shortly after a successful re-closing. However, after a relatively short period of time, the line can be successfully energized due to drying out of the contamination layer. In order to account for this when designing for contamination, conservative assumptions are made while evaluating average outage rates.

The basic steps necessary to select and dimension insulators are:

1. Characterize the environment in terms of both the type of contamination and its severity (Section 4.8.2).
2. Select the insulator characteristics that would be best suited to this environment—that is, the type of insulating material and the insulator profile (Section 4.8.3).
3. Determine the required insulator length or creepage (Section 4.8.4 and 4.8.5).

These steps will each be explained in the sections as indicated above.

4.8.2 Characterizing the Environment and its Severity

In designing transmission system insulation for contamination, it is essential to know the degree of contamination over the area where the power transmission system is to be constructed. Several methods to assess the site severity have been described in the literature (CIGRE 1979b; Lambeth et al. 1972). These methods range from very simple, such as directional dust deposit gauges, to complex, such as automated surface conductivity measurements (CIGRE 1994a). Also, not all methods are equally suited to assess the severity of a site, depending on the type of pollution present. Whereas the measurement of the Equivalent Salt Deposit Density is preferred at sites with solid, or predeposited, contamination, it may underestimate pollution levels at sites with liquid (or instantaneous) contamination. A first step in a site assessment should, therefore, be to determine the predominant type of contamination. Thereafter, the site assessment technique best suited to the particular circumstances can be selected. The most well-known site assessment techniques are listed in Figure 4.8-1 (CIGRE 2000b). These techniques can generally be classified as either a direct environmental measurement or a measurement of the insulator performance in the particular environment.

In the sections that follow, only a brief overview of the methods are given since they are well described in the standards and literature.

The results from the site severity measurements are used to classify the site according to a set of predetermined severity levels to allow the use of standardized insulation solutions. In Table 4.8-1, the five site severity categories used by the IEC are listed (IEC Forthcoming b), together with example descriptions of typical environments, based on the contamination accumulation characteristics of standard-shape insulators. It should be noted that these descriptions are illustrative only and not intended as a tool for site severity classification.

Environmental Severity Measurement

Environmental measurements aim to quantify the amount of contaminants at a particular site. The measurements can either be directly used to select the required insulator dimensions, based on service experience, or they can be used to specify a laboratory test. In both cases, a "calibration" curve is necessary that relates the site assessment measurement directly to either the insulator performance or the measure of severity used in the laboratory test method (Lannes and Schneider 1997).

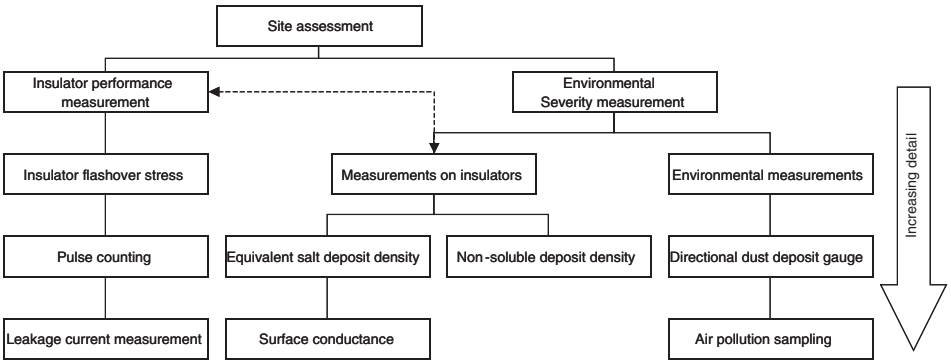

Figure 4.8-1 An overview of some site assessment techniques.

Table 4.8-1 Site Severity Classification and Sample Descriptions of Typical Environments (IEC Forthcoming b)

	Example Description of Typical Environment
Very Light	> 50 km from any sea, desert, or open dry land > 10 km from man-made pollution sources (e.g., industrial and agricultural activity such as crop spraying) or within a shorter distance, but: • the prevailing wind is not directly from these pollution sources • and/or subjected to regular monthly rain washing
Light	10-50 km from the sea, a desert, or open dry land 5-10 km from man-made pollution sources (e.g., industrial and agricultural activity such as crop spraying) or within a shorter distance, but: • the prevailing wind is not directly from these pollution sources • and/or subjected to regular monthly rain washing
Medium	3-10 km from the sea, a desert, or open dry land 1-5 km from man-made pollution sources (e.g., industrial and agricultural activity such as crop spraying) or within a shorter distance, but: • the prevailing wind is not directly from these pollution sources • and/or subjected to regular monthly rain washing or further away, but: • a dense fog (or drizzle) often occurs after a long dry pollution accumulation season (several weeks or months) • and/or heavy rains with a high conductivity occurs • and/or there is a high NSDD level, typically between 5 and 10 times the ESDD level
Heavy	Within 3 km of the sea, a desert, or open dry land Within 1 km of man-made pollution sources (e.g., industrial and agricultural activity such as crop spraying) or with a greater distance, but: • a dense fog (or drizzle) often occurs after a long dry pollution accumulation season (several weeks or months) • and/or there is a high NSDD level, typically between 5 and 10 times the ESDD
Very heavy	Within the same distance of pollution sources as specified for "Heavy" areas and: • directly subjected to sea-spray or dense saline fog • or directly subjected to contaminants with high conductivity, or cement type dust with high density, and with frequent wetting by fog or drizzle • Desert areas with fast accumulation of sand and salt, and regular condensation • Areas with extreme levels of NSDD, more than 10 times the level of ESDD

Furthermore, it is advisable to complement the measurements described below with a chemical analysis to identify the soluble deposits on insulator surfaces. This is especially useful in industrial areas where a great variety of chemicals may be deposited onto the insulators.

The environmental severity measurement methods can be described as follows:

ESDD and NSDD Measurement
(**E**quivalent **s**alt **d**eposit **d**ensity = ESDD, **N**on**s**oluble **d**eposit **d**ensity = NSDD)

The amount of soluble and nonsoluble contaminants on an insulator surface is determined by swabbing the insulator to obtain a solution of the contaminants, which is then analyzed to assess the contamination layer:

- **ESDD.** The amount of soluble contaminants is expressed as the equivalent deposit of sodium chloride on the total surface area of the insulator—in mg/cm^2—which has the same conductivity as that of the actual deposit dissolved in the same volume of water (Chisholm et al. 1994).

- **NSDD.** The amount of nonsoluble deposits is expressed as the weight of these deposits per unit square area of the insulating surface, also expressed in mg/cm^2.

These methods are being standardized by the IEC for the measurement of solid, or predeposited, contamination (IEC 60815 Forthcoming b). Applet A-1 can be used to calculate the ESDD and NSDD values from the measured conductivity of the contamination solution and weight of the nonsoluble residue.

The amount of contamination on the insulators is not constant. It accumulates on the insulators during periods without rain and is removed from the insulator during wet conditions. Thus it appears that the contamination on the insulator varies randomly over time, providing the equilibrium deposit has been reached. For the dimensioning process, it is necessary to know the statistical distribution of the maximum value of contamination stress on the insulator since:

- The peak value represents the weakest condition of the insulator.
- The peak occurs normally at the start of a natural cleaning event, which is also the time when the insulator has the greatest probability for flashover.

Usually the statistical distribution of the ESDD is characterized by its 2% value, which is the value that will be exceeded in 2% of the cases. It can be appreciated that a substantial number of measurements are required to get a good estimation of this value. As a result, it may be necessary to perform the ESDD measurements over an extended period of time. In some areas, notably those with extended dry periods, it may take several years to get a sufficient number of data points.

Another problem is that the peak values of the contamination severity occur at random. It is, therefore, difficult to time the ESDD measurements to obtain these peaks. From a practical point of view, the measurements are most often performed at a fixed time interval, resulting in a loss of accuracy in the evaluation of the maximum values, since the peak values are not necessarily measured. This error can be minimized by adjusting the sampling interval to be appropriate for the type of environment. Table 4.8-2 presents rough estimates for the different types of environment to help the user to choose an optimal measurement interval when this latter approach is followed (CIGRE Forthcoming b).

Standard insulator discs are used when attempting to quantify the severity of the environment for insulator selection purposes. When evaluating the accumulation characteristics of specific designs, the insulator under investigation is utilized. If the insulator is to be applied in a string, then the effect of the adjacent discs needs to be accounted for.

ESDD and NSDD measurements on a standard disc or longrod type insulator can be classified according to the diagrams in Figures 4.8-2 and 4.8-3, respectively (IEC Forthcoming b). This classification system takes account of the fact that the flashover performance deteriorates for increasing levels of nonsoluble deposits.

Table 4.8-2 Typical Measuring Intervals to Determine Maximum ESDD Values (CIGRE Forthcoming).

Type of Environment	ESDD Measurement Interval
Desert	From 12 to longer than 24 months
Coastal	1-6 months depending on duration of dry season or just after a rapid pollution event
Industrial	12-24 months
Agriculture	3-6 months
Inland (Low pollution)	3-6 months

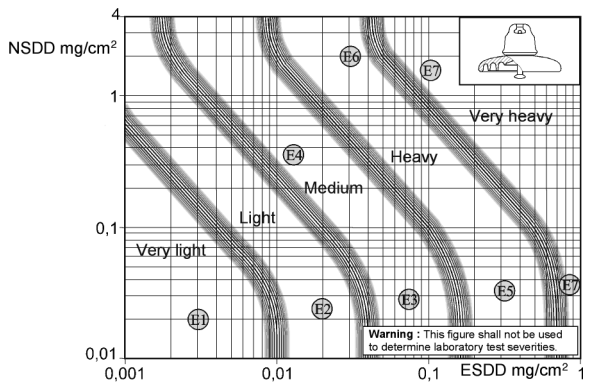

Figure 4.8-2 Solid type contamination: Relation between ESDD/NSDD and the site pollution severity for standard-shape disc-type insulator (IEC Forthcoming b).

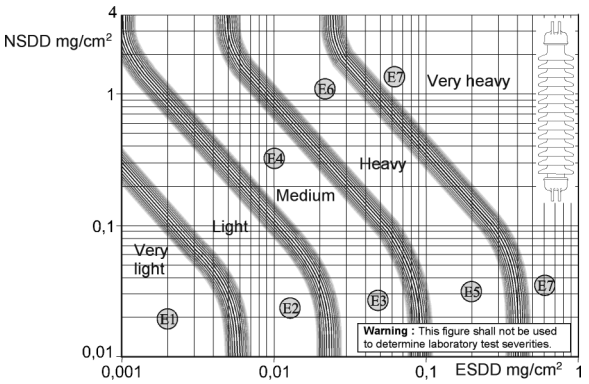

Figure 4.8-3 Solid type contamination: Relation between ESDD/NSDD and the site pollution severity for standard longrod type insulator (IEC Forthcoming b).

It should be noted that the ESDD does not always give a true value for the conductivity of the contaminant in actual service conditions. Two cases are worth mentioning:

- **Contamination with Different Types of Salts.** Insulators contaminated with different types of salts behave differently under natural wetting conditions, leading to different levels of flashover for identical ESDD values. This is primarily because of the difference in the hygroscopic characteristics of the deposited materials. For instance, gypsum has only 2% solubility, whereas sodium chloride has 40% solubility. Under natural wetting conditions, insulator surfaces contaminated with gypsum are not as conductive as those contaminated with sodium chloride because the amount of water on the surfaces is not sufficient to dissolve all of the gypsum. However, the gypsum is completely soluble if between 1000 and 2000 ml water is used to measure the ESDD (Lin et al. 1992; Ramos et al. 1993). This may result in an over-estimation of the contamination severity.
- **Encapsulation with Hydrophobic Silicone Oils.** Silicone rubber insulators may encapsulate pollutants on their surface with hydrophobic silicone oils. A portion of the contaminants are, therefore, not available to dissolve when the insulator is naturally wetted. When the ESDD measurement is performed, the hydrophobicity encapsulation is broken down, and all the salts are included in the measurement, leading to an over-estimation of the contamination severity on the insulator (Kindersberger and Kuhl 1991; Xidong et al. 1994; Engelbrecht et al. 2000).

Directional Dust Deposit Gauges

This is another method that is being standardized by the IEC. It can be used on sites independent of the contamination type—i.e., solid or liquid. With this method, a standardized gauge is used to collect windborne contaminants in a container over a monthly period (see Figure 4.8-4) (Lambeth et al. 1972). In this case, the contamination severity is expressed as the "Dust deposit gauge index – soluble," which is the average volume conductivity of the four containers, each dissolved in 500 ml water. Figure 4.8-5 shows the severity classification proposed by the IEC for this method (IEC Forthcoming b).

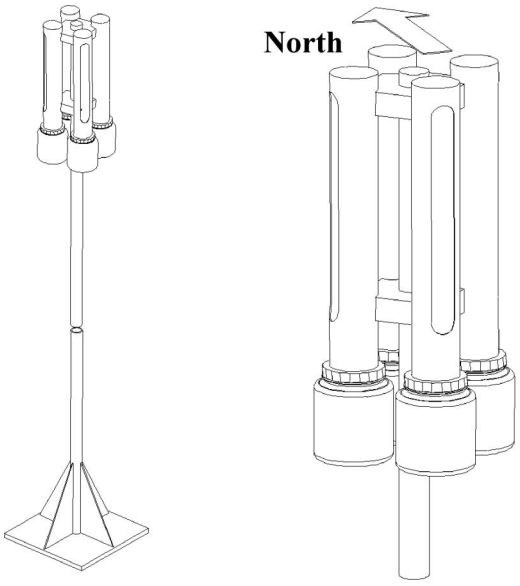

Figure 4.8-4 A directional dust deposit gauge.

It is recommended to "correct" the site severity classification for the presence of nonsoluble deposits, which is the average weight of the nonsoluble contaminants collected in the four containers, called the "Dust deposit gauge index – nonsoluble." Based on the average measured value over a year, a correction is made as follows (IEC Forthcoming b):

- No correction is made if the yearly average weight is below 0.5 g.
- The severity class is increased with one level if the average range value is between 0.5 and 1.0 g.
- The severity class is increased by two levels if the average value is higher than 1.0 g.

Air Pollution Sampling

A commercial standardized instrument is used to determine the amount and characteristics of the airborne pollution at a site, often called dustfall. A correlation needs to be established between the measurement performed and one of the standardized pollution severity measurements. For example, in Canada, it was found that the maximum buildup of ESDD over the winter months had a high correlation with "winter monthly dustfall," a standard environmental measure for local pollution (Chisholm et al. 1993):

$$ESDD_{Season\ peak} \approx 9 \times \left(\text{Dustfall}_{g/m^2/month}\right)^2 \qquad 4.8\text{-}1$$

Surface Conductance/Conductivity

The surface conductance, which is the ratio of the power frequency current flowing over a sample insulator to the applied voltage, is measured by "meggering" the insulator. The applied voltage should be high enough to obtain a good current reading, but not too high or of too long a duration, to avoid heating and discharge effects. Several automated instruments have been developed that measure

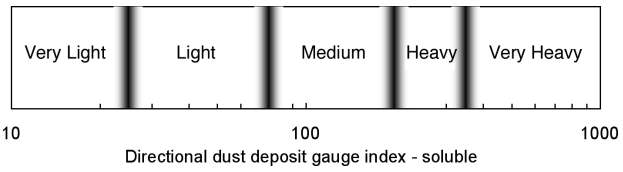

Figure 4.8-5 Relation between the average monthly directional dust deposit gauge index (soluble) and the site pollution severity (IEC Forthcoming b).

the surface conductance at preset intervals (CIGRE 1994a). The most sophisticated of these include built-in artificial wetting so that the surface conductance can be measured in dry weather conditions.

Surface conductance is not directly usable, since it is dependent on the dimensions of the insulator that is being measured. Therefore, it is common to calculate the surface conductivity from the surface conductance measurements with the help of the form factor, described in Section 4.2. The surface conductivity can also be measured directly with a hand-held probe, such as the one described in IEC 60507 (IEC 1991).

An approximate relationship between surface conductance and ESDD is:

$$ESDD_{mg/cm^2} \approx 0.01 \times \left(\text{Surface Conductivity}_{\mu S}\right) \quad 4.8\text{-}2$$

Surface conductance measurements are particularly suited for the measurement of the effective contamination severity on polymer insulators. These measurements can be made without disturbing the pollution layer—and destroying the encapsulation effect of silicone oils, if present. Several probes have been developed for this measurement (Kindersberger and Kuhl, 1991; Xidong et al. 1994). This conductance measurement can also be expressed in terms of the apparent salt deposit density (ASDD), which can be directly compared to ESDD measurements on the same insulator to obtain an indication of the extent of the encapsulation effect.

Insulator Performance Measurement

The performance of insulators can be measured as follows.

Insulator Flashover Stress

This is a very simple method to determine the minimum required length of insulators at a site. A sample insulator string is energized and a number of insulators are shorted out with explosive fuses, as shown in Figure 4.8-6. The fuses are selected so that the string length is successively increased with one, or more, discs if the leakage current reaches critical levels, or flashover occurs. This method is best applicable on disc-type insulator strings.

Pulse Counting

Pulse counting is one of the very first insulator monitoring methods that were developed. A counter is used to count the current pulses above a predetermined threshold. These counters can be made very simple and robust.

Leakage Current Measurement

The most sophisticated of the insulator performance measurements is the monitoring of leakage current over the insulator. This is readily enough done in a relatively controlled environment, such as an insulator testing station or a testing laboratory. A number of devices have been developed for on-line leakage current monitoring on line or substation insulators. These instruments are, however, rather expensive, which limits their widespread use.

Leakage current is used especially in areas with liquid contaminants. For such cases, the site severity is characterized by the equivalent Salt-Fog test severity that will result in the same level of peak current when performed on an identical insulator and voltage stress (see Figure 4.8-7) (Verma et al. 1978). In the revision of the IEC 60815, this is called the Site Equivalent Salinity (SES) (IEC Forthcoming b).

Contamination Maps

It would be desirable to arrive at a contamination map in which the degree of contamination condition is shown in the same manner as the isokeraunic levels for lightning

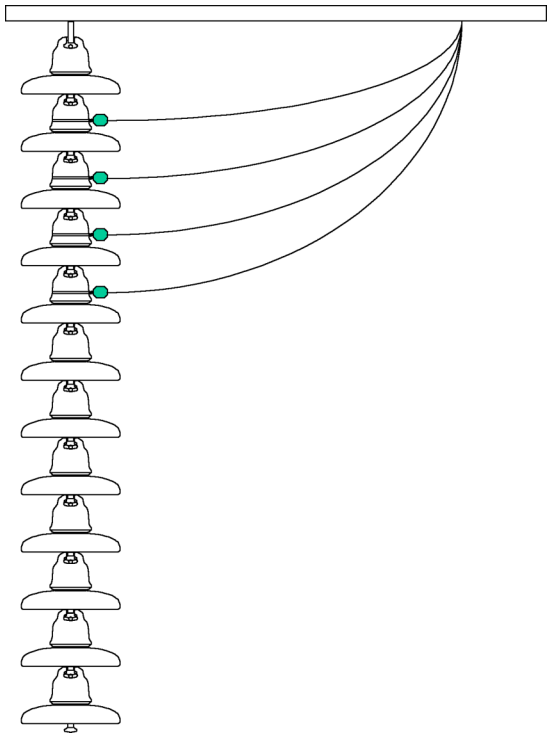

Figure 4.8-6 Application of explosive fuses to determine the minimum insulator flashover stress.

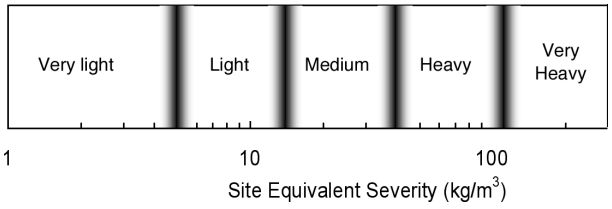

Figure 4.8-7 Relation between the site equivalent severity and the IEC pollution classification (IEC Forthcoming b).

(Kimoto et al. 1972). This will require an intensive investigation over large areas for several years, because the deposition of contaminants varies with weather conditions, such as wind and precipitation, and with specific locations. There is, of course, still much uncertainty surrounding the knowledge of weather conditions. In particular, it should be emphasized that many past contamination flashovers were caused by unusual weather conditions, such as an exceptional salt storm or a long dry period that allowed a heavy accumulation of pollutants (CRIEPI 1968; Sporn et al. 1964; Massey 1972). Also, industrial pollution levels change with the activity of industry in the vicinity of power systems. Application of air pollution controls should reduce artificial pollution in general.

It is recognized that the prediction of contamination conditions is an arduous and continuing task. In one country, the contamination map has been revised three times in 10 years (CRIEPI 1968). It is, therefore, advisable to use as far as possible automated, very simple site-assessment techniques, such as air pollution sampling. Figure 4.8-8 shows a typical example of how dustfall measurements have been used to obtain a pollution map of an area of heavy industry on the east shore of Lake Ontario. The HV transmission lines adjacent to this heavy industry will be exposed to relatively severe ESDD levels of up to 0.6 mg/cm^2.

4.8.3 Choice of Material

In the past, the choice of insulator material has often been based on historical experience and the confidence that has been gained in a specific product. As was highlighted in Section 4.4, all insulator technologies have their strengths and weaknesses. The choice of material is, therefore, a balancing act, where the advantages and disadvantages need to be weighed against each other in order to find the optimal solution. A broad overview of some of the advantages and disadvantages of using a particular technology are listed in Table 4.8-3.

In many companies, the decision to utilize glass or porcelain has been taken long ago and is generally based on many years of service experience. The electrical performance of these two materials is, for all practical purposes, the same, and the choice of material rests on previous good or bad experience. In comparison, polymer insulators have

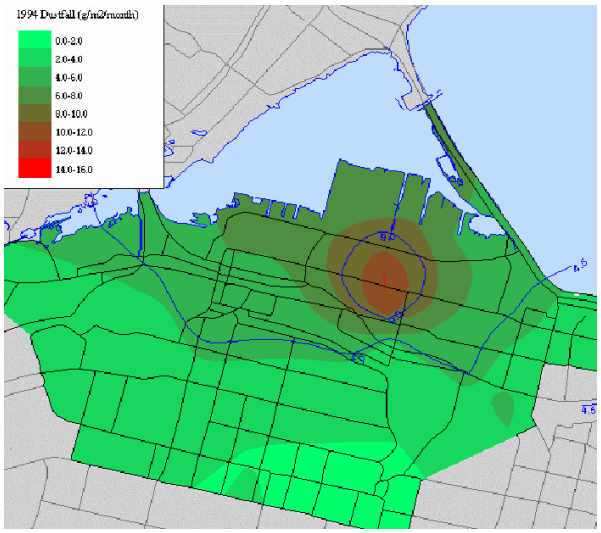

Figure 4.8-8 Typical variation in dustfall near urban industrial area of Hamilton, Ontario.

Table 4.8-3 Advantages and Disadvantages Associated with Different Insulator Technologies

Technology	Advantage	Disadvantage
Glass	– Give visual indication of internal defects – Good puncture resistance – Proven long-term reliability – Insulators from different manufacturers are interchangeable and generally have similar performance	– Prime targets for vandals because of shattering – Surface may be etched by long-term dry-band arcing resulting in shattering – May require long insulator strings in polluted conditions – Heavy – Lack of availability in certain regions
Porcelain	– Surface glazing resistant to etching from dry band activity – Do not shatter when shot by vandals – Proven long-term reliability – Insulators from different manufacturers are interchangeable and generally have similar performance	– May contain hidden internal defects – May require long insulator strings in polluted conditions – Heavy – Lack of availability and time to delivery in certain regions
Polymer	– Lighter weight (easier to handle and ship) – Lower cost – Better availability and shorter lead times – Enables single-pole structures (i.e., post application) – Better shock loading characteristics (post only). – Less susceptible to vandalism – Better contamination performance	– Unknown life expectancy – Limited service experience – Different designs, materials, and manufacturing processes between suppliers. – More susceptible to damage during handling. – May contain hidden defects – Concerns regarding live working – Difficult to identify high risk units prior to failure

been introduced relatively recently, and the designs of most manufacturers have evolved over time. Results from service inspections are also not always relevant due to the many revisions and refinements to the designs, and to the materials and manufacturing processes that have been made to improve the product and address degradation and failure modes. This is compounded by the facts that: (a) each manufacturer employs different materials, construction details, and manufacturing processes; and (b) many utilities are not certain of what vintage units they have in-service on a specific structure.

The aim of this section is, therefore, to focus more on the selection of polymer insulator materials than on glass or porcelain.

Insulator Selection Considerations

The following factors need to be considered when selecting the type of insulator to be utilized.

Cost and Availability

As manufacturing techniques improve, polymer insulators are becoming more cost competitive, and their inherently shorter lead times often make polymer insulators more attractive. Their light weight may also reduce shipping, handling, and most significantly, installation costs (EPRI 2003b; Burnham et al. 1994).

Standardization

Unlike porcelain and glass insulators, the basic dimensions and designs of polymer insulators are not well defined. Differences in materials and manufacturing techniques are significant, making the choice between different manufacturers' designs difficult. Utilities have to survey manufacturing techniques, materials, and designs to determine which is best for their environment and application. Often there are trade-offs to be made.

There are no standard connection lengths for polymer insulators. Concerns have arisen when replacing in-service units since connection length changes can have an effect on conductor tension and sag. Certain manufacturing processes allow the manufacture to almost any predefined length, while other processes are less flexible. Due to industry pressures, most manufacturers have addressed this issue by providing a comprehensive range of lengths.

There is no standardization of corona ring designs, attachment mechanisms, or effective performance criteria. The only performance criteria that has been put forward has been by EPRI and STRI, where the E-field is recommended to be below specific levels on the rubber housing and the end fitting seal (EPRI 1998; *Insulator News and Market Report* 2002).

Not only is it difficult for the utility engineer to evaluate differences in corona ring designs, but it may also result in confusion in the field. It is not uncommon to find corona rings from one manufacturer installed on another manufacturer's units. Since each manufacturer utilizes a unique attachment method specific to their end fitting design, a corona ring from another manufacturer may be installed in an incorrect location or backwards.

Power Arc Performance

The ability of polymer insulators to withstand power arcs terminating directly on the end fittings may be divided into three categories:

1. Short-term mechanical performance
2. Long-term mechanical performance
3. End fitting seal performance

Testing has indicated that there may be a short-term loss in mechanical strength during the power arc to approximately 60% of the ultimate strength of the insulator. For the design tested, this reduction corresponded to 80% of the specific mechanical load (SML) (Matsouka et al. 1998). Long-term reductions of 10 to 20% in ultimate mechanical strength have also been observed in testing. For the design tested, the long-term strength of units was above the SML. Since polymer insulators are applied at less than 50% of SML for extreme loading conditions, concerns are reduced (Matsouka et al. 1998)

Damage to the end fitting seal resulting in exposure of the fiberglass rod is a concern. Certain designs appear to be inherently more susceptible than others. The removal of galvanization and the resulting localized corrosion is of lesser concern. Figure 4.8-9 shows examples of units removed from service with damaged end fittings due to power arcs (EPRI 2004c). Standard tests exist to determine the ability of insulator strings to withstand power arcs. The tests specify how the power arc tests should be performed, together with visual and mechanical criteria by which the insulators are assessed after the test (IEC 1997 b).

The use of corona rings or arcing horns will reduce the effect of power arcs. Both the energized and grounded end fittings need to be addressed. Manufacturers should be consulted as to whether units that have experienced flashover should be removed from service.

Live Working

Concerns have been raised over working with polymer insulators under energized conditions. These concerns arise in two circumstances:

- **Installing new units.** Unlike manufacturers of porcelain/glass insulators, manufacturers of polymer insulators do not perform electrical routine tests on individual

polymer insulators, due to the high voltages required for such testing. In order to address this concern, some utilities test, tag, and package all new polymer insulators intended to be installed under energized conditions. Another approach is to utilize a high-voltage test set in the field to test the units. Utilizing the transmission line being worked on as a test source is another, although somewhat controversial, approach proposed (Harmon et al. 1996).

- **Working with or around in-service units.** Effective techniques to determine the condition of an in-service polymer insulator with respect to energized work remain illusive. Although concerns may arise for both the mechanical and electrical condition of in-service units, the mechanical concerns can be negated by installing strain sticks prior to applying mechanical load to the supported conductor. However, techniques are not available to assess whether a conductive (or semi-conductive) defect of sufficient size exists. Research projects are under way at EPRI and other institutions to address this issue (EPRI 2003d; EPRI 2004d).

Audible Noise, EMI, and RIV

Polymer insulators have been applied in some situations to address audible noise, EMI, and RIV complaints due to discharge activity. The unwanted discharge activity may have occurred due to contamination or poor connection between individual porcelain/glass bells on lightly loaded strings.

Figure 4.8-9 Examples of damage to end fittings due to power arcs.

High-Temperature Conductors

The maximum permissible conductor temperature has been generally limited by the maximum allowable conductor sag, which, in turn, is determined by conductor clearance regulations. Conductor sag is a function of the properties of the conductor, the current flowing through the conductor, mechanical load, ambient temperature, prevailing wind, and environmental conditions. In order to increase the power throughput, new conductors have been designed that have reduced sag at elevated temperatures. Some of these new conductors are able to operate at temperatures exceeding 200˚C (392˚F) without compromising clearance regulations.

With the advent of these new conductors, the factor limiting the temperature at which conductors may operate may shift from conductor sag to the maximum operating temperature of the attached line hardware and associated components. One of the components considered to be vulnerable to elevated temperatures is the polymer insulator due to the material used in its construction. Manufacturers of polymeric insulators generally specify a maximum ambient operating temperature of 50˚C (122˚F), and it is a concern that elevated conductor temperatures may lead to this value being exceeded.

A number of tests have been performed on polymer insulators connected to high-temperature conductors to determine the temperatures that the insulator end fittings will be subjected to. Figure 4.8-10 shows the results of some of these tests.

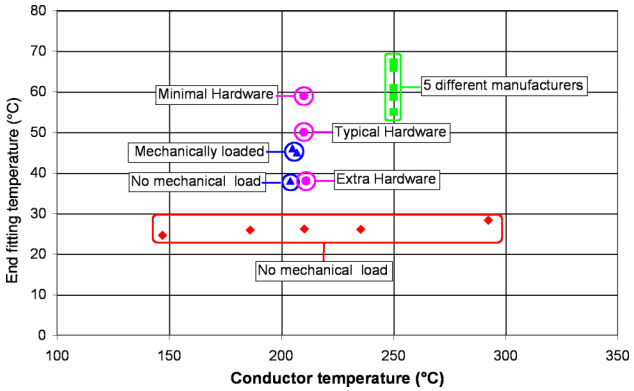

Figure 4.8-10 Summary of results obtained by different organizations with respect to the end fitting temperature of an insulator for different conductor temperatures. Ambient temperature in all cases was between 20 and 25ºC (EPRI 2000b, 2001b).

It was found that the polymer insulator end fitting temperature was a function of (EPRI 2001b):

- Conductor temperature
- Applied mechanical load. (Tests performed with no load provide lower end fitting temperatures due to the poor contact between the hardware. A relatively modest load of 235 kg (520 lb) ensures effective contact.)
- End fitting design of the polymer insulator.
- The type and length of hardware connecting the conductor and the polymer insulator.

It can be seen from Figure 4.8-10 that, in some cases, end fitting temperatures of almost 70°C were reached for conductor temperatures of 250°C when the ambient temperature was 25°C.

It has been indicated by a number of insulator manufacturers that these levels of end fitting temperature can be withstood. In a survey of manufacturers, the maximum recommended end fitting temperatures varied between 70° and 90°C, depending on manufacturer (EPRI 2001b).

Not evaluated or investigated in the testing was the impact of ambient conditions or solar radiation. The effect of these high temperatures on the long-term performance remains under investigation.

Ease of Inspection

Identifying high-risk polymer insulators prior to failure remains an issue. Conditions indicating an increased risk are relatively small, and inspection distances are large (EPRI 2003c; CIGRE 1996; Spangenberg and Riquel 1997). As the population of installed polymer insulators ages, utilities will be faced with an increased challenge. Detailed close-up visual inspection, at distances less than 0.5 to 1 m, remains the most effective method of inspection, but is impractical and not cost effective. It also requires considerable inspector expertise (EPRI 2004c).

Development of the EPRI daytime corona camera was intended to assist in this regard, but it has limited application since it does not address the main failure mode, brittle fracture (EPRI 2001d).

Developments currently under way to improve inspection methods, include:

- Inspection technique to evaluate the resonant characteristics of insulators (EPRI 2004b).
- "Self diagnosing" polymer insulator (EPRI 2003e).
- Design and vintage identification guides to assist in the identification of high-risk designs (EPRI 2004e).

These developments are currently under way and it is uncertain whether they will fully resolve the issue.

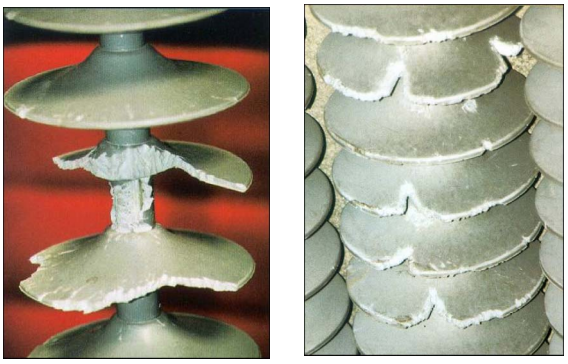
Wood Pole Fires

The use of polymer insulators has been effectively applied to reduce the occurrence of wood pole fires by reducing the leakage current. Silicone rubber units have been applied in most cases due to their hydrophobic properties and hence lower leakage currents.

Storing, Transporting and Installing

The root cause of numerous failures has been handling damage. The light weight and, apparent "toughness" of polymer insulators and the small size of the critical damage that they can incur appear to make polymer insulators more susceptible to handling damage. Education of warehouse and field personnel is essential to reduce the number of handling-related failures. Both utility and contractor personnel need to be addressed. A number of guides and an educational video are available to assist in this regard (EPRI 2001a, 2001c; CIGRE 2001).

Animal Damage



Polymer insulators at a number of utilities have experienced damage from rodents and birds, as shown in Figure 4.8-11.

Rodent damage has occurred to units while stored in warehouses or shipping yards. Effective packaging and storage procedures can be put in place to reduce concerns.

Utilities in Australia and the United States have experienced bird damage on installed units. Damage is more prevalent prior to energization; however, damage to energized units has also been reported. The cover-up of installed units prior to energization has been implemented to reduce damage.

Vandalism

Polymer insulators have been effectively applied in situations where vandalism is high. Unlike porcelain or glass units, polymer insulators provide little gratification when struck by a bullet and present a smaller profile to aim at (Burnham and Waidelich 1997).

Rodent Damage Bird Damage

Figure 4.8-11 Examples of rodent and bird damage to polymer insulators.

On the other hand, gunshot damage is difficult to identify on polymer insulators and can have a catastrophic result if the rod is exposed.

Resources

When determining which type of insulator, or what design of insulator to utilize, engineers can draw on a number of resources, including:

- Compliance with national and international standards
- Field experience
- Accelerated aging tests
- Stress testing
- Published application guides

International and National Standards

There is a wide range of international and national standards. In this document reference will be made to both IEC and ANSI standards. A list of the relevant IEC and ANSI/IEEE standards is provided in Tables 4.8-4 and 4.8-5.

Table 4.8-4 IEC Standards and Reports Covering AC Transmission Line Insulators

Code	Year	Title	Remarks
IEC 60383-1	1993	Insulators for overhead lines with a nominal voltage above 1000 V - Part 1: Ceramic or glass insulator units for a.c. systems - Definitions, test methods and acceptance criteria	
IEC 60383-2	1993	Insulators for overhead lines with a nominal voltage above 1000 V - Part 2: Insulator strings and insulator sets for a.c. systems - Definitions, test methods and acceptance criteria	
IEC 60305	1995	Insulators for overhead lines with a nominal voltage above 1000 V - Ceramic or glass insulator units for a.c. systems - Characteristics of insulator units of the cap and pin type	
IEC 60433	1998	Insulators for overhead lines with a nominal voltage above 1 000 V - Ceramic insulators for a.c. systems - Characteristics of insulator units of the long rod type	
IEC 60720	1981	Characteristics of line post insulators	
IEC 62217	New	Polymeric insulators for indoor and outdoor use with a nominal voltage greater than 1 000 V - General definitions, test methods and acceptance criteria	
IEC 61109	1992	Composite insulators for a.c. overhead lines with a nominal voltage greater than 1000 V - Definitions, test methods and acceptance criteria	Being Updated
IEC 61466-1	1997	Composite string insulator units for overhead lines with a nominal voltage greater than 1000 V - Part 1: Standard strength classes and end fittings	
IEC 61466-2	2002	Composite string insulator units for overhead lines with a nominal voltage greater than 1 000 V - Part 2: Dimensional and electrical characteristics	
IEC 61952	2002	Composite line post insulators for a.c. overhead lines with a nominal voltage greater than 1 000 V: definitions, test methods and acceptance criteria	Being Updated
IEC 60120	1984	Dimensions of ball and socket couplings of string insulator units	
IEC 60372	1984	Locking devices for ball and socket couplings of string insulator units - Dimensions and tests	
IEC 60471	1977	Dimensions of clevis and tongue couplings of string insulator units	
IEC/TR 60575	1977	Thermal-mechanical performance test and mechanical performance test on string insulator units	
IEC/TR 60797	1984	Insulators for overhead lines with a nominal voltage above 1000 V - Residual strength test for ceramic or glass string insulator units after mechanical damage of the dielectric	Being Updated
IEC/TS 61211	1994	Insulators of ceramic material or glass for overhead lines with a nominal voltage greater than 1000 V - Impulse puncture testing in air	Being Updated
IEC 60575 TR	New	Thermal-mechanical performance test and mechanical performance test on string insulator units - Development of the tests	
IEC/TS 61467	1997	Insulators for overhead lines with a nominal voltage above 1000 V - a.c. power arc tests on insulator sets	Being Updated
IEC 60437	1997	Radio interference test on high-voltage insulators	
IEC 60507	1991	Artificial pollution tests on high-voltage insulators to be used on a.c. systems	
	New	Minimum test requirements to cover brittle fracture of line composite insulators	Being Considered
IEC/TS 62073	2003	Guidance on the measurement of wettability of insulator surfaces	
IEC/TR 60815	1986	Guide for the selection of insulators in respect of polluted conditions	Being Updated
IEC 61467	1997	Insulators of ceramic material or glass for overhead lines with a nominal voltage greater than 1000 V – AC power arc tests on insulator sets	
CIGRÉ TB-158	2000	Polluted insulators: A review of current knowledge	
CIGRÉ	new	Guidelines for selection and dimensioning: Part 1: General principles and the a.c. case	Being Prepared

Table 4.8-5 ANSI standards and IEEE Guides Covering AC Transmission Line Insulators

Code	Year	Title	Remarks
ANSI C29.1	1988	Test methods for electrical power insulators	Revised 2002
ANSI C29.2	1986	Insulators – Wet process porcelain and toughened glass suspension type	Revised 1999
ANSI C29.4	1989	Wet Process porcelain insulators –strain type	Revised 2002
ANSI C29.7	1996	Porcelain Insulators high voltage line post type	Revised 2002
ANSI C29.11	1989	Tests to composite suspension insulation for overhead transmission lines	Revised 1996

ANSI C29.17	2002	For insulators – composite line post type	
IEEE Std 987	2001	IEEE Guide for Application of Composite Insulators	
IEEE Std 4	1995	IEEE Standard Techniques for High-Voltage Testing:	Amended 2001

The ANSI/IEEE standards listed in Table 4.8-5 refer to American Society for Testing and Materials (ASTM) that describe additional or complementary test methods to verify electrical, mechanical, physical, and chemical properties of the materials used in insulators. These test methods include:

Electrical Properties

- Dielectric strength (ASTM D 149)
- Dissipation factor (ASTM D 150)
- Arc resistance (ASTM D 495)
- Tracking and erosion resistance (ASTM D 2303)

Mechanical Properties

- Impact resistance (ASTM D 256)
- Tension (ASTM D 412)
- Compression (ASTM D 575)
- Fatigue (ASTM D 623)
- Tear (ASTM D 624)
- Shear (ASTM D 732)
- Flexural (ASTM D 790)
- Hardness (ASTM D 2240)
- Creep (ASTM D 2290)

Physical Properties

- Thermal expansion (ASTM D 696)
- Thermal resistance (ASTM D 756)

Chemical and Environmental Properties

- Fungi resistance (ASTM G 21)
- Chemical resistance (ASTM D 471)
- Ozone resistance (ASTM D 1149)
- Corona resistance (ASTM D 2275)

There are some differences in the terminology used in IEC and ANSI standards, as highlighted in Table 4.8-6.

Manufacturers' products are expected to comply with all requirements outlined in the applicable standards. It is often useful for decision makers to determine whether the product design complies with standards that may not be mandatory in their region.

Some of the "tracking and erosion tests" described in the standards are often called "aging tests" in the literature. It is important to note that these tests are not "accelerated aging tests" in the sense that these tests do not simulate exactly the real-life degradation conditions, nor do they accelerate them to give a life-equivalent test in a short time. Rather these tests use continuous, cyclic, or combined stresses to try to detect potential weaknesses that could compromise the insulators performance in-service. These tests can best be described as "screening tests" (IEC 1992; CIGRE 1999a; CEA 1996).

Field Experience

Even though an insulator may have passed all of the tests identified in the relevant international and national standards, further information is often required to obtain an

Table 4.8-6 Comparison of the Terminology used in IEC and ANSI

IEC	ANSI/IEEE	Definition
Design tests	Prototype tests	The purpose of these test are to verify the suitability of the design, materials and method of manufacture. Results are valid for the whole class of insulator. These tests do not provide an indication of life expectancy.
Type tests	Design tests	The purpose of these tests is to verify the main characteristics, which depend mainly on size and shape.
Sampling tests	Sample tests	These tests are for the purpose of verifying other characteristics, including those depending on the quality of manufacture and on materials used. They are made on insulator samples taken at random from production lots.
Routine tests	Routine tests	The aim of these tests is to eliminate insulators with manufacturing defects. They are made on every insulator of the production lot.

indication of the life expectancy for the environment and application in which the unit will be applied.

Field experience is one of the best methods to obtain life expectancy and performance information since the artificial stresses in aging/flashover tests are negated. This information is often not available since decades worth of experience is ideally necessary and the designs of units manufactured today are different from those manufactured 20 years ago.

When determining whether field experience information is relevant to a new installation, one must determine whether aging and flashover mechanisms are similar. Considerations include:

- Difference in environment between the field units being reviewed and the region in which the new units are to be applied. Care should be taken when basing the decision for units to be applied in a highly contaminated environment, on field units installed in a low contamination region and vice-versa.
- Differences in designs, manufacturing methods, and materials between the field units and the new units.
- Changes in the design of units presently manufactured and the field units.
- Differences in voltage level—to ensure that similar aging mechanisms occur (e.g., wet corona activity).
- Configuration and corona ring application, since the E-field distribution has a significant effect on the aging characteristics.
- Differences in mechanical loads—both everyday and under extreme loading conditions.

Not withstanding the above considerations, field experience remains the best resource on which to base a decision. Three areas from which this experience may be obtained include:

- Utility experience
- Test lines and structures
- Test stations

Utility experience on similar units installed in a similar environment for prolonged durations is required. Since modern-day polymer insulators only became available in the late 1970s, and since some of the designs changed significantly until the 1990s, this data is often not available. Approaches to reviewing field data should involve removal of units and include detailed visual inspection and dissection, and mechanical and electrical tests. Leakage current measurement, discharge observations, weather data, and material analysis have also been performed.

Care should be taken to ensure that field units reviewed are representative of the units being considered for application in terms of design, manufacturing, voltage level, and application. With a thorough understanding of the differences, these factors can often be accounted for in the decision-making process.

During the advent of polymer insulators, a number of utilities applied small numbers on test structures or installed test lines. The information from these installations has provided important guidance and verification. Since many of these test installations were initiated prior to mass production, units may have been hand crafted or not representative of the designs available today. Differences in environment, insulator design, voltage, and application should be noted when utilizing this information.

A number of outdoor test stations exist where large numbers of test units have been installed and monitored on a regular basis. In some cases, these test stations were also instrumented for leakage current measurement and weather parameters. Observations and analyses were performed using a range of techniques.

Test stations have been constructed in both high- and low-contamination locations (Houlgate and Swift 1990; Houlgate 1993; Vosloo and Holtzhausen 1996; Gutman et al. 1999; Maxwell et al. 2002), which have provided valuable information. In some cases, the test sites have been located in extremely highly contamination environments to accelerate degradation. Care needs to be taken when interpreting results to ensure that the aging and flashover mechanisms in these harsh environments are representative of the application in which new units will be installed.

Configurations in test stations should also be applied in a manner that the E-field distribution is similar to that in service. The voltage levels should also be representative. Test stations that provide an acceleration aging environment, due to exceptionally harsh environmental conditions not experienced on normal transmission lines, should be considered as an accelerated aging test rather than a field test when considering experience.

Multi-Stress Accelerated Aging Tests

Since the required life expectancy for polymer insulators is often 30 years or more, a number of accelerated aging tests have been used worldwide to evaluate the long-term performance of polymer insulators. The accelerated aging tests are intended to simulate specific environments, around which an aging cycle is developed. The design of the cycle to accelerate aging is dependent on the primary aging mechanism under consideration. For example, if a highly contaminated environment is being considered, the number of pollution events in a year may be increased. In

the case of an aging test simulating a low-contamination environment, the number, or duration, of wetting events may be increased

When considering the results of an existing test, or implementing a new aging test, care should be taken to consider the environment in which units will be installed, and to evaluate the primary and secondary degradation modes. The aging cycle should be designed to simulate the degradation phenomena that will occur in the field as accurately as possible. If a degradation mode is introduced that does not occur in the field, the results may not be relevant.

Acceleration rates quoted for the individual tests are only approximate and are specific to the environment being simulated. Determining the acceleration rate requires a thorough understanding of the aging mechanisms, and in some cases, research performed at a later date may require initial acceleration rates be adjusted. For example, at the time of development of the EPRI "Deserts with a Distinctly Cold Season" aging test, the assumption was made that elevated temperature was the primary aging process. Future research indicated that time of wetness was the primary aging factor; hence the initially calculated acceleration factor of between 12 and 20 was revised at the end of the test to between 7 and 14 (EPRI 2000a).

In designing an aging cycle, care has to be taken to allow rest periods where silicone rubber-based insulators are able to recover their hydrophobicity. The inclusion of these rest periods was not always accounted for in early accelerated aging tests. The required conditions and duration of rest periods remain undefined and an area of ongoing research.

Comparison of accelerated aging test results against field-aged units, to confirm that the aging mechanisms are relevant, is essential. In a number of cases, the accelerated aging results have compared favorably with field-aged and outdoor test station units (Maxwell et al. 2002; EPRI 2000a, 2004a).

A number of tests, to determine the long-term performance, have also been developed to assess the performance of one, or possibly two, components of an insulator, but not the entire insulator (e.g., end fitting seal or rubber). Examples include the incline plane test, EPRI's end fitting seal test, and EPRI's long-term dynamic and mechanical loading tests. These tests do not provide an indication of life expectancy; rather they provide a performance comparison between different designs or highlight design weaknesses in the component being evaluated. Summaries of these tests, together with recently implemented tests, are described in Section 4.5.1 (EPRI 2002b; CEA 1996; CIGRE 1999a)

4.8.4 Flashover Probability of Contaminated Insulators

The flashover probability of a contaminated insulator string during critical wetting conditions is a function of both the contamination severity and the applied voltage. An increase in either of these variables leads to a higher flashover probability, as illustrated in Figure 4.8-12.

Since variable voltage tests are easier to perform, it is usual to express the probability for flashover in terms of voltage at a constant pollution severity. In most cases, flashover probability as a function of applied voltage is approximated by a normal distribution function (Carrara and Hauschild 1990). However, a Weibull distribution function has also been used to take account of the truncation of the distribution function. That is, at a specific contamination severity, there is a voltage below which flashover is not possible (Ivanov and Solomonik 1995).

This distribution function is usually characterized by the critical or 50% flashover voltage (V_{50}) and the standard deviation (σ). It has been shown that laboratory tests have a normalized standard deviation (i.e., σ / V_{50}) of between 6 and 10%. For field tests, it is approximately 20%. This difference between laboratory and natural testing can be ascribed to the larger variation in wetting and contamination distribution on the insulator surface under service conditions.

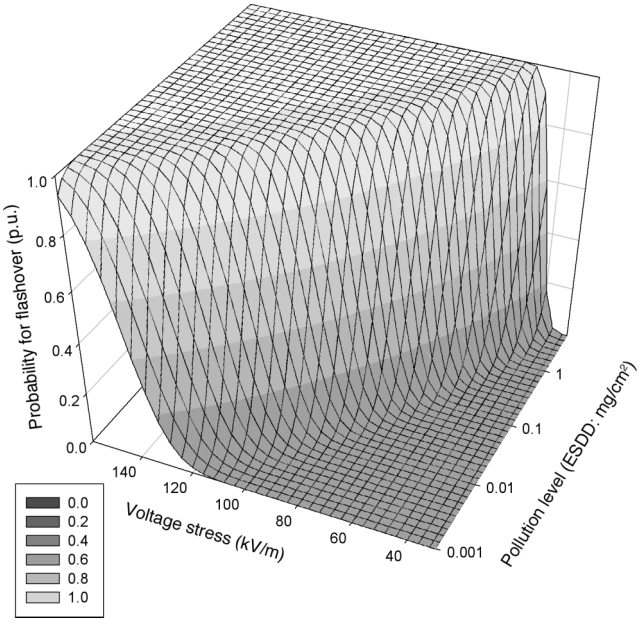

Figure 4.8-12 A three-dimensional representation of the probability for flashover during critical wetting as a function of the voltage stress across the insulator and the pollution severity level.

When considering the flashover probability of a transmission line, or station, it is also necessary to take account of the number of insulator strings that are exposed to the same environment. The Risk of flashover increases with more insulator strings exposed to the environment. The flashover probability of "n" insulator strings, "P_n", can be calculated from the flashover probability of one insulator string, "P_1" as follows:

$$P_n = 1 - (1 - P_1)^n \qquad 4.8\text{-}3$$

This relationship assumes that all the strings have the same single-string flashover probability and that they are statistically independent. It is, therefore, only possible to apply this relationship to a group of strings if they all are exposed to the same contamination severity, and all subjected to the same wetting conditions. The assumption of statistical independence implies that the flashover mechanism on one string does not affect the mechanism of others. Consequently, this relationship cannot be applied to closely spaced strings where the sub-strings are close enough to interact.

An experimental study was conducted for a setup of 14 parallel strings of eight-unit, Type A-11 insulators to prove the validity of this relationship. The results of these tests and two computed curves are plotted on normal distribution paper in Figure 4.8-13. Curves are shown for an assumed standard deviation, 10% and 8%, respectively of the V_{50}.

The relationship between flashover voltage and the number of strings in parallel is shown in Figure 4.8-14. In this figure the flashover voltage of all the strings in parallel is expressed in percentage of the V_{50} of a single string, while assuming a normal or Gaussian distribution function, with a normalized standard deviation of 10%.

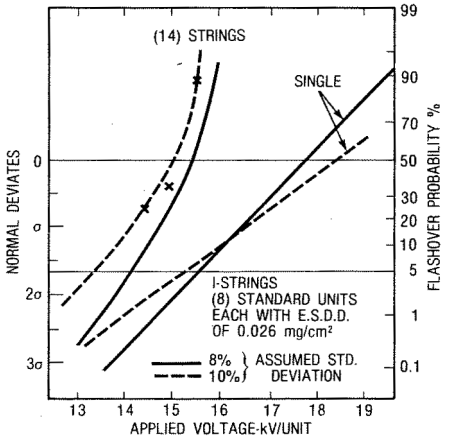

Figure 4.8-13 Test results of flashover probability of 14 I-strings.

For a single string, the withstand voltage (i.e., 10% flashover voltage, V_{10}) is 84% of $V_{50,}$ but this percentage deteriorates as the number of parallel strings increases. For example, a section of single-circuit, 10-mile-long, transmission line with four suspension towers per mile would contain 120 vertical strings. Under contaminated conditions, the withstand voltage of these 120 strings together would only be about 69% of the V_{50} of a single string.

The decrease of flashover voltage with the number of strings shows a trend of saturation for the case of more than 100 strings. For instance, the difference in withstand voltage between 100 and 500 strings is about 6.5%.

It is also necessary to take account of the effect of the parallel strings when performing laboratory tests on naturally contaminated insulators removed from a line that has experienced flashover. The naturally contaminated single string that has a V_{50} of 135% of the nominal line-to-ground voltage may be indication enough to verify that a contamination flashover has indeed taken place. This is because the V_{50} of 120 strings is 75% that of a single string, as shown in Figure 4.8-13. It was often found that units that experienced flashover have higher flashover voltages, from 110 to 150% of the nominal line-to-ground voltage, during laboratory testing.

These points emphasize that contamination flashovers on transmission lines, in areas of widespread contamination, occur at much lower voltages than the test voltages used in the laboratory (where the number of parallel strings is limited). This should be carefully reviewed during line design.

4.8.5 The Insulator Dimensioning Process

To dimension an insulator, the following aspects need to be considered:

- Basic Lightning Impulse Insulation Level (BIL) or Lightning Critical Impulse flashover

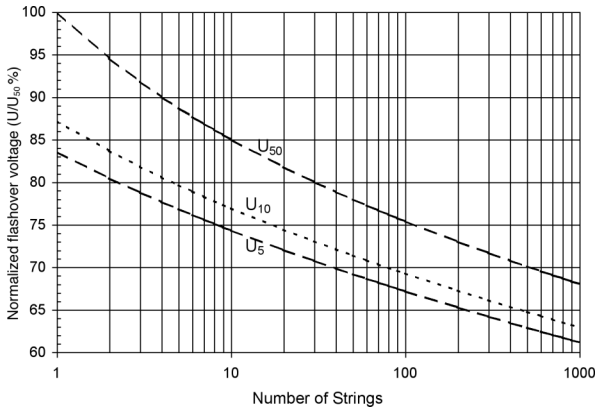

Figure 4.8-14 Relationship between flashover voltage of a single string and multiple strings, for 10% standard deviation.

- Basic Switching Impulse Insulation Level (BSL) or Switching Critical Impulse flashover
- Uncontaminated dry and wet power frequency flashover
- Contamination flashover
- Mechanical strength

In this section, the description of the dimensioning process will only cover the contamination requirements since the lightning and switching aspects are treated in Chapter 3, and the mechanical characteristics fall outside the scope of this book. The uncontaminated dry and wet power frequency flashover voltage is rarely a dimensioning criterion, so they will not be discussed further.

The aim of any dimensioning method is to select the properties of the insulator so that it has an acceptable flashover performance for its whole service life. This means that an insulator must be selected so that it can withstand the stresses placed on it without failing. It would be very easy if the insulator had a well-defined strength above which it will fail and below which it will withstand, and if the stresses to which it is subjected had a definitive maximum value that would never be exceeded. In reality, both the stress and the strength are probabilistic variables. That is, the stress placed on the insulator varies randomly over time, and for any particular level of stress there exists a probability that the insulation will flash over. As a result, there is always a chance that the stress may exceed the strength, leading to a flashover.

The risk of flashover can be determined with reference to Figure 4.8-15, as follows:

- The insulators are energized with an ac voltage with constant amplitude, corresponding to the maximum continuous operating voltage. In special cases, where the insulators are exposed to extended periods of temporary overvoltages, it could be necessary to base the design on a higher voltage level.

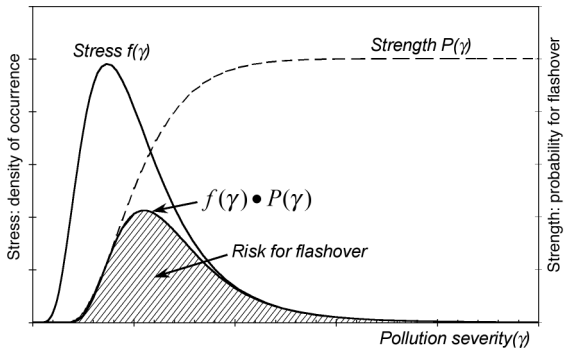

Figure 4.8-15 The stress-strength concept for the calculation of the risk of flashover with respect to polluted conditions.

- The variation of the pollution stress to which the insulator is exposed is represented by the probability density function "$f(\gamma)$", which is expressed in terms of the site severity "γ".
- A cumulative distribution function "$P(\gamma)$" describes the strength of the insulation—that is, the probability of flashover as a function of the same measure of site severity "γ" as was used to describe the pollution stress.
- The multiplication of the f and P functions gives the probability density of flashover of the insulator at the given site, and the area under this curve expresses the risk of flashover.

The risk of flashover can be minimized by "moving" the P curve to the right relative to the f curve—i.e., by selecting an insulator with a higher flashover strength, taking into account reasonable economics. In practice, it is not always possible to evaluate the risk of flashover in this way since these probabilistic functions are often time consuming or difficult to obtain. Generally the following methods are used, listed from simple to complex:

- Service experience
- Selection of creepage distance
- Deterministic method using laboratory tests
- Statistical method utilizing flashover performance data

Service Experience

In a great majority of cases, there are operating lines or substations in the area for which the insulation needs to be designed. If these installations have had an acceptable performance, the same insulation configuration can be used. Results from different voltage levels may even be extrapolated, based on the linearity principle discussed in Section 4.6.5. When introducing a new type of insulator, some network owners have opted for establishing test stations where the performance of insulators can be evaluated under natural conditions without risking system security. This provides a secure way to dimension insulators, but unless special testing is performed (e.g., using explosive fuses to determine the insulator flashover stress), this method does not offer much to optimize the insulation length. The IEC recommends that typically a period of 5-10 years of service, and 2 to 5 years in testing stations, may be needed to be able to adequately select insulators based on service experience (IEC Forthcoming b). These values are naturally dependent on the characteristics of the environment and the testing philosophy used.

Selection of Creepage Distance

Most national and international standards provide a simple table with four or five site severity categories and corresponding levels of minimum creepage distance. The site severity is determined through one of the methods described in Section 4.8.2 or by using a set of descriptions

Table 4.8-7 IEC and ANSI Guidelines for the Selection of Creepage Distance for Different Site Severity Classes

Pollution Class	Unified Specific Creepage Distance (mm/kV_{p-g})
1. Very light	22
1. Light	28
2. Medium	35
3. Heavy	44
4. Very heavy	55

of typical environments provided in the standard. The recommended creepage distance levels listed in the IEC and ANSI guidelines are provided in Table 4.8-7.

As discussed in Section 4.6.3, when using this method, many factors other than creepage distance that affect the insulator flashover strength need to be factored in. Documents providing leakage distance recommendations, therefore, contain a set of limits within which the creepage distance recommendations are valid. In some cases, correction factors are provided to adjust the recommended values for insulators outside these limits (Vladimirski et al. 2001). In other documents, such as the revision of the IEC 60815 Draft, factors are only provided to compensate for the effect of diameter, whereas profiles that fall outside the limits are disqualified (IEC Forthcoming b).

This method makes it possible to specify insulators, within a limited profile range, based on the collected long-term service and test experience of many countries without the need to perform additional laboratory or field-testing. All insulators within the profile limitations and with the minimum required creepage distance are approved for service.

Deterministic Method

The deterministic approach is used when there is insufficient statistical information available to warrant a full risk analysis. A minimum performance criterion is specified based on a worst-case analysis. Laboratory testing may be used to verify that a candidate insulator fulfills this criterion. With reference to Figure 4.8-16, this approach can be described as follows:

1. The maximum site contamination severity that the insulation will be exposed to is determined through site severity measurements or a subjective judgment based on the available site severity information.
2. The minimum contamination severity that the insulator must withstand is selected so that it exceeds the maximum site severity with a safety factor, which is chosen to cover the uncertainties in the designer's evaluation of the strength and stress parameters.
3. Candidate insulators may then be subjected to a withstand or flashover test to verify that their characteristics are above the minimum level determined in the previous step. The test method used is selected to be representative of the service environment.

Step 1: Determine the Maximum Site Severity

More often than not, an insufficient number of site severity measurements will be available. Depending on the number of measurement points available, the user may choose one of several strategies to estimate the maximum contamination severity:

- The user has many (i.e., more than 30) measurements available: The maximum site severity is then simply taken as the maximum value of the values available.
- The user has several measurement values available but not sufficient to feel confident that the maximum value can be taken as representative. This would be the case where the user has between 10 and 30 points available. In this case, it can be assumed that the measurements provide a good estimate of the average contamination severity of the site. The average value of the measurements, ($\gamma_{average}$), is then calculated, and the maximum site severity, (γ_{max}), can be estimated with:

$$\gamma_{\max} = \gamma_{average} \cdot e^{\left[2.06 \cdot \sigma - \frac{\sigma^2}{2}\right]} \qquad 4.8\text{-}4$$

  Where σ is the standard deviation of natural logarithm of the site severity measurements. Typical values of σ for ESDD measurements range between 0.4 and 0.9.
- The user has only single measurement values available. In this case, it would be best to assume that measured values correspond to the mode—i.e., the most likely level of pollution severity. In this case, the maximum

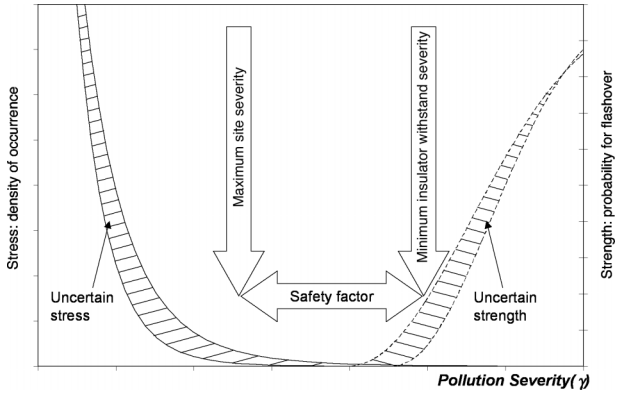

Figure 4.8-16 A graphical illustration of the deterministic approach.

site severity can be calculated from the most likely level of pollution severity, (γ_{mode}):

$$\gamma_{max} = \gamma_{mode} \cdot e^{\left[2.06 \cdot \sigma + \sigma^2\right]} \quad 4.8\text{-}5$$

Where the other parameters are as above.

Step 2: Determine the Minimum Contamination Withstand Severity

The minimum withstand is determined by multiplying the maximum site severity by a safety factor, which should be determined by taking the following factors into account:

- Number of insulators that will be exposed to the same environment (i.e., parallel insulators).
- Differences in pollution accumulation characteristics of the insulator used for the site pollution severity measurement and the candidate insulator. See Section 4.3.2.
- If contamination measurements were performed on unenergized units, it could be necessary to adjust the measured values if heating by leakage current contributes significantly to the contamination deposit.
- Difference in pollution type of the pollution deposit at site and in the test. It was shown in Section 4.6.5 that low-solubility salts have a higher flashover value than marine salt contamination under Clean-Fog tests. In some cases, it may be warranted to test at a lower severity level with the standard test to adjust for this.
- Differences in the uniformity of the pollution deposit at site and in the test and the wetting conditions in service and those during the test; the effects of these two factors have been shown in Section 4.6.5.
- Differences in the equipment assembly.
- Effect of aging on the pollution catch and wettability of the insulation during the expected lifetime.
- Number of critical wetting events per year.

Statistical flashover risk calculations have been performed to obtain a guideline for suitable safety factors that can be used in a deterministic design (Engelbrecht et al. 2005). The results are presented in Figure 4.8-17, which shows the safety factor as a function of the number of insulators exposed to the same environment (i.e., parallel insulators). These calculations were based on the following assumptions:

- The risk of flashover is once in 50 critical wetting events—i.e., 0.02.
- The contamination comprises mostly marine salt.
- The insulator flashover voltage determined during testing has a normalized standard deviation, C_{ins}, of between 6 and 10%.
- The statistical distribution of site severity can be described as lognormal, with a standard deviation of the logarithm of the severity between 0.4 and 0.9.
- The withstand characteristic of the insulator is described by the voltage or contamination severity, where the insulator has a 10% flashover probability.

For typical lines, as indicated by the shaded area in Figure 4.8-17, the safety factor lies between 1.3 and 1.8.

Step 3: Verify the Insulator Withstand Characteristic with Laboratory Tests

The performance of the insulator can be verified by laboratory tests. In the standards, withstand tests are described that consist of a maximum of four tests during which only one flashover is allowed. These tests aim to show that the insulator does not have a flashover probability of below 10% for the voltage and contamination severity at which the test was performed. There is an uncertainty in the test outcome, however—i.e., an insulator with a lower than 10% flashover probability may pass the test, because only a limited number of tests are performed.

It is possible to overcome this lack of discrimination by performing more than the prescribed four laboratory tests, but this can be costly. Another method is to perform the withstand test at a higher voltage or contamination severity to compensate for the limited number of tests performed.

For line insulators, it is more feasible, however, to base the verification tests on determining the 50% flashover voltage, V_{50}. This can be achieved by a relatively small number of tests if variable voltage application techniques are used (Lambeth 1988). These tests are performed at the minimum withstand severity, as determined by the deterministic method. The withstand voltage, V_{10}, for the tested can then be calculated by:

$$V_{10} = (1 - 1.28 \cdot c_{ins}) V_{50} \quad 4.8\text{-}6$$

where C_{ins} is the normalized standard deviation of the flashover voltage, which is typically on the order of 0.06 to 0.1 for laboratory tests.

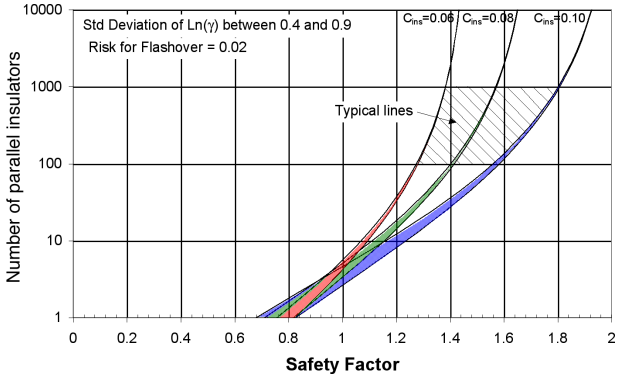

Figure 4.8-17 Typical range of a safety factor for transmission-line insulators (Engelbrecht et al. 2005).

The insulator is approved for service if the calculated withstand voltage level is above the maximum continuous operating voltage.

Statistical Method

A statistical method can be used to calculate the required insulator dimensions for a specific site based on a full risk of flashover assessment. When performing the statistical method, the following aspects should be taken into account:

- Number of insulators that will be exposed to the same environment (i.e., parallel insulators).
- Differences in pollution accumulation characteristics of the insulator used for the site pollution severity measurement and the candidate insulator. See Section 4.3.2.
- If contamination measurements were performed on unenergized units, it could be necessary to adjust the measured values if heating by leakage current contributes significantly to the contamination deposit.
- Difference in pollution type of the pollution deposit at the site and in the test. It was shown in Section 4.6.5 that low-solubility salts have a higher flashover value than marine salt contamination under Clean-Fog tests. In some cases, it may be warranted to test at a lower severity level with the standard test to adjust for this.
- Differences in the uniformity of the pollution deposit at the site and in the test, and the wetting conditions in service and those during the test; the effects of these two factors have been shown in Section 4.6.5.
- Differences in the equipment assembly.
- Effect of aging on the pollution catch and wettability of the insulation during the expected lifetime.
- Number of critical wetting events per year.

The statistical method methodology has the following steps:

1. Site contamination severity and wetting intensity
   - *Input:* A sufficient number of site severity measurements.
   - *Output:* A probability density function describing the site severity.
2. Insulator flashover characteristic
   - *Input:* Laboratory flashover test results at a range of contamination severity.
   - *Output:* A curve describing the flashover voltage as a function of the contamination severity.
3. Insulator flashover probability as a function of the pollution severity
   - *Input:* A curve describing the flashover voltage as a function of the contamination severity.
   - *Output:* The flashover probability as a function of the contamination severity for a specific insulator length.
4. The effect of parallel insulators
   - The probability function obtained in step 3 is adjusted for the number of parallel insulators.
5. Risk of flashover evaluation
   - *Input:* A probability density function describing the site severity.
     The flashover probability as a function of the contamination severity for a specific insulator length and number of parallel insulators.
   - *Output:* The risk of flashover.

Each will be discussed in some detail below with the help of a practical example. In this example, ESDD measurements are used, since it is the most representative of the American environment. It should be noted that this method is essentially the same for other site severity and laboratory testing techniques, such as the Site Equivalent Salinity and the Salt-Fog test.

Step 1: Site Contamination Severity and Wetting Intensity

With sufficient pollution-severity measurements available, a suitable distribution function can be fitted to obtain a statistical description of the pollution stress at the site. An example of ESDD measurements on a standard-shape glass disc insulator string over a period of 55 months is shown in Figure 4.8-18.

These values are sorted from low to high, and each point represents a *1/(number of data points)* drop in the cumulative probability. A suitable cumulative distribution function, such as the lognormal distribution function, can be fitted through these points by utilizing statistical techniques (e.g., the method of maximum likelihood) or by graphical means (i.e., a straight line fit on lognormal graph

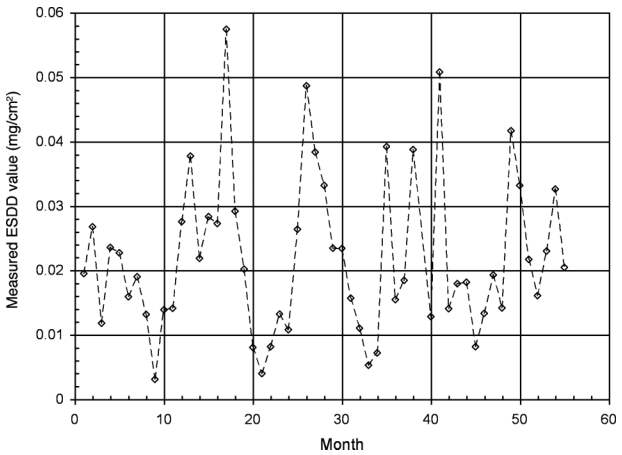

Figure 4.8-18 ESDD measurements at a coastal site.

paper) (Carrara and Hauschild 1990). The sorted site severity measurements and the fitted distribution function are shown in Figure 4.8-19.

The pollution severity of a site is usually characterized by the 2% severity, which is the severity having a 2% probability of being exceeded, and the standard deviation of the logarithm of the site severity measurements. In the example presented here, the 2% severity level is an ESDD level of 0.06 mg/cm^2 and the standard deviation of ln (ESDD) of 0.55.

It has been suggested that double-contingency analysis be performed (see Section 4.8.1) to take account of the independent variation of the contamination severity and the degree of wetting (Suzuki et al. 1999). This would require a two-dimensional risk-of-flashover assessment. However, this approach is rarely feasible, as the insulator strength is not evaluated under different wetting conditions (i.e., the standard laboratory tests only test insulators under critical wetting conditions). To enable a single-contingency analysis, it is conservatively assumed that all wetting events are critical.

Step 2: Insulator Flashover Characteristic

The insulator flashover probability needs to be described in terms of the contamination severity. In order to do this in a cost-effective way, laboratory tests (e.g., Clean-Fog —see description in Section 4.5.2) are performed to determine the 50% flashover voltage, (V_{50}), and standard deviation, (σ), at two or, preferably, more test severities. A power law function can then be fitted through the data points to obtain a mathematical description of the V_{50} as a function of the contamination severity, as discussed in Section 4.6.5. An example of such a relationship is shown in Figure 4.8-20. This example uses the average relationship for standard-shape insulators listed in Table 4.6.1 for the Clean Fog test.

This V_{50} curve can then be used to calculate a family of curves, each describing a different probability of flashover, as shown in Figure 4.8-20. This is relatively easily done by using the inverse probability function characteristics found in standard tables. For example, at a specific contamination severity and assuming a normal distribution function, the 10% flashover value, V_{10}, can be calculated from the 50% flashover voltage, V_{50}, and the normalised standard deviation, $c_{ins} = \sigma_{ins} / V_{50}$, from Equation 4.8-6.

Similar relations exist for the other flashover probabilities.

Step 3: Insulator Flashover Probability as a Function of the Pollution Severity

The curves in Figure 4.8-20 can then be used to derive a function describing the probability of flashover in terms of the contamination severity of a specific insulator. This process is illustrated in Figure 4.8-21 for an insulator with a unified specific creepage distance of 28 mm/kV. As illustrated in the figure, the probability of flashover for each contamination level is where the service stress line intersects with the probability curves. It can also be derived analytically if the insulator flashover voltage is described by a Weibull distribution function (Engelbrecht et al. 2004).

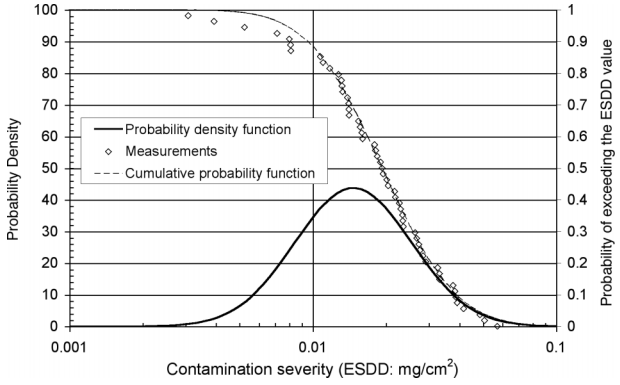

Figure 4.8-19 Typical results from pollution site severity measurements and the fitted lognormal distribution.

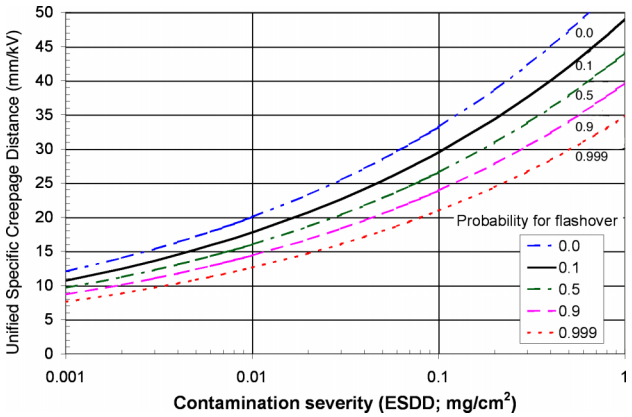

Figure 4.8-20 Insulator flashover characteristic as derived through laboratory tests. The standard deviation is assumed to be 8%. (The solid curve is the withstand characteristic (V_{10}) of the standard shape insulator presented in Figure 4-6.8.)

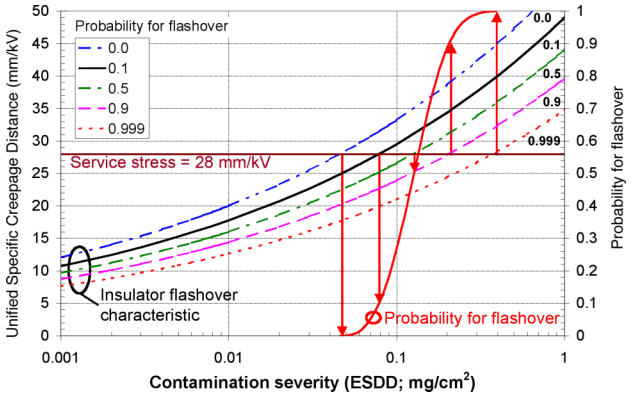

Figure 4.8-21 Derivation of the insulator flashover probability as a function of contamination severity.

Effect of Parallel Insulators

The next step is to take account of the number of insulators exposed to the same conditions. As mentioned previously this can be done with the relationship:

$$P_n = 1 - (1 - P_1)^n \qquad 4.8\text{-}7$$

Figure 4.8-22 shows the flashover characteristic of one insulator, from Figure 4.8-21, and that derived for 120 parallel insulators.

Evaluation of the Risk of Flashover

Enough information is now available to evaluate the risk of flashover for 120 insulators installed in the environment with a severity characteristic as derived in the first step. This is shown in Figure 4.8-23, where the contamination severity density function (from Figure 4.8-19) is multiplied with the insulator flashover probability curve (from Figure 4.8-22), and the area beneath this derived curve is the risk of flashover. This has numerically been calculated to be 0.028, or approximately one flashover in 36 critical wetting events.

With this calculation the fraction of critical events that will lead to flashover has been determined. This value can be expressed as the contamination flashover rate (CFOR) per year by taking account of the average number of wetting events (N_{events}) that take place each year:

$$CFOR = N_{events} \cdot \text{Risk per event} \qquad 4.8\text{-}8$$

For a site where there are 10 critical wetting events per year, the CFOR can be calculated as 0.28 flashovers per year, or on average one flashover each 3.6 years.

If this flashover rate is unacceptably high, an insulator with a higher unified specific creepage distance is selected and the risk of flashover is re-evaluated. This process is repeated until an insulator with an acceptable risk of flashover is found.

This calculation can then be repeated at different contamination severities to obtain a "design curve" for that particular insulator type. An example of such a curve is shown in Figure 4.8-24 in comparison with a typically used creepage distance requirement. The performance is expressed in risk of flashover per critical wetting event.

A software implementation of the statistical method has become available, and its results show good agreement with Russian dimensioning criteria (Gutman et al. 2004).

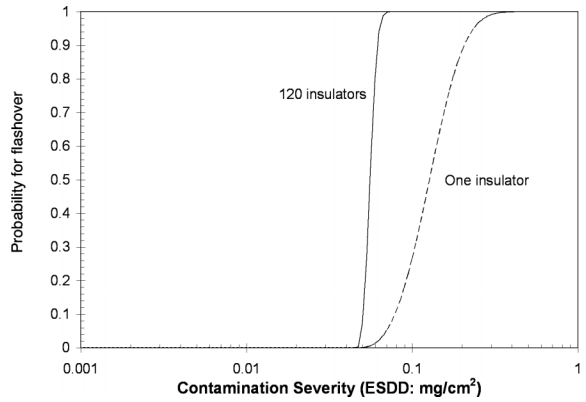

Figure 4.8-22 The derived probability for flashover characteristic for one and 120 insulators.

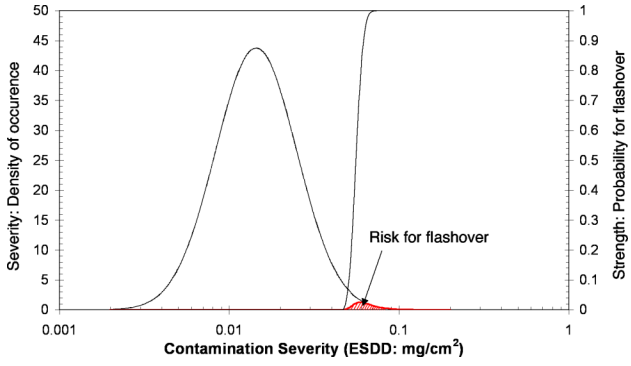

Figure 4.8-23 Calculating the risk of flashover from the site severity and the insulator flashover characteristic.

4.9 ELECTRIC FIELD ON INSULATORS AND GRADING RINGS

4.9.1 E-Field Distribution on Polymer Insulators

The E-field distribution on the surface of and within polymer insulators is a function of numerous parameters including voltage class, insulator design, tower configuration, phase spacing, etc. The following discussion will provide generalized information that relates to the E-field

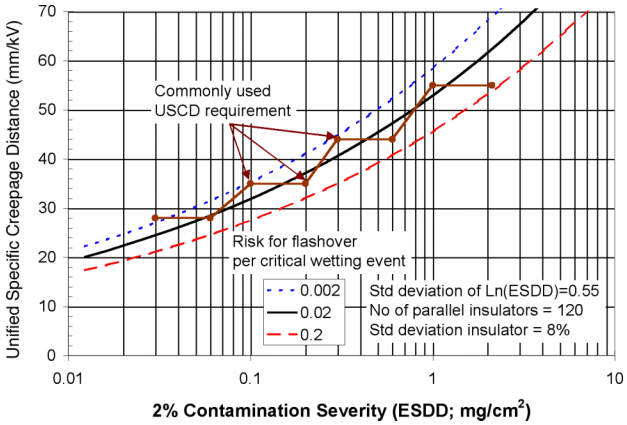

Figure 4.8-24 Design curve for a typical standard-shape disc insulator for three different levels of the risk of flashover.

distribution of most transmission-line applications. It should be kept in mind that there are applications, both on transmission lines and in substations, where the E-field distributions will differ from those presented in the following section.

In general, the E-field magnitudes are larger close to the energized and grounded ends of a polymer insulator. In some cases, the position of highest E-field occurs adjacent to the end fitting, while in other cases, it may occur a short distance away from the end fitting. The case where the position of highest E-field magnitude occurs adjacent to the end fitting is illustrated in Figure 4.9-1 that shows a shaded plot of the E-field magnitude distribution on the polymer weathershed surface of a 230-kV suspension polymer insulator as well as lines of equal potential.

As can be seen from Figure 4.9-1, the magnitude of the E-field close to the energized end is higher than that at the grounded end. It can also be seen from the equipotential lines surrounding the polymer insulator in Figure 4.9-1 that the direction of the E-field is mainly axial—i.e., in the same direction as the fiberglass rod (EPRI 1999; Zhao 2000; CIGRE 1992c).

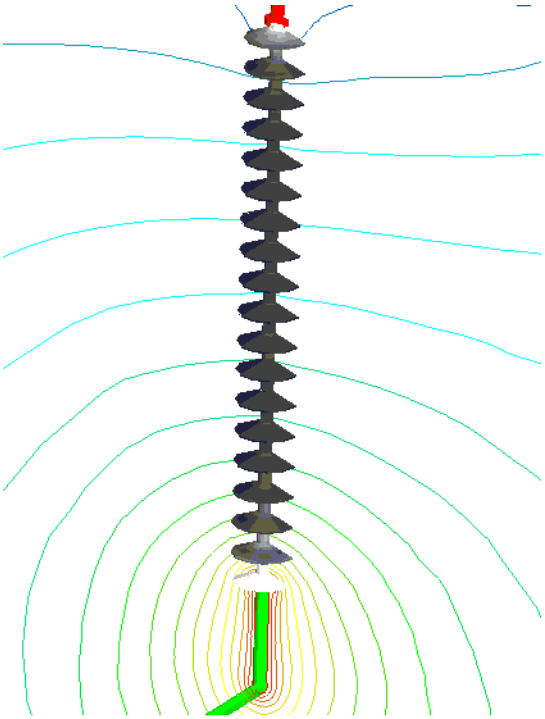

Figure 4.9-1 Shaded plot of the E-field distribution on the surface of a polymer insulator and the equipotential lines in the air surrounding the unit. The E-field magnitude is indicated in grayscale, with white being the highest and black the lowest.

Figure 4.9-2 is a plot of the normalized E-field magnitude within the fiberglass rod of a 115-kV I-sting measured along an axial line.

As can be seen from Figure 4.9-2, the E-field magnitude is high at the energized end and decreases exponentially. The field magnitude increases again at the grounded end, but the maximum value reached is lower than that at the energized end.

Although the distribution indicated in Figure 4.9-2 is common for many situations, there are applications where this may not be the case. Most significantly, for certain designs of overhead transmission-line polymer insulators, the corona ring results in the highest E-field magnitude occurring a short distance away from the end fitting rather than adjacent to the end fitting. An example of this is illustrated in Figure 4.9-3.

It can be seen in Figure 4.9-3 that the presence of the corona ring has shifted the position of highest E-field three sheds away from the energized end fitting. It should be noted that the application of a corona ring does not always result in the point of maximum E-field being shifted away from the area adjacent to the end fitting. Whether this will occur depends on the dimensions of the corona ring, its location, and the configuration geometry (EPRI 1999; Kondo 2002).

Factors That Influence the E-Field Distribution

Numerous factors influence the E-field distribution of polymer insulators. The most important factors include (EPRI 2003a):

1. Insulator geometry including weathershed system, fiberglass rod, and end fittings.

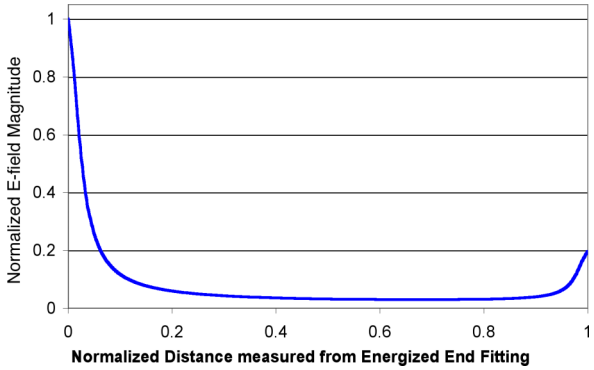

Figure 4.9-2 Example of the normalized E-field magnitude within the fiberglass rod of a suspension I-string 115-kV polymer insulator determined using three-dimensional finite elements modeling. The axial measurement line starts at the energized end fitting and ends at the grounded end fitting.

2. Electrical properties of polymer weathershed, fiberglass rod material, and any semiconductive grading that may be included.
3. The dimensions and position of the corona rings, as well as the attachment hardware.
4. The geometry of the attachment hardware, conductor bundles, grounded hardware, and line structure.
5. The orientation of the polymer insulator and its physical relationship to the attachment hardware, corona rings, conductor bundles, grounded hardware, and line structure.
6. Energized line voltage.
7. Presence of nearby phases.

Each of these parameters needs to be taken into account when determining the E-field distribution of a polymer insulator utilizing either modeling or measurement techniques. Depending on the case, these parameters may have a larger or reduced effect on the E-field distribution.

Due to the dependence of the E-field distribution on this range of parameters, identical polymer insulators applied in different situations may have different E-field distributions, and similarly, different polymer insulator designs applied in the same situation may have different E-field distributions.

Regions of Interest

There are three main regions of the polymer insulators where the distribution of the E-field distribution magnitude is of interest:

1. Within the fiberglass rod and polymer weathershed material.

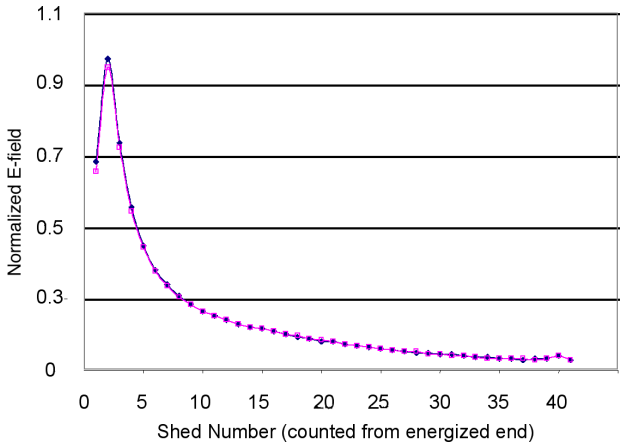

Figure 4.9-3 E-field profile measured along a suspension 500-kV V-sting polymer insulator using a field probe. The unit has a corona ring in place on both the live and grounded ends.

2. On the surface, and in the air surrounding, the polymer weathershed surface and surrounding the end-fitting seal.
3. On and in the air surrounding the metallic end fittings and attached corona rings.

If the E-field magnitude in any of these three regions exceeds critical values, unwanted or excessively large magnitudes of discharge activity may occur, affecting either the long- or short-term performance.

Discharge Activity

The presence, location, and magnitude of discharges are a function of both the E-field magnitude and direction. Four categories of discharges are of concern:

- **Discharges internal to the fiberglass rod and polymer weathershed material or at the interface between the rod and weathershed system.** If a critical E-field magnitude is exceeded, defects (such as voids or inclusions) may result in internal discharge activity. This internal discharge activity may result in destruction of the rod or weathershed material (Cherney 1991).
- **Corona discharges on the surface of, or in contact with, the polymer weathershed material and/or end-fitting seals.** Corona activity, either under dry or wetting conditions, has been shown to result in degradation or changes in the surface properties of the polymer weathershed material. Figure 4.9-4 is an example of such discharge activity (Phillips et al. 1999a, 1999b; Moreno and Gorur 2003; Lopez et al. 2001).

  Arcing activity that may occur in the high E-field region under wetting conditions will also result in degradation of the rubber material and/or end fitting seal. Arcing activity is generally more damaging than corona activity due to its high-energy nature. Arcing may occur between patches of water on the surface of the polymer insulator.

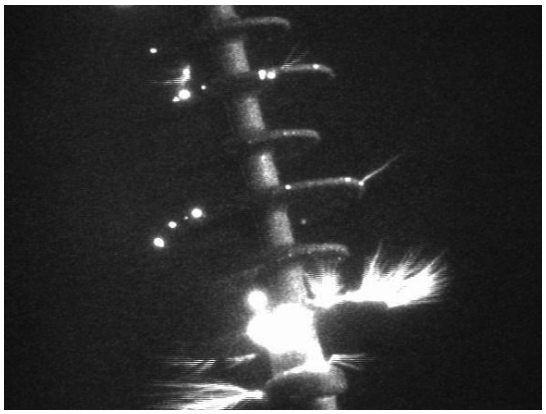

Figure 4.9-4 Example of discharge activity in contact with weathershed material.

This activity is more likely on surfaces that have lower values of hydrophobicity (EPRI 2003a).

Research has shown that corona activity, due to water drops or poorly graded metallic end fittings, may result in a hydrophobic surface losing some of its hydrophobicity. This loss of hydrophobicity allows patches of water to form that, in turn, result in arcing activity. The high energy of the arcing activity may result in more severe degradation of the rubber material.

- **Dry band arcing under contaminated conditions.** Under critical wetting conditions, contaminated insulators may have leakage currents and dry band arcing on the polymer weathershed surfaces. The occurrence and magnitude, and hence the destructive nature of the arcs, are influenced by the E-field magnitude.

  Electrostatic forces result in contamination and moisture being drawn in the direction of the high electric field, resulting in increased accumulation in the high E-field magnitude regions. This effect is considered secondary for polymer insulators applied on ac transmission lines.
- **Corona activity from metallic end fittings or corona rings.** High E-field magnitudes on the surface of the metallic end fittings and corona rings can result in corona activity under dry conditions. These discharges result in electromagnetic interference and/or audible noise that, in turn, may result in customer complaints. If this discharge activity is in contact with the rubber weathershed system or end fitting seal, degradation may occur. Figure 4.9-5 shows such activity (ANSI 2002c; EPRI 2001d).

Critical E-Field Values

In order to prevent or reduce the discharge activity, the maximum E-field magnitude in various regions should be kept below critical values. The following critical values have been mentioned in the literature. The values are for dry uncontaminated polymer insulators and are indicated in kV/cm (rms.):

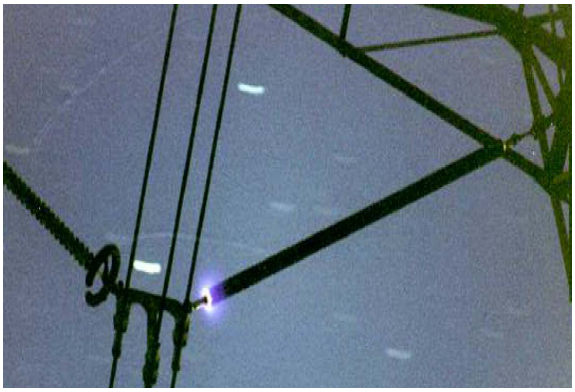

Figure 4.9-5 Image of corona activity from the metallic end fitting of a 500-kV insulator installed without a corona ring.

1. Internal to the fiberglass rod and rubber weathershed material: 30 kV/cm.
2. Surface E-field magnitudes on weathershed material: 4.5 kV/cm (rms) measured 0.5 mm above the surface of the sheath (EPRI 1998, 1999).
3. Surface E-field magnitudes on the metallic end-fittings and corona rings: These should be controlled such that the unit passes the radio corona / interference test indicated in ANSI and IEC standards (ANSI 2002c; IEC 2002a). A surface gradient of 21 kV/cm is often used as a reference value for hardware design (Kuffel and Zaengl 1984).

Correction factors need to be applied to the E-field magnitudes surrounding the metallic and corona rings to account for changes in relative air density if the unit is to be applied at altitudes above sea level (IEEE 1995).

No altitude corrections have been developed for the critical E-field magnitudes on weathershed magnitudes. Using standard altitude correction methods in this case is considered to be conservative, as the onset of corona from water drops is strongly dependent on the electrohydrodynamic forces. This has been shown for water drops attached to conductors (Phillips et al. 1996).

Factor 2 above, the E-field on the surface of the weathershed material, is usually the controlling value when considering corona ring and end-fitting design.

Control of E-Field Distribution

The E-field distribution may be controlled by:

1. **Polymer insulator end fitting design.** The design of the end fitting has an influence on the E-field distribution within the polymer insulator, on the surface of the weathershed material, and on the surface of the metallic end fittings. Large end fittings with rounded edges tend to reduce the maximum magnitude of the E-field in proximity of the end fittings. This grading of the E-field is integral in the design of the insulator. This obviously cannot be changed once a specific insulator design has been selected; however, it may need to be accounted for when selecting an appropriately dimensioned corona ring.
2. **Corona ring application and design.** The application of appropriately designed corona rings is also used to reduce the maximum E-field magnitudes and move the position of the maximum E-field away from the end-fitting (as the end-fitting seal is considered critical). The dimensions and location of the corona ring have a significant influence on the E-field distribution. Figure 4.9-10 shows an example of the E-field profile of a polymer insulator both with and without a corona ring installed. Corona ring design and application are discussed in more detail later in this section.

Corona rings are generally designed and tested for standard transmission-line applications. If polymer insulators are applied in nonstandard applications (e.g., in substations), the standard recommendations may not apply. Modeling and testing may be necessary (IEEE Forthcoming b). Figure 4.9-6 is an example of discharge activity from an insulator installed in a substation with a standard transmission-line corona ring that was inadequate for this application.

It is not uncommon for corona rings to be incorrectly installed in the field. Rings may be installed in the incorrect location with respect to the end fitting, not be sufficiently tightened, installed backwards (as shown in Figure 4.9-7), or not installed at all. In order to overcome these concerns, insulator manufacturers have designed attachment methods that minimize installation errors. An effective education and inspection program can limit errors.

3. **Application and Design of Extra Hardware.** The application of extra hardware—such as arcing horns, extra links, and additional field grading devices—influences the E-field distribution of the polymer insulator. For example, if an extra shackle or link is inserted between the polymer insulator and the conductor, it will increase the maximum E-field magnitude on the polymer insulator; similarly, if an arcing horn is applied, the maximum E-field may be reduced. Hardware that is in proximity to the polymer insulator has the largest effect on the E-field distribution. Hence, when an appropriate corona ring is being designed, selected, and evaluated for a specific application, the presence of hardware in proximity needs to be accounted for.

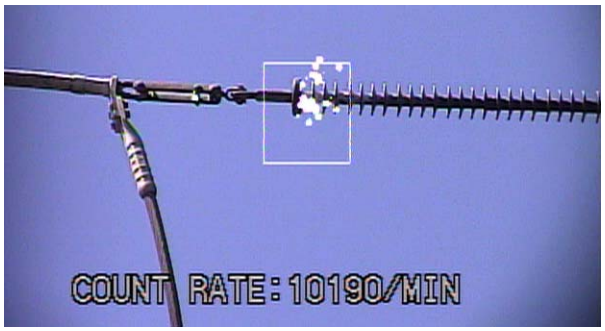

Figure 4.9-6 Corona activity from a 230-kV polymer insulator applied in a nonstandard application in a substation.

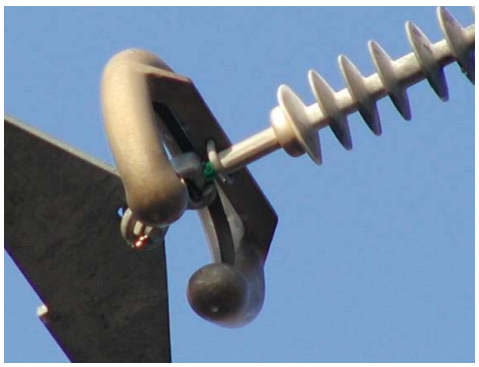

Figure 4.9-7 Corona ring installed backwards and in the incorrect location at 230 kV (EPRI 2004c).

Determination of E-Field Distribution on Polymer Insulators

The E-field distribution on polymer insulators may be determined by either modeling or measurement.

Modeling

Commercially available software packages employing one of the two mathematical methods for determining E-field distributions can be used: the finite element method (FEM) or the boundary elements method (BEM) (EPRI 1999). In order to obtain accurate results, the following needs to be accounted for in the model:

1. Three-dimensional nature of the problem.
2. Dimensions and material properties of the polymer insulator.
3. Dimensions and position of the corona ring.
4. Dimensions and material properties of the structure.
5. Conductor bundle.
6. Hardware that attaches the polymer insulator to the conductor and structure.
7. Nearby phases.
8. The presence of the earth (i.e., ground plane) and the height above.
9. Voltages (potential) of the components being modeled.

The degree to which all of the above are taken into account varies as a function of the region of interest and nature of the configuration. For example, if one was interested in the E-field distribution in the air surrounding the corona ring of a 500-kV insulator, it may not be necessary to take into account the separate properties of the fiberglass rod and rubber, while if one was interested in the E-field distribution inside the rod itself, one needs to take into account the different dielectric constants of the rod and rubber.

Whether each of the factors listed above should be accounted for, and to what degree, has been documented in reports and can be determined by sensitivity analyses (EPRI 1999). As computing power becomes more accessible and affordable, it will become increasingly feasible to include more detail in the modeling, resulting in improved accuracy.

Figures 4.9-1 and 4.9-2 are examples of outputs of such modeling, while Figure 4.9-8 is an example of the geometry of a 500-kV model to determine the E-field distribution on V-string insulators (EPRI 1999).

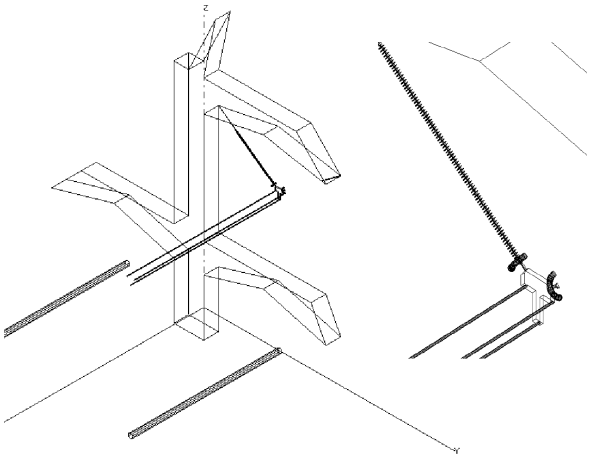

Figure 4.9-8 Example of a 500-kV three-phase geometry model. In this case, the presence of the nearby phases was accounted for by single conductors with the same equivalent radius as the bundle. It was only necessary to account for the presence of the dielectric material of the unit of interest.

Measurement

The E-field distribution may be measured using a range of techniques (Hartings 1994; Vaillancourt et al. 1997):

- By observing the deflection of phosphor bronze wire probe (Gosho 1969; Shen et al. 2004).
- Electro-optic space potential probes (Hartings 1994; Vaillancourt et al. 1997).

Measurement of E-field distribution has some limitations, including:

- Inability to measure in regions of interest—i.e., internal to the insulator or close to the rubber weathershed surface.
- Probe may distort the E-field being measured, reducing accuracy.
- Techniques are expensive and time consuming.

Representation of E-Field Magnitudes on Polymer Insulators

Since one is usually interested in the E-field close to the energized end fitting, the E-field is usually considered to be sinusoidal. Therefore, the rms E-field magnitude is usually considered (see Chapter 7 for more detail on E-field magnitudes). The E-field magnitudes may be represented in two forms: shaded plots or line plots. Figure 4.9-9 shows a shaded plot of the E-field magnitude surrounding the live end of a 500-kV polymer insulator (EPRI 1999).

As can be seen from Figure 4.9-9, the field magnitude is high surrounding the corona ring and live end fitting. The fields on the surface of the polymer insulator reduce as the distance from the end-fitting increases.

Line plots of the E-field magnitude are often plotted along the length of the insulator. Since one is often interested in the E-field in the air along the sheath of the unit, the measurement line often passes through the sheds of the unit. Figure 4.9-10 is an example of line plots for a polymer insulator both with and without a corona ring installed.

The sudden dips in the E-field magnitude in Figure 4.9-10 are when the measurement line passes through the rubber weathershed material, which has a permittivity higher than that of air, (ε_r approximately 4).

The influence of applying a corona ring is also evident in Figure 4.9-10. It can be seen that the peak E-field is

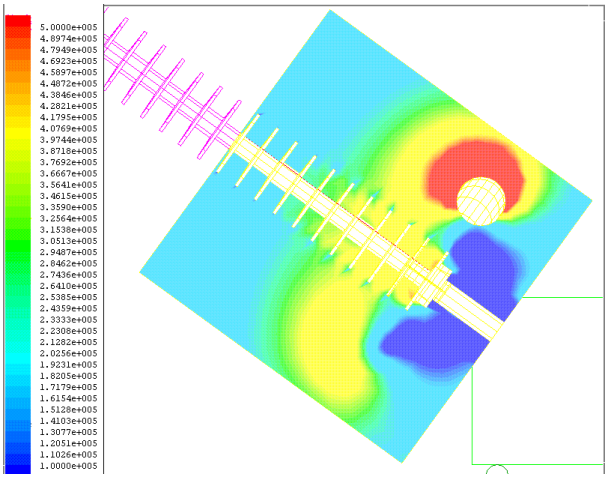

Figure 4.9-9 Example of shaded plot describing the E-field in the air surrounding the energized end fitting of a 500-kV polymer insulator.

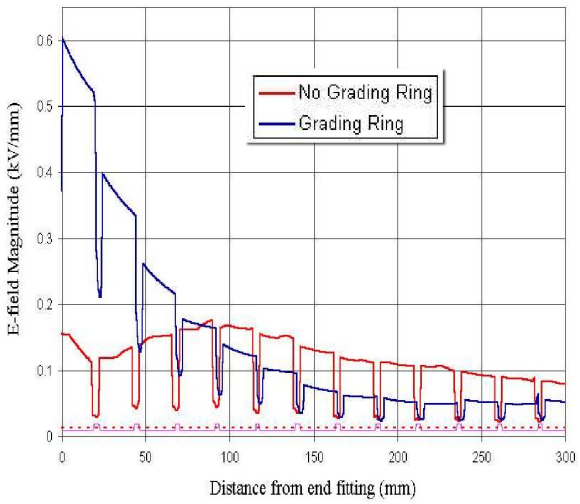

Figure 4.9-10 E-field magnitude in the air along the surface of a polymer insulator for 300 mm away from the live-end fitting. The E-field magnitude profile is shown both with and without a corona ring.

reduced in magnitude and shifted away from the end-fitting to between the third and fourth sheds.

E-Field Magnitudes on Polymer Insulators

The E-field magnitudes on polymer insulators may be divided into three areas of interest:

1. E-field magnitudes on the surface of, and surrounding, both the rubber weathershed material and the end fitting seal.
2. E-field magnitudes internal to the polymer insulator.
3. E-field magnitudes on the surface of the metallic end fittings and corona rings.

- **E-field magnitudes on the surface of, and surrounding, both the weathershed material and end fitting seal.** A considerable amount of modeling of configurations has been performed by numerous organizations. In some cases, different organizations have modeled the same configuration and compared results, illustrating that the results are repeatable. This has been done using both BEM and FEM modeling.

  Figure 4.9-11 plots the peak rms—E-field magnitudes as a function of system voltage for a range of configurations compiled by EPRI (EPRI 2002c). As can be seen, the suggested E-field magnitude level of 0.45kV/mm is exceeded in a number of cases, indicating inadequate corona ring designs. Utilities need to work together with insulator manufacturers to ensure that the E-field grading is acceptable to ensure life expectancy.

- **Internal E-field Magnitudes.** Figure 4.9-12 shows the maximum E-field magnitudes calculated internal to a

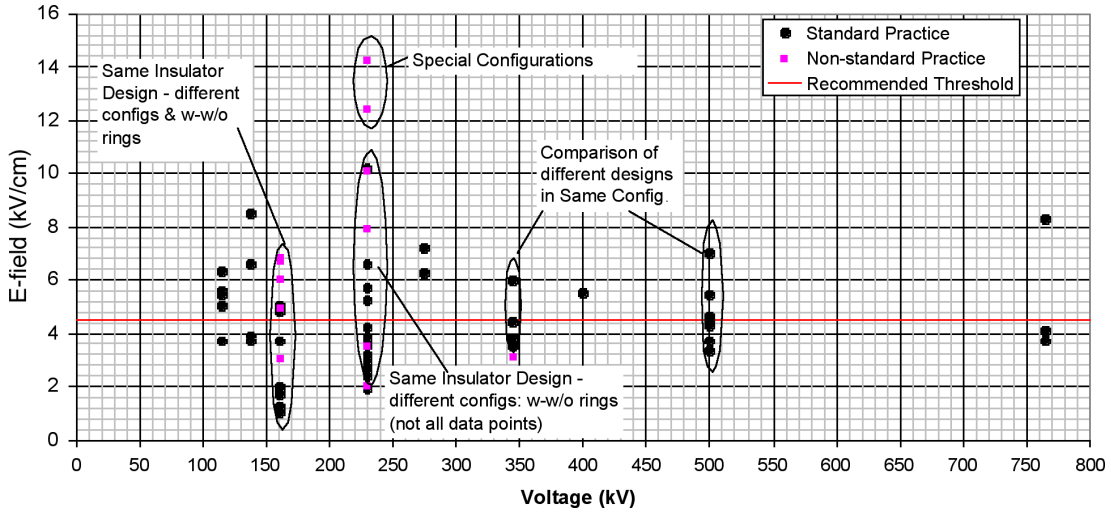

Figure 4.9-11 Maximum E-field magnitudes (rms) on the sheath sections of polymer insulators modeled as a function of system voltage. (All models account only for the presence of a single phase.) (EPRI 2002c).

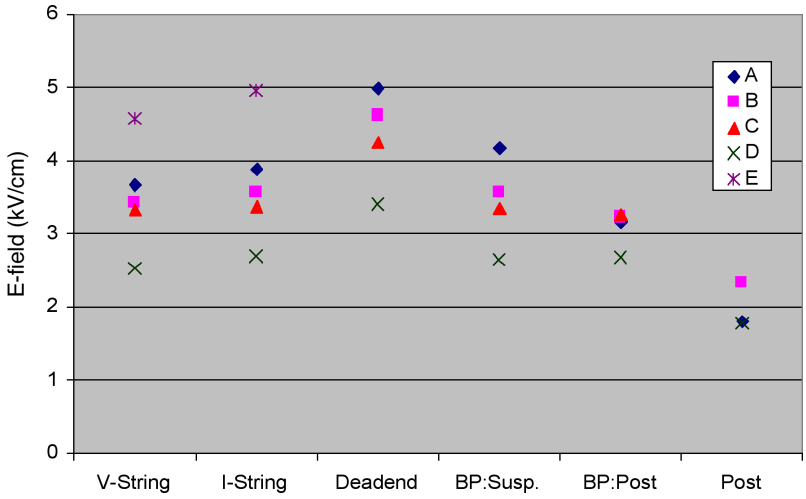

Figure 4.9-12 Maximum E-field magnitudes (rms) internal to a 230-kV polymer insulator applied in different configurations. For each configuration, the geometry is identical with only the manufacturer differing. (BP = braced post—all models account only for the presence of a single phase.)

230-kV polymer insulator in different configurations for five different manufacturers. As can be seen, the E-field magnitudes vary from 1.78 to 5 kV/cm, depending on the insulator/corona ring design and configuration. These levels are considerably lower than the critical 30 kV/cm mentioned previously.

- **E-field magnitudes on the surface of the metallic end-fittings and corona rings.** International and national standards and utility specifications require that insulators are corona free under dry conditions. This is verified by testing (IEC 1997 b; ANSI 2002a; IEEE Forthcoming b). The surface E-field magnitudes on the end fittings and the corona rings are, therefore, lower than the corona onset threshold. Figure 4-9.5 is an example of an insulator with dry corona activity from the end fitting due to elevated E-field magnitudes on the metallic surfaces (note: a corona ring was required for this application but was not installed).

Design and Selection of Corona Rings

Design of Corona Rings

In their simplest form, corona rings may be considered as toroids with three basic dimensions: overall diameter, *D3*, diameter of cross section, *D4*, and distance from end fitting, *L3*, shown in Figure 4.9-13.

Dimensions *D3*, *D4,* and *L3* may be optimized to ensure that the E-field distribution is within the required limits. Often there are limitations on the maximum and minimum dimensions. For example, the maximum value of *L3* may be defined due to strike distance requirements.

Applet I-2, Electric Field Distribution for Polymer Insulators (Effect of Dimensions and Location of Corona Ring) allows the user to investigate the effect of the corona ring, conductor, and end fitting dimensions on the E-field distribution. Although Applet I-2 takes into account the three-dimensional nature of the problem, it does not take into account the presence of the rubber or rod material. Hence Applet I-2 cannot be used to calculate the magnitude of the E-field accurately; however, the trend will be correct.

Often corona rings supplied by insulator manufacturers are not toroidal; rather, they have a horseshoe shape to allow for easy attachment after the insulators have been installed. Figure 4.9-14 shows some examples of corona rings provided by a number of manufacturers.

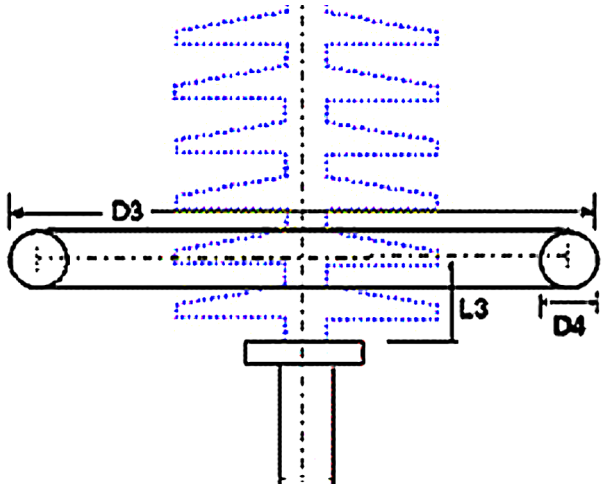

Figure 4.9-13 Definition of corona ring dimensions.

Figure 4.9-14 Examples of corona rings provided by different manufacturers for a range of applications. Both split ring and horseshoe types are shown. Note the different attachment mechanisms.

Corona rings are attached to the insulator end fittings using a variety of methods, depending on the insulator manufacturer. Some manufacturers have attempted to design attachment methods that prevent rings being incorrectly attached by field crews with varying success. Rings are not interchangeable between manufacturers due to difference attachment methods and end fitting designs.

Selection of Corona Rings

To address the aforementioned issues, corona rings are applied in many configurations. Although generic recommendations may be made, they often result in misapplication due to the variety of applications and the lack of definition of key parameters, such as ring size and location. It is preferable that the rings be selected based on E-field modeling, together with testing in accordance with electric field-based methods (IEEE Forthcoming b).

Recommendations in Table 4.9-1 are generic and do not take into account corona ring size or differences in configurations. The authors caution the reader in using the table for nonstandard applications.

As can be seen from Table 4.9-1, there is a degree of uncertainty in the recommendations for voltages between 100 and 161 kV—i.e., 115, 132, and 138 kV. The recommendations in Table 4.9-1 are an area of ongoing research, and the authors recommend that readers investigate the latest research results to determine the best application guidelines.

At voltages greater than 345 kV, separate E-field grading devices attached to the energized hardware may be used, together with the corona rings attached to the polymer insulator. The combination of the corona rings and grading devices controls the distribution of the E-field.

Due to the differences in geometry it may be possible to select different corona ring designs for suspension and dead-end applications on the same line. Most utilities select only one size to reduce confusion both during construction and maintenance.

It should also be noted that the dimensions and locations of corona rings from various manufacturers vary considerably, as do the E-field distributions as shown in Table 4.9-2

Table 4.9-1 Generic Recommendations for Corona Rings. (Note that ring dimensions and locations are not defined. Note that this table is under continual development as the industry's understanding of the issue increases.) (EPRI 1999,1998).

Insulator Type	System Voltage (kV)				
	V < 100 kV	100 kV < V < 161	161<= V < 230	230 <= V <= 345	345 < V
Suspension Units	-	Line-end maybe	Line-end	Line-end	Line-end Ground-end
Dead-End Units	-	Line-end maybe	Line-end	Line-end	Line-end Ground-end
Phase-to-Phase Spacers	-	Maybe both ends	Both ends	Both ends	Both ends
Braced Post	-	Maybe live end of suspension unit	Live end of suspension unit	Live end of suspension unit	
Line-Posts	-	-	Line-end maybe	Line-end	

Table 4.9-2 Comparison of Generic Recommendations Obtained for Four Different Insulator Designs (It should be noted that these are generic recommendations; manufacturers may adjust recommendations for different configurations or situations.)

	Manufacturer W		Manufacturer X		Manufacturer Y		Manufacturer Z	
	Energized end	Grounded end	Energized end	Grounded end	Energized end	Grounded end	Energized end	Grounded end
<138kV	None	None		None	None	None	None	None
161kV	None	None	6.4" or 7.8"	None	None	None	None	None
200-230kV	8"	None	6.4" or 7.8"	None	8"	None	11"	None
300-345kV	12"	None	7.8"	None	12"	None	11"	None
400kV	12"	8"	13.8"	None	12"	None (1)	15"	None (1)
500kV	15"	12"	17.7"	7.8"	17"	8"	15"	11"
756kV	15"	12"	(2)	(2)	17"	12"	16"	16"

Notes: 1. May be required in certain applications. 2. Special design required.

and Figure 4.9-11. Therefore it is impossible to determine the correct corona ring based on Table 4.9-1 alone since only whether one needs a ring is defined rather than the dimensions and location. Often E-field modeling is performed with the unit installed in the configuration of interest to confirm that the E-field magnitudes are kept below the limits specified in the sections above. Details on the correct E-field modeling methods to utilize are provided elsewhere (EPRI 1999, 1998).

A number of practical considerations need to be accounted for when designing/selecting a corona ring:

- A reasonable clearance is necessary between the corona ring and the weathershed system of the insulator being graded and nearby insulators.
  - –Concerns have been raised in braced post configurations, where the suspension unit corona ring touches the sheds of the post unit.
  - –Small gaps between the corona ring and the first shed have been shown to result in high levels of discharge activity.
- Interference between the corona ring and other hardware.
- Ease of installation and removal when insulator is installed.
- Should not prevent access to end hardware for live line work (e.g., access to cotter key).
- Have a simple locking/keying mechanism to ensure that it is installed in the correct location/position.
- The ring should be able to withstand the required level of vibration.
- Power arc termination on the ring should not expose the end fitting seal or weathershed system to undue stresses.
- The corona ring should be able to withstand specific levels of power arc current without sustaining considerable damage.
- The resulting reduction in the dry arc distance needs to be considered.
- Inclusion of corona rings in certain V-string (and possibly I-string) applications has increased the risk of bird streamer outages.

The selection or corona rings is often complicated when units from a range of manufacturers are installed on the same system. Since corona rings are manufacturer-specific, different corona ring designs need to be stocked for maintenance purposes, and maintenance staff need to be trained to select the correct ring for the insulator selected.

4.9.2 E-Field Distribution on Glass and Porcelain Insulator Strings

The E-field distribution on disc-type insulator stings is considerably different from polymer insulators due to the presence of the metallic cap and pins along the entire length of the unit. The self and mutual capacitance between the cap and pins have the effect of grading the field along the string length, resulting in maximum E-field magnitudes at the sting ends that are generally lower than that of a polymer insulator installed without a corona ring in the same application.

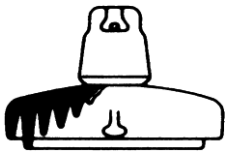
The E-field distribution on disc-type insulators may need to be considered for the following reasons:

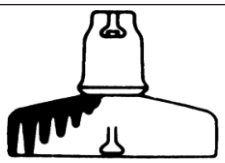
- Corona activity under dry conditions may result in customer complaints due to audible noise or electromagnetic interference.
- Corona activity under dry conditions in the pin region may damage the grout, reducing the life expectancy. See Figure 4.9-15.
- Corona activity under dry conditions may result in damage to the glaze on porcelain units after extended exposure.
- Corona activity on the metallic surfaces under dry conditions may result in loss of galvanization, which, in turn, may result in localized corrosion after extended exposure.

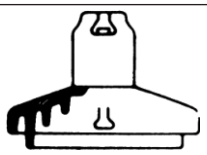
Figure 4.9-15 *Top:* Images of corona activity on the first bell of a 765-kV insulator string with no grading devices installed. *Bottom:* Corona activity surrounding the pin of a porcelain insulator disc under dry conditions.

- Corona activity and/or high E-fields may damage the porcelain bulk material, resulting in donut-type failures, as previously discussed. See Figure 4.9-15 (Jagtiani and Booker 1995).
- Puncture due to lightning impulses. See Chapter 6 (Section 6.5.4).
- Corona-induced flashovers in clean environments (Landy and Reynders 2003).

Unlike polymer insulators, wet corona activity on porcelain and glass insulator stings is generally not a consideration due to the durability and aging characteristics of porcelain and glass.







To address the above issues, corona rings and arcing horns may be applied. Another benefit of applying rings and horns is that they are often the preferential termination point for power arcs reducing the probability of damage to the insulator. Corona rings and arcing horns are usually applied to the line end hardware, not to the insulators themselves. The rings are designed to prevent corona from the hardware, as well as grade the E-field in, on, and around the insulators themselves.

Corona rings and E-field grading hardware are generally not utilized directly on insulator strings for applications at voltages lower than 345 kV. Field grading of 765-kV insulator strings has been shown to be important to prevent customer complaints and avoid reduction in life expectancy (see Chapter 15). Arcing horns have been applied at all voltage levels.

APPENDIX 4.1 INSULATOR TYPES REFERRED TO IN THIS CHAPTER

CHAPTER 5

Switching Surge Performance

Luciano Zaffanella

This chapter discusses the strength of phase-to-ground and phase-to-phase transmission-line insulation when subject to switching surges. The chapter describes switching impulse test methods and provides flashover voltages versus distances for various types of insulation arrangements. The chapter also reviews the effects on switching impulse strength of several factors, including surge shape, atmospheric conditions, and gap geometry. Physical models are provided that describe the mechanism of switching surge flashover. The chapter also discusses the impact of switching surges during live line maintenance and the application of insulation strength data to transmission line design.

Dr. Luciano E. Zaffanella is one of the original authors of *EPRI Transmission Line Reference Book*. When the first and second editions were published he was directing General Electric's staff that was operating Project UHV on behalf of EPRI. Under his direction this project became a High Voltage Transmission Research Center, an internationally renowned facility for the study of overhead high voltage transmission lines with HVAC voltages up to 1500 kV three-phase, and HVDC voltages of + and – 1200 kV, including their switching surge performance. His research into the switching impulse strength of air insulation started before joining GE when he was managing the Research Section of CESI in Milan, Italy. He pioneered research into phase-to-phase switching impulse strength, behavior of gaps at low flashover probability, effect of air density on switching impulse strength, and switching impulse tests on outdoor full-scale transmission line tower insulation systems for Ultra High Voltages. His research on switching surge strength is documented in about 15 IEEE and CIGRE papers.

5.1 INTRODUCTION

External insulation of transmission systems must withstand, with a high degree of reliability, both transient and power frequency voltage stresses. Among the transient voltage stresses, particular attention must be given to those created by system operations—i.e., the voltage surges that may occur at line energization, or as a result of fault clearing or reclosure after clearing a fault. These voltage stresses are called *switching surges*. Chapter 3 discusses how these stresses are generated, how their magnitudes can be calculated, and how the surge amplitudes can be controlled. This chapter discusses the strength of transmission-line insulation elements when subjected to switching surges. The transmission-line insulation elements that are discussed consist of air gaps and insulators in various arrangements.

This chapter reports strength data obtained in high-voltage laboratories around the world using *switching impulses*—i.e., voltages that have the general shape of an impulse approximating the shape of actual switching surges. The switching impulses used to develop strength data for various insulation systems vary in shape. Particular attention is given to switching impulses with a shape that corresponds to the lowest possible flashover voltage for the same crest value. Studies of switching surge strength started in the 1960s simultaneously with the growth of EHV transmission, when it was found that switching impulses of the worst shape and polarity could cause flashovers of air gaps at unexpectedly low voltages. In addition, it was found that the relation between the length of air gaps and their switching surge strength is markedly nonlinear. Thus, switching surges become of increasing concern as the transmission voltage increases. It was this concern that caused a proliferation of research on the switching surge strength of air gaps and insulators during the 1970s and 1980s, when there were prospects for construction of UHV transmission in several countries.

The previous edition of this book, written at a time when there was a rapid increase in the use of higher voltage lines and there was a prospect of transmission lines with voltages above 1000 kV, emphasized the data on long air gaps. The current chapter presents data that cover the entire range of transmission voltages starting from 220/230 kV.

The design of several transmission-line elements is determined by the power frequency voltage and by lightning. Lightning may control the length of insulator strings, especially for lower voltage lines and in conditions of high ground resistance or high incidence of lightning. The power frequency voltage controls the design of insulator strings in contaminated conditions. The power frequency voltage controls also the air clearance between the conductors and the grounded objects when the conductor and insulator string swing in conditions of extreme winds. Conductor and insulator swings are of concern also for switching surges. However, the wind pressure used for switching surge design is generally assumed to be much lower than for the power frequency voltage because of the extremely low probability of coexistence of elevated winds and elevated switching surges.

Power frequency voltages influence the choice of the distances between phases because of the need to limit radio and audible noise. This is particularly true for voltages of 345 kV and above. Switching surge stresses between phases are seldom a limiting factor, except perhaps for compact lines at lower voltages, for which corona effects may not be significant. Power frequency voltages, rather than switching surges, often control the height of the conductors above ground because of the need to maintain adequate clearances in extreme conductor temperature conditions and also to limit the electric field induction in vehicles and the electric field at ground.

Although switching surges at the lower line voltages may not have as much an impact on line design as the case would be for UHV transmission, their consideration continues to be necessary. Once the insulation for power frequency and lightning is satisfied, the switching surge performance must be verified. In most cases, power frequency and lightning requirements control the insulation, and lines have a very low or no risk of failure due to switching surges. This is due in large part to the use of modern methods to limit switching surge amplitude, as discussed in Chapter 3.

The insulation utilized in transmission systems must be sufficient to ensure reliable operation of the line at all times. However, a line designed for no insulation failures may be extremely expensive, and the increased reliability may not be justifiable. The problem of designing insulation for switching surges is complicated because of the great variety of surges and meteorological conditions that the line may experience, and because of the statistical fluctuations of the insulation strength itself. Switching surges appear in all shapes and with different amplitudes. Each type of surge may occur during most meteorological conditions, all of which affect the flashover strength differently. The larger surges occur more rarely than the smaller ones, and the largest possible surge may have an extremely low probability of occurrence in actual service. The expense of providing insulation sufficient to withstand such a surge may be so great that it may be more practical to take the risk, clear the infrequent fault, and reclose. When reclosing breakers are utilized, flashover on transmission lines does not usually result in permanent failure or in unacceptable stability problems. The probability of successful reclosing

is quite high, thus encouraging efforts toward designing the lines to meet a given reliability criterion rather than attempting to ensure that no flashover will ever occur.

This chapter begins by briefly reviewing the principal variables in switching surge flashover. Sections 5.3 and 5.4 describe the switching impulse flashover process and test methods and equipment. In Sections 5.5 through 5.7, the discussion reviews the switching impulse strength of air gaps, line insulation, and station insulation. Techniques for characterizing phase-to-phase switching surge strength are covered in Section 5.8. Section 5.9 explains a calculation method for determining the flashover probability with voltage. The effects of various factors on switching impulse strength—including waveshape, air density and humidity, and rain and other wet- weather conditions—are described in Sections 5.10 through 5.12. Section 5.13 considers the risk of failure of phase-to-ground insulation.

The chapter concludes in Section 5.14 with a discussion of switching surge during live line maintenance. For most modern lines, the clearances between conductors and towers are designed to allow live-line maintenance operations on the line, such as replacing insulator strings. To ensure the safety of the personnel performing these operations, the gaps between conductive tools or personnel and conductors or energized hardware must not flashover even assuming the worst possible switching surge. In order to limit tower insulation requirements that this condition would impose, some utilities use portable gaps to control where a possible switching surge flashover occurs. This chapter also discusses other issues where switching surges impact live-line maintenance: the strength of air gaps with floating objects and the performance under switching surges of insulator strings with broken insulators, an issue of importance in order to assess when insulator strings must be changed.

Switching surge design methods may be very refined. It is possible to assess the relative frequency of occurrence of all the combinations of surges and meteorological events, combine stress with strength taking into account the probabilistic nature of the two and the entire set of insulation systems that are stressed, evaluate the risk of insulation failure, and evaluate how this risk would change as insulation type and dimensions are changed. These methods require special computer programs and a systematic evaluation of meteorological conditions and surge shapes and amplitudes. This chapter provides the strength data in the form of probability of flashover for different insulation types, surge amplitudes, shapes, and meteorological conditions. Insulation strength may be obtained from the many curves presented in this chapter or by applying an analytical model, which is described in Appendix 5.2.

In addition, the user may exercise the following applets:

- Applet S-1: "Switching Surge Flashover Model." The user who is interested in a particular insulation system may exercise Applet S-1 to calculate the critical 50% flashover voltage. This applet is based on an advanced model of the discharge process developed following great advances in the understanding of the mechanism of switching surge flashover. Despite the progress in analytical modeling, the use of data obtained from full-scale switching impulse tests is still preferable.
- Applet S-2: "Risk of Failure." This applet may be used to calculate the risk of failure for a transmission line subject to a set of switching surges. This applet accounts for the statistical distribution of surges, the statistical nature of switching surge strength, the statistics of weather conditions, and the number of insulating elements. With regard to the insulation strength, the standard error in the determination of the flashover voltage in tests among different laboratories is about 3%. This error, in combination with the standard deviation of the flashover voltage (see Section 5.9) and in combination with the accuracy expected from the determination of surge amplitudes in an actual system means that the risk of failure of phase-to-ground insulation of a line can be determined within about two orders of magnitude, for instance 1 in 10^4 instead of 1 in 10^6 surges. The use of absolute risk of failure values may seem questionable in view of such apparently poor accuracy. However, the use of a relative risk of failure is a useful tool to compare different designs. In most cases, even the most conservative switching surge risk of failure values may be significantly lower than those due to lightning and power frequency.
- Applet S-3: "Analysis of Results of Switching Surge Tests." This applet considers a switching impulse test consisting of a series of applied impulses with different crest voltages, each resulting either in a withstand or a flashover. The applet calculates the best estimates of the two parameters that define the switching impulse strength: 50% flashover voltage and standard deviation.

5.2 PRINCIPAL VARIABLES IN SWITCHING SURGE FLASHOVER

5.2.1 Switching Surges and Switching Impulses

Throughout this chapter, the terms "switching surge" and "switching impulse" are used. A *switching surge* is a transient overvoltage occurring on a power system as a result of a switching operation. A switching surge is a stress, specifically a voltage stress, applied to the power system insulation. A switching surge may result in a fault—i.e., the failure of an insulation element, such as a particular air gap. The failure consists of a flashover followed by a power

arc. The insulation failure of one element equates to the insulation failure of the entire line or system to which that element belongs; it will require a momentary or permanent de-energization of the line to clear the fault and restore the voltage. The generation, measurement, calculation, and control of switching surges are described in Chapter 3.

A *switching impulse* is a voltage transient produced in the laboratory for insulation testing. Amplitudes and shapes of switching surges differ from surge to surge. In contrast, switching impulses have shapes, often standardized, that try to reproduce the shape of the most frequently occurring or of the most severe switching surges. Laboratory tests are conducted by repeated application of switching impulses to a test object, normally an element of the external insulation of transmission lines or substations. External insulation consists of air gaps or insulators or their combination. External insulation is usually "self-restoring", meaning that it regains its strength after the application of a switching impulse, whether or not the impulse caused a flashover.

The strength of an insulation element is determined with switching impulse tests, consisting of a number of applications of impulses with varying amplitudes, each resulting in either a *withstand* or a *flashover*. Testing techniques are described in Section 5.4. A complete knowledge of stresses (switching surges), number and types of insulation elements, and their strength is needed to assess the risk of failure of an entire line. This issue is discussed in Section 5.13.

The switching impulse strength of elements of the external insulation of lines is a statistical quantity, because it fluctuates from one impulse to another even when all the test parameters are kept constant. In addition, the strength depends on:

- Polarity
- Waveshape
- Geometry of the insulation element under test
- Meteorological parameters: temperature, air pressure, humidity, rain, and other foul-weather conditions

5.2.2 Switching Impulse Polarity

The switching impulse strength is greatly affected by the polarity of the surge because of the asymmetry of the geometry of practical insulation elements. In most cases the grounded electrode is either the ground plane or a massive structure or the combination of the two. The dimensions of the energized electrode, however, are much smaller. Thus the electric field in the gap between the electrodes is very nonuniform with the higher field intensity at the energized electrode. The switching surge flashover is initiated by positive polarity streamers, which are predischarge phenomena occurring at the positive electrode. For most practical configurations the positive-polarity switching surge strength is lower than the negative-polarity switching surge strength. The more nonuniform the field, the more pronounced is the polarity effect. In power systems, positive- and negative-polarity surges occur statistically with the same frequency and amplitude. Phase-to-ground insulation of transmission lines and stations designed to withstand positive-polarity surges is minimally affected by negative-polarity surges. Therefore, it is common practice in the design of phase-to-ground insulation to disregard switching surges of negative polarity.

5.2.3 Switching Impulse Waveshape

The switching impulse strength of external insulation does not depend on the crest value of the applied voltage alone. Since the early stages of switching surge research, it was found that flashover could be obtained with lower crest voltages when the impulse has a shape similar to a switching surge, which reaches crest with a time much longer than for lightning impulses (a few microseconds) but much shorter than a power frequency waveform (4.2 ms for 60 Hz, 5 ms for 50 Hz). Indeed this worrisome peculiarity spurred the large amount of research conducted in high-voltage laboratories around the world, particularly in the period from 1960 to 1980.

Switching surges have a wide variety of waveshapes. Because the waveshape has a significant influence on the flashover strength, one of the first requirements of switching surge insulation research has been to adopt some sort of consistent waveshape for testing purposes. The waveshape most frequently used to emulate switching surges is a double exponential wave generated by a conventional impulse generator, such as the double exponential waveform shown in Figure 5.2-1. The wave has a "front" and a "tail," separated by the "crest." A double exponential waveform is characterized by two parameters: the time-to-crest, defined as the time interval between the beginning of the impulse and the instant when the voltage reaches its peak value (crest value), and the time-to-half value, defined as the time interval from the beginning of the impulse and the instant on the tail of the impulse when the voltage is one-half of the crest value. The time-to-crest, t_{cr}, of double exponential waveforms used during switching impulse tests usually ranges from 50 μs to 1000 μs. The time-to-half value usually ranges from 3 to 10 times the time-to-crest value. Flashovers may occur either on the front, at the crest, or on the tail of the waveform. For each gap, there is a critical time-to-crest for which the insulation strength reaches a minimum. It is interesting to note that flashovers generally occur on the tail for waveforms with time-to-crest shorter than critical, and on the front for waveforms longer than critical.

Long front waveforms, with times-to-crest greater than 1000 μs, are often more conveniently generated with a transformer, using different techniques of which the most common consists of discharging a capacitor into the low-voltage winding (Thione et al. 1975; Lloyd and Zaffanella 1981). Transformers can be cascaded for the purpose of generating switching impulses with higher crest values by discharging a capacitor in the low-voltage winding of each transformer in the cascade. Transformers are used to generate switching impulses because of the desire for a better emulation of the actual overvoltages occurring in high-voltage systems and also for performing switching impulse tests between phases, for which two generators are required. The resulting waveform, shown in Figure 5.2-1, is similar to the function *1-cos(ωt)*. Because flashovers, if any, occur on the front of the transformer-generated waveform, the shape of the waveform after crest is not important and, therefore, these waveforms are characterized by the time-to-crest only. A transformer-generated waveform stresses external insulation differently than a double exponential waveform of the same crest value and time-to-crest. The important parts of the flashover process, such as leader inception and propagation (see Section 5.3), take place at voltages between 60-75% and 100% of the crest value of impulses corresponding to a 50% probability of flashover. Thus the "active" portion of the waveform may be defined as that between the 70% point and the crest value of the impulse. The duration of the active portion is $t_{0.7} = T_{100} - T_{70}$. A double exponential waveform and a transformer-generated waveform having the same value of $t_{0.7}$ cause the same stress, even though their times-to-crest are quite different. Transformer-generated waveforms are characterized by $t_{cr,eq}$ (equivalent time-to-crest), which is the time-to-crest of a double exponential waveform with the same crest value and causing the same stress. For instance, a transformer-generated impulse with a time-to-crest of 1700 μs and a $t_{0.7}$ of 840 μs is equivalent to a double exponential waveform with a time-to-crest of 1220 μs and time-to-half value equal to 5 times the time-to-crest. Therefore, $t_{cr,eq}$ = 1220 μs. The ratio between t_{cr} and $t_{cr,eq}$ of a transformer-generated waveform depends somewhat on the time-to-half value; for a time-to-half value equal to 5 times the time-to-crest, the ratio is about 1.4 (Arada et al. 1973; EPRI 1982).

Switching impulse tests have also been performed with nonconventional impulse waveforms, such as waveforms with a double peak (Menemenlis et al. 1978b), waveforms with a double impulse (Les Renardieres Group 1978), and waveforms with a bump on the crest (Carrara et al. 1970; Lalot and Hutzler 1978), mainly for the purpose of understanding the flashover mechanism. The influence of a preceding voltage stress was also studied, using the ac power frequency voltage or a dc voltage before the impulse (Watanabe 1968; Knudsen and Iliceto 1970). These studies did not result in changes in the application of switching impulse data to line design. The voltage stress is defined by crest value and equivalent time-to-crest of the impulse. Several sets of data showing the dependence of switching impulse strength, expressed in terms of the 50% flashover voltage, V_{50}, (see Section 5.4), on time-to-crest, t_{cr}, have been generated by various researchers and are shown in Sections 5.5, 5.6, and 5.10. Qualitatively this dependence is shown in Figure 5.2-2.

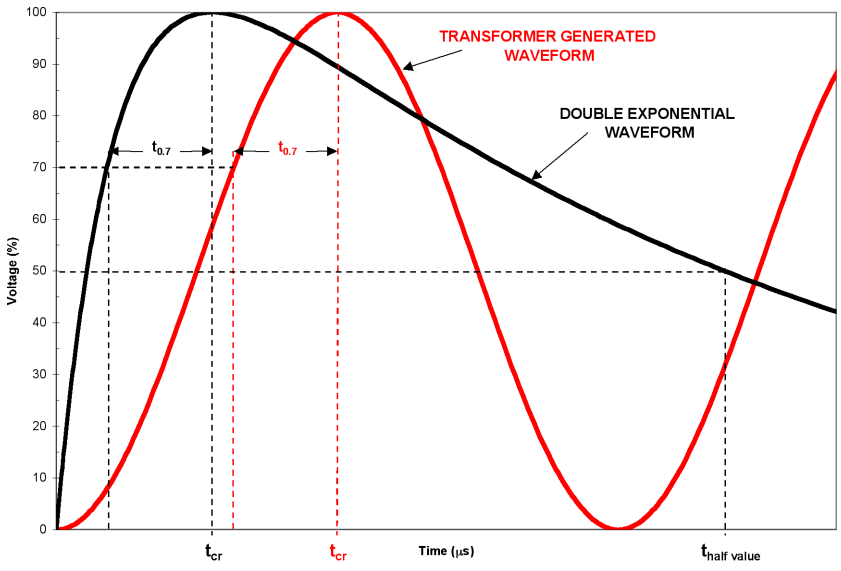

Figure 5.2-1 Typical switching impulse waveforms: double exponential and transformer-generated.

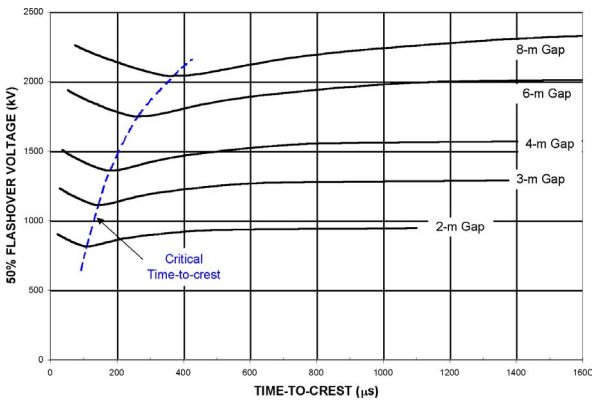

Figure 5.2-2 Examples of dependence of switching impulse strength on time-to-crest.

Switching surges encountered in power systems have times-to-crest ranging from 50 μs to 2000 μs or more (AIEE 1961; IEEE 1966; see also Chapter 3). As the crest values of the surges are reduced by means of advanced methods, such as circuit breakers with resistor insertion, the surges become longer, closely resembling a half-cycle of power frequency oscillation. Thus in those systems for which surge limitation is important, the great majority of the equivalent times-to-crest will be greater than 1000 μs.

5.2.4 Influence of Geometry on Switching Impulse Strength

The switching impulse strength of air gaps is not only a function of the gap length but also of the shape of the two electrodes between which a flashover may occur. For phase-to-ground insulation, the two electrodes are the line (or "energized") electrode and the grounded electrode. For phase-to-phase insulation, both electrodes are energized.

The shape of the electrodes influences the flashover process and the switching surge strength, especially for large gaps (i.e., gap length greater than 2 m). If the energized electrode has small dimensions, such as a rod or a small conductor, the presence of the ground plane or of large structures causes pronounced reductions in phase-to-ground flashover strength for positive polarity switching surges. The physical size of a tower can adversely influence the breakdown strength of the insulation, particularly if the tower approximates a ground plane. Small, lightweight towers have greater switching impulse strength than large massive ones with the same gap length. The walls of a laboratory may enhance the ground plane effect. Adequate laboratory clearances for reliable results must be considered (Carrara and Zaffanella 1968). When tower insulation is tested using a laboratory mockup, it is important to perform the tests outdoors using a full-scale model, which includes placing the conductors at the proper height above ground. Earlier tests of 345-kV and 500-kV tower insulation performed inside high-voltage laboratories showed a lower strength than when the same configurations were tested outdoors.

A large amount of research on the switching impulse strength of air gaps was performed on electrodes with simple geometry, some of which do not bear much resemblance to typical line or station configurations but were useful to develop today's knowledge of the flashover process. The technical literature reports results of tests on the following basic phase-to-ground electrode configurations:

- Rod-plane (see Section 5.5.1)
- Rod-rod, vertical arrangement (see Section 5.5.2)
- Rod-rod, horizontal arrangement (see Section 5.5.3)
- Sphere-plane (see Section 5.5.4)
- Conductor-plane (see Section 5.6.5)

Of particular interest is the rod-plane configuration, because it exhibits the lowest switching impulse strength, which occurs for positive polarity impulses of critical shape. It is about 400 kV/m for a 1-m gap, and it decreases with gap length to about 105 kV/m for a 30-m gap. At the other end of the spectrum, the strongest gap is the plane-to-plane, whose strength is about 3,000 kV/m independently of the shape of the impulse and gap length. The positive-polarity 50% flashover voltage of a rod-plane configuration is often taken as the reference value. The strength of any other configuration with the same gap spacing is defined by the "gap factor," which is the ratio between the positive polarity 50% flashover voltage of the configuration and the positive polarity 50% flashover voltage of a rod-plane configuration (Paris 1967). The gap factor of any configuration is always greater than or equal to one.

The technical literature reports results of tests on the following basic phase-to-phase electrode configurations:

- Rod-rod, horizontal arrangement (see Section 5.8)
- Conductor-conductor, horizontal arrangement, short section (see Section 5.8)

A large amount of test data is available also on more practical phase-to-ground line and station insulation, with or without the presence of insulators and with or without the presence of corona shields or similar hardware:

- Conductor-to-grounded object on the ground plane (see Section 5.6.5)
- Conductor with protrusion (broken spacer)-to-ground plane (see Section 5.6.5)
- Conductor-to-tower leg (see Section 5.6.4)

- Conductor-to-tower window (see Section 5.6.1)
- Conductor-to-tower, outside phase (see Section 5.6.2)
- Conductor-to-bus support structure (see Section 5.7.3)
- Horizontal insulator string, corona shield-to-support structure (see Section 5.7.2)

Finally, data on practical phase-to-phase line and station insulation configurations are also available:

- Conductor-to-conductor, long span (see Section 5.8)
- Corona shield-to-corona shield (see Section 5.8)

5.2.5 Meteorological Influence on Switching Impulse Strength

The most important weather parameters affecting the switching surge design of transmission lines are: air density, humidity, rain, and wind. Air density and humidity affect the switching impulse strength of air gaps.

Rain may affect the switching impulse strength of insulators, but it does not cause any appreciable change in the strength of air gaps. Heavy streams of water cascading over insulators greatly reduce the negative-polarity switching impulse strength, sometimes even reducing it below the positive-polarity strength. The conductivity of the water plays a significant role (Malaguti and Zaffanella 1968). The effect of rain is minimal for very long strings, such as those for 500-kV or 765-kV transmission or for V-strings (Kachler et al. 1971a).

When insulator strings are free to swing in the tower window or on an outside phase, a conservative design requires an increased horizontal gap distance to reflect that a switching surge may occur when the insulator string is swinging closer to a tower leg (see Section 5.13 and Appendix 5.1).

5.2.6 Statistical Fluctuations in Switching Impulse Strength

Nowhere in the insulation area is the statistical nature of the breakdown process in a gaseous dielectric more apparent than in switching impulse breakdown. After all determinable meteorological, geometrical, and electrical influences have been accounted for, a significant element of randomness persists.

The variation in strength of a single insulation element, when tested repeatedly under the same apparent conditions, is such that its flashover voltage may be expressed only in terms of probability. This is why the switching impulse strength is characterized by the 50% flashover voltage, V_{50}. This is the voltage at which 50% of the applied impulses result in a flashover and the other 50% result in a withstand. The flashover probability varies with voltage according to a distribution, which, for practical design purposes, can be assumed Gaussian. This was shown to be valid at least down to voltages equal to V_{50} — 4 times the standard deviation (see Section 5.9). On normal probability paper the flashover probability versus voltage is represented by a straight line. This distribution is defined by:

$$p(V) = \frac{1}{\sigma\sqrt{2\pi}} \cdot \int_{-\infty}^{V} e^{-\frac{1}{2}\left(\frac{x-V_{50}}{\sigma}\right)^2} dx \qquad 5.2\text{-}1$$

$p(V)$ is the flashover probability, V_{50} is the voltage corresponding to a 50% probability of flashover, and σ is the standard deviation.

A reliable value of the standard deviation is difficult to obtain with a single test with a limited number of repeated voltage applications. It is much better to use median values of the standard deviation derived from a large number of tests on similar insulation type and geometry. The value of the standard deviation depends on waveshape, polarity, geometry, and weather conditions. For gaps in which the energized electrode resembles a rod and for positive polarity waveshapes having critical time-to-crest, the median value of the standard deviation is between 4 and 5% of V_{50}. A conservative value equal to 5% is generally used. For gaps in which the energized electrode is a conductor or is close to a conductor, the median value of the standard deviation is less than or equal to 3% of V_{50}.

Even if V_{50} and σ are accurately determined, their values fluctuate for reasons that are often unknown. Comparisons of test results among different laboratories demonstrate that the results obtained by one laboratory deviate from those obtained by another, both working at their highest degree of accuracy. The differences in V_{50} are of a statistical nature. The magnitude of the standard deviation of all possible measurements of the V_{50} obtained in different laboratories is assumed to be about 3% (Brasca et al. 1967).

5.3 FLASHOVER MECHANISM

There are two reasons for the importance of switching surges in transmission-line design. First, the waveshape of the surges may fall in the region of times-to-crest, which, for positive polarity, are critical for the insulation strength of air gaps of typical overhead lines and stations—i.e., the strength is much lower than for lightning impulses and for power frequency voltages of the same amplitude. Second,

switching impulse strength increases less than proportionally with the gap length, whereas the increase in lightning impulse strength is linear with gap length.

To explain these phenomena, many studies of the physics of switching impulse flashover in air have been performed by researchers in high-voltage laboratories around the world (Ganger and Maier 1972; Les Renardieres Group 1972; Menemenlis and Isaksson 1974; Les Renardieres Group 1974; Baldo et al. 1975; Hutzler and Hutzler 1975, Menemenlis and Isaksson 1975; Suzuki 1975; Menemenlis and Harbec 1976; Les Renardieres Group 1977; Los and Schneider 1978; Menemenlis et al. 1978a; Alexandrov and Podporkyn 1979; Alexandrov et al. 1980; Alexandrov and Podporkyn 1982). As a result, much is known about the flashover mechanism, and several models based on physical considerations have been developed to determine the strength of air gaps (Lemke and Mosh 1973; Jones 1973; Carrara and Thione 1976; Kline 1977; Los 1978; Hutzler and Hutzler 1978; Rizk 1989a, 1989b, 1992, 1993, 1995, 1996; Podporkin 1995). What is summarily described in this chapter is the result of a considerable amount of work performed by many researchers over several years. The cited references provide a much more in-depth description to the interested reader.

The electric field in insulation configurations of overhead transmission lines and stations is highly divergent, and is much larger at the energized electrode than at the grounded electrode. When a positive-polarity switching impulse is applied, the positive electric field occurring at or near the energized electrode may cause the initiation of a process that may eventually lead to a flashover of the entire gap and that, under certain critical conditions, corresponds to the lowest possible flashover voltage. Most research has been focused on these critical conditions.

An example of flashover produced by applying a positive polarity switching impulse to a high-voltage conductor suspended by insulators in a tower window is shown in Figure 5.3-1.

The positive-polarity switching impulse flashover process can be broken down into different successive stages:

- In the first stage there is no discharge, while the voltage rises from zero to the corona inception voltage.
- At a certain voltage there is the first appearance of corona, called “first corona.” Corona appears as a bundle of filaments called “streamers” that start from the same point on the high-voltage electrode. Streamers emit mostly blue and ultraviolet light. Each streamer follows a different path from the previous one except for a short stem that is common to all (see Figure 5.3-2). Streamers propagate at a velocity of a few meters per microsecond and, for divergent field distributions, penetrate the gap up to distances from a few tens of centimeters to a few meters. The streamer length depends little on the gap spacing, but mainly on the degree of nonuniformity of the electric field in the gap and on the corona inception field, which may have wide statistical fluctuations from one impulse to the next. The electric field necessary for streamer initiation is predominantly a function of the shape of the high-voltage electrode, increasing with its radius of curvature. For smooth bundle conductors, a streamer inception field of about 36 kV/cm was measured (Los and Schneider 1978). The streamer inception field depends also significantly on the rate of rise of the voltage, being larger for a faster rising front. If the electrode is below a critical size, differences in streamer activity have no impact on the flashover voltage, which is dominated by the phenomena occurring during later stages of the flashover process. Corona emits light, which is detectable using photomultipliers, and causes a current pulse with short front times (tens of nanoseconds) and short tail times (hundreds of nanoseconds). First corona may be followed by a dark period during which there are no discharges because the space charge produced by the streamers reduces the electric field at the electrode below the value necessary to initiate more streamers. There is no ionization activity for a time dependent on the rate of rise of the voltage. Following the dark period, another burst of corona, or secondary corona, occurs. The propagation of the streamer depends on the degree of nonuniformity of the electric field in the gap. If the field is uniform, the streamers reach the ground electrode, secondary emission is produced there, and the discharge current is increased until a direct breakdown occurs.

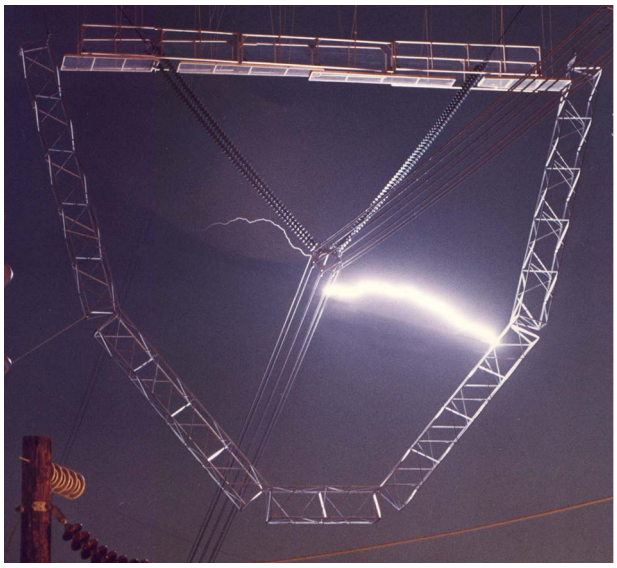

Figure 5.3-1 Switching impulse flashover of a tower window gap.

- The most important stage in the flashover process is the formation of a leader and the propagation of the leader into the gap. With or without a dark period, corona is followed by the initiation of a highly ionized channel called a "leader." The leader channel has a high conductivity and a radius of about 1 mm. The leader starts from the tip of the streamer stem (see Figure 5.3-2) and proceeds into the gap, often along a crooked path and in an irregular fashion characterized by sudden arrests of its propagation, pauses, restrikes, and restarts. At the tip of the leader the electric field is very intense and causes the formation of leader corona, composed of a bundle of luminous streamers. The luminosity of the leader is low, but its various phases can be detected using image converter cameras because of the luminosity of leader corona. Restrikes can be detected because of the illumination of the leader. The number of restrikes depends on the length of the gap. For a 5-m gap, there is at most one restrike; for a 10-m gap, there could be up to five restrikes. Under the critical conditions leading to the lowest switching impulse strength of the gap, the leader propagates in a fairly continuous and mostly straight fashion. The leader is the most important feature of the flashover process, and its properties have been extensively measured. It appears that the leader axial velocity (velocity of the leader tip projection on the axis of the gap) is about constant and equal to 1 ~ 2 cm/μs. As the leader progresses, a charge of 40 ~ 50 μC/m of axial leader length is injected into the gap. This charge resides near the leader channel and forms a space charge column with a radius of the order of 0.5 m. The electric field along the leader channel varies from a value of about 400 kV/m for a newly formed channel segment to an ultimate value of 50 kV/m with a time constant of about 50 μs. The potential at the tip of the leader remains about constant and equal to the leader inception voltage. The left side of Figure 5.3-1 shows the path of a leader that did not develop into a flashover. The brightness of this leader's channel is caused by the sudden transfer of the leader space charge to the high-voltage electrode when the voltage collapsed to zero. Without the voltage collapse, the leader would not have been visible.
- The final stage of the flashover process is the "final jump." When the leader bridges about two-thirds of the gap, its velocity suddenly and dramatically increases and, with a final jump, flashover of the gap occurs. The final jump occurs when streamers from the tip of the leader reach the grounded electrode (see Figure 5.3-2). The gap bridged by the streamers at that moment is called the "height of the final jump." Just before the final jump occurs, the mean electric field along the unbridged gap is 400–500 kV/m, while the electric field at the grounded electrode is lower and must reach a critical value to cause flashover.
- Usually no significant discharge activity appears at the negative electrode until the flashover process is nearly complete.

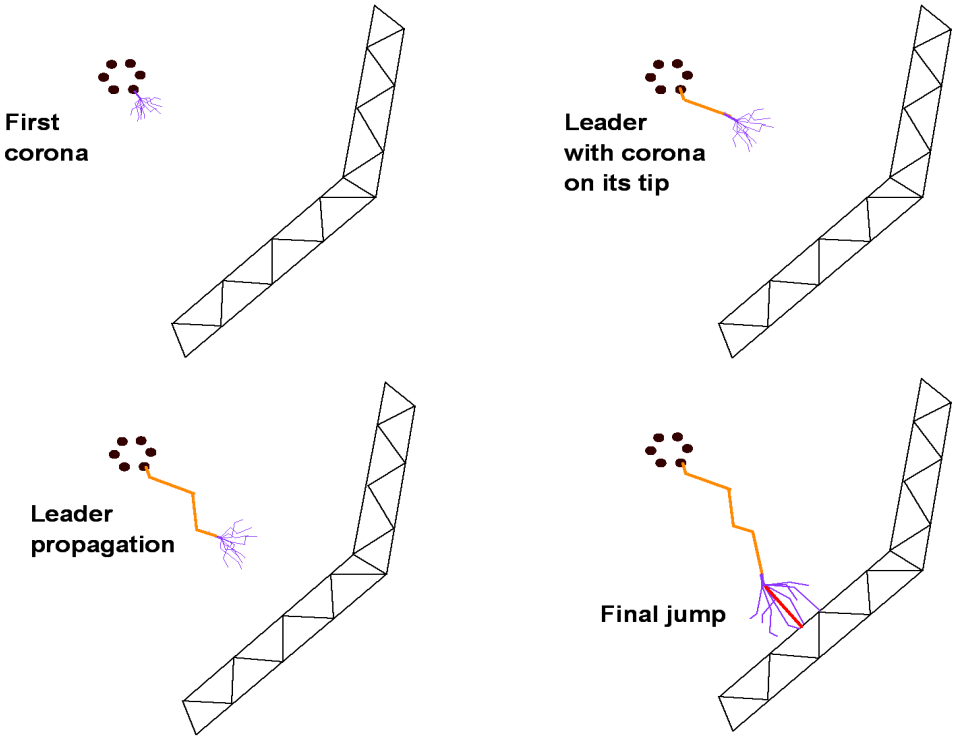

Figure 5.3-2 Stages of the positive switching impulse flashover process.

- Leader initiation and propagation depend on the geometry of the electrodes and on the shape and crest value of the applied voltage. There are critical waveforms for which these phenomena occur in such a way to cause flashover with the lowest possible value of crest voltage. These waves have been determined experimentally for a number of gaps. Models of the flashover process have focused on predicting the critical flashover voltage. Appendix 5.2 describes the most practical and promising model developed so far, based on the work of (Carrara and Thione 1976; Rizk 1989a, 1989b). The critical flashover voltage of any practical gap can be determined by exercising Applet S-1.

5.4 SWITCHING IMPULSE TESTING TECHNIQUES

5.4.1 Switching Impulse Generators, Test Circuits, Test Objects

Switching impulse tests are performed in high-voltage laboratories either indoors or outdoors. Outdoor tests are preferable whenever the dimensions of the test object are significant relative to the distances to the laboratory walls or test equipment. Tests performed indoors would result in lower flashover voltages, unless the dimensions of the test hall are much larger than the height of the energized electrode above ground (Carrara and Zaffanella 1968). Transmission-line tower design has been developed with full-scale models erected outdoors (Rohlfs et al. 1961; Kalb 1963; Johnson et al. 1963; Rawls et al. 1964; Atwood et al. 1965; Aubin et al. 1966; Guyker et al. 1966; Armstrong and Miller 1967; Saruyama et al. 1967; Hauspurg et al. 1969; Kachler et al. 1970; Dillard and Hileman 1970; Annerstrand et al. 1971; Pokorny and Flugum 1975; Young et al. 1980; Cortina et al. 1985; Yasui and Murooka 1988; Kim et al. 2000)

Switching impulse tests may be performed using either conventional impulse generators, such as that shown in Figure 5.4-1 or transformers, single or cascaded, such as those shown in Figure 5.4-2. Typical schematics of the test

Figure 5.4-1 Conventional impulse generator for generating double exponential waveforms at the EPRI Laboratory in Lenox, MA, USA.

Figure 5.4-2 Cascaded transformers for generating oscillatory waves at the EPRI Laboratory in Lenox, MA, USA.

circuits are shown in Figure 5.4-3 for the conventional impulse generator, and in Figure 5.4-4 for the transformer-generated impulses.

A switching impulse is generated by charging capacitors and then discharging them using various techniques. The impulse is applied to a test object, which may be a piece of equipment or an insulation element of overhead transmission lines or substations. For phase-to-ground switching impulse tests, the impulse is applied between the high-voltage electrode of the test object and ground, to which all the grounded parts of the test object are connected. The

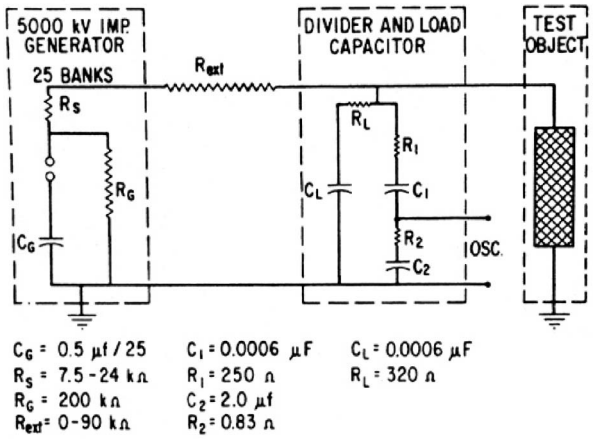

Figure 5.4-3 Schematic of a double exponential switching impulse testing circuit.

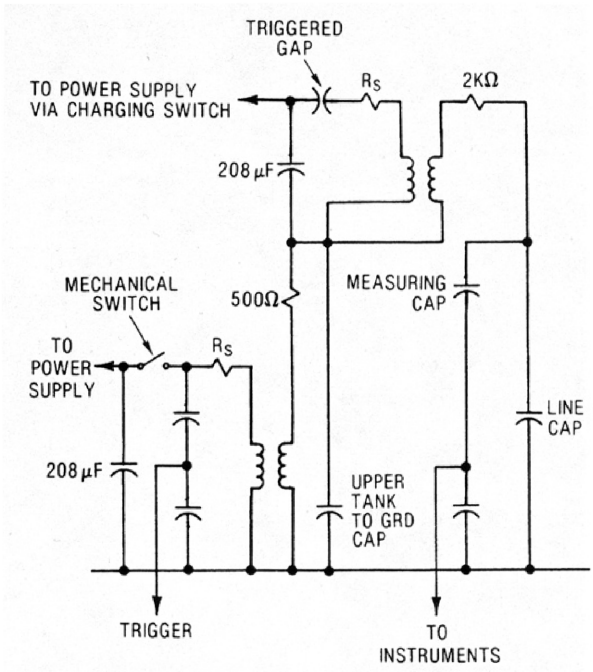

Figure 5.4-4 Schematic of a transformer-generated switching impulse testing circuit.

applied impulse is defined by its polarity (positive or negative applied between high-voltage electrode and ground), its crest voltage, and its waveform. The waveform is defined by the time-to-crest and the time-to-half value. Most important, for switching surge design of line insulation, is the time-to-crest—actually, the time-to-crest of the equivalent double-exponential waveform described in Section 5.2. The procedure and definitions relative to phase-to-phase tests are discussed in Section 5.8.

The result of the application of a switching impulse may be either a *withstand* or a *flashover*. The insulation elements of overhead lines and substations are self-restoring—i.e., their strength is not affected by a previous flashover. Therefore, a switching impulse test may consist of a series of switching impulse applications with the same or different crest voltages, some of them resulting in withstand and some in flashover. Normally, the time-to-crest is kept constant throughout the test, and the crest voltage is varied.

The crest voltage and sometimes the time-to-flashover are measured at each application. The voltage is measured using high-voltage capacitive dividers and analog or digital oscilloscopes. Calibration must be done by comparison with approved devices. Calibration can also be done using sphere gaps, which have a very well-defined strength (Gockenbach 1991). With switching impulses of positive polarity, flashovers frequently occur at random times before the crest. In presenting the results of flashover tests, the relationship of flashover probability to voltage is expressed in terms of the prospective crest value. The results of a test—i.e., the results of a series of voltage applications—are the 50% flashover voltage, V_{50}, and the standard deviation, σ. These two parameters define the strength of the test object for the time-to-crest and polarity of the applied switching impulse. The 50% flashover voltage is the prospective crest voltage of the impulse that has 50% chance of causing a flashover (and 50% chance of being withstood). The standard deviation is an important parameter that is used to define the strength at low flashover probabilities if the shape of the curve defining probability of flashover versus prospective crest voltage can be assumed Gaussian (see Section 5.9).

The test object is generally a mockup of an insulation system that may include conductors, insulator strings and associated hardware, and tower members. The final geometry must be replicated as close as possible, including the height of the conductors above ground. The walls of the laboratories must be as distant as possible in order not to affect the electric field near the high-voltage electrode and in the gap where flashover may take place. It is always preferable to perform tests on full-scale models of the line insulation systems erected outdoors. The conductor geometry

must also replicate the eventual geometry as closely as possible, although it is not necessary to use stranded conductors. The conductors must extend sufficiently on either side of the location where the flashover is expected to occur. The conductors must be terminated in a way to avoid flashovers to ground or other grounded objects from unintended locations. The high-voltage lead connecting the output of the impulse generator or the test transformers to the test objects must be placed away from the critical parts of the test object and from ground. If the test setup is not carefully designed, anomalous flashovers may occur during switching impulse tests with positive polarity (see Section 5.6.6).

All the parameters that affect the strength must be carefully defined and measured. These include: gap geometry and in particular the dimensions of the high-voltage electrodes and the gap length, temperature, air pressure, humidity, and precipitation. Often the results of a test are modified by applying weather correction factors in order to obtain the strength that would have been obtained under standard atmospheric conditions (see Section 5.11).

5.4.2 Test Methods

The two significant parameters that define the results of a switching impulse test are the 50% flashover voltage, V_{50}, and the standard deviation, σ. Various practical test methods to determine one or both of these parameters with the highest possible accuracy for a given number of voltage applications have been developed (Brasca et al. 1967; Brown 1969; Carrara and Dellera 1972; IEC 60-1 1989; IEEE Std 4 1995).

Ordinary Method (Multilevel Method)

The ordinary method, used in most past switching impulse tests, consists of applying a number of impulses (e.g., 20) with the same crest value at each of a number (e.g., 5) different voltage levels in a flashover probability range from below 20% to above 80%. The flashover fraction is determined at each level and is plotted versus the voltage level on normal probability paper. Assuming that the curve describing flashover probability versus voltage is a Gaussian (see Section 5.9), a straight line is fitted to the results. An example of this procedure is shown in Figure 5.4-5. The intersection with the 50% line gives V_{50} and the standard deviation, in per unit, is given by Equation 5.4-1.

$$\sigma = \frac{V_{50} - V_{15.9}}{V_{50}} \qquad 5.4\text{-}1$$

Up and Down Method

The most efficient method for the accurate determination of V_{50} is the "up and down method": the crest voltage of each impulse is adjusted depending on the result of the previously applied impulse—namely, the voltage level is increased or decreased by a fixed step, ΔV, depending on whether the previous result was a withstand or a flashover, respectively. The first useful application is defined as the one whose result is different from that of the successive application. The impulses that are applied before the first useful application are discarded. If there are N useful impulse applications, the 50% flashover voltage is calculated averaging the crest values of all the N impulses.

Extended Up and Down Method

If the curve describing flashover probability versus voltage is considered to be Gaussian (see Section 5.9), the most efficient method for the accurate determination of σ is the "extended up and down method." This consists of the regular up and down method used to determine V_{50}, plus a special up and down method devoted to the determination of V_x, where x is a low flashover probability. In the extended up and down method, N series of M impulses with the same crest value are applied. The crest voltage of a series depends on the results of the previous series: the voltage level is increased or decreased by a fixed step, ΔV, depending on whether all the M impulses of the previous series were withstood or if at least one impulse resulted in a flashover, respectively. The standard deviation is then calculated from V_{50} and V_x. For instance: with M = 10, x = 6.7%, and

$\sigma = \frac{V_{50} - V_{6.7}}{1.5}$; with $M = 20$, $x = 3.4\%$, and $\sigma = \frac{V_{50} - V_{3.4}}{1.83}$.

Analysis of Data Using the Principle of Maximum Likelihood

The determination of V_{50} and σ can be done independently of the test method using the principle of maximum likelihood (Brown 1969; IEEE Std 4 1995). The flashover probability function, $p = f(V)$, is assumed Gaussian. The probability that a flashover occurs at the i_{th} switching impulse application is $p_i = f(V_i, V_{50}, \sigma)$, where V_i is the crest voltage of the applied impulse. The probability that a withstand occurs is $q_i = 1 - f(V_i, V_{50}, \sigma)$. The likelihood function, L_i, is equal to p_i if the result is a flashover and is

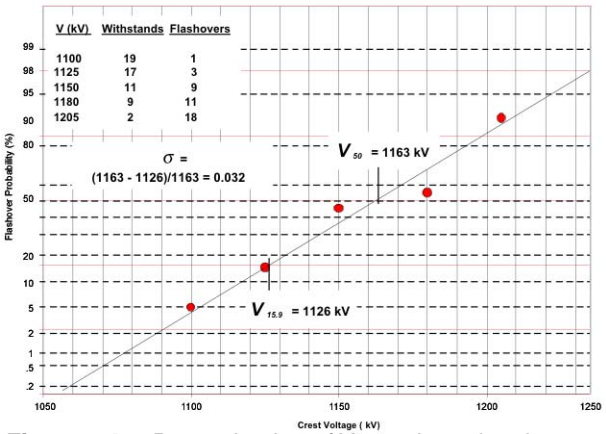

Figure 5.4-5 Determination of V_{50} and σ using the ordinary method.

equal to q_i if the result is a withstand. Given a series of N voltage applications, the likelihood of obtaining the actual results is the product of the individual likelihoods:

$$L = \prod_{i=1}^{N} L_i \qquad 5.4\text{-}2$$

The likelihood, L, is a function of the assumed values V_{50} and σ. The best estimates of the values of V_{50} and σ are those that maximize the likelihood: $L(V_{50}^*, \sigma^*) = L_{\max}$. The x% confidence interval of the estimates can be found by determining the range of values of V_{50} and σ for which the likelihood is greater than $2\frac{(100-x)}{100}L_{\max}$. For instance, the 95% confidence limits of the 50% flashover voltage are V_{50}^{lower} and V_{50}^{upper}, these limit values being such that $L(V_{50}, \sigma^*) > 0.1 \cdot L_{\max}$ for any V_{50} in the entire interval between the two limits.

Calculations of V_{50} and σ and of their confidence intervals can be done using Applet S-3, "Calculation of the 50% Flashover Voltage and Standard Deviation from a Set of Test Data". For example, the principle of maximum likelihood applied to the series of tests shown in the insert of Figure 5.4.5 gives the following results: V_{50} = 1163.4 kV (95% CI from 1151.1 to 1176.1 kV) and σ = 3.38% (95% CI from 2.42% to 5.23%). Comparison with the visual fitting of a straight line to the data points in the figure is quite favorable. The principle of maximum likelihood has the advantage of taking into account also the impulse applications at voltage levels where there were no flashovers or no withstands, whereas the visual straight-line fitting cannot utilize these data.

5.5 SWITCHING IMPULSE STRENGTH OF SIMPLE AIR GAPS

5.5.1 Rod-Plane

The switching impulse strength of air gaps depends on the geometry of the electrodes and on the polarity of the impulse. The strength of an air gap is characterized by the 50% flashover voltage, V_{50}, and by the standard deviation, σ. The lowest values of V_{50} occur for a positive polarity impulse applied to a rod protruding toward a plane. For this reason this configuration has been studied extensively for design purposes (Rohlfs et al. 1961; Udo 1965; Watanabe 1967; Paris 1967; Carrara and Zaffanella 1968; Paris and Cortina 1968; Kachler et al. 1970; Harada et al. 1970; Carrara et al. 1970; Harada et al. 1971; Barnes and Winters 1971; Carrara and Zaffanella 1972; Harada et al. 1973; Gallet et al. 1975; Suzuki and Miyake 1975; Lloyd and Zaffanella 1981; EPRI 1982; Cortina et al. 1985) and to gain an understanding of the physical mechanism of switching surge flashover (Les Renardieres Group 1972; Les Renardieres Group 1974; Baldo et al. 1975; Carrara and Thione 1976; Les Renardieres Group 1977; Rizk 1989a, 1989b, 1992). An exhaustive compilation of published data was prepared as a part of an EPRI project on live line work (Gela 1994).

The 50% flashover voltage of rod-plane gaps is a function of the time-to-crest of the impulse. For a given gap length and a given weather condition (relative air density and absolute humidity), there is a critical time-to-crest that corresponds to the lowest V_{50}. The corresponding voltage is $V_{50,crit}$. $V_{50,crit}$ is a nonlinear function of the gap length. An interpolation of available test data for rod-plane gap lengths between 1 and 23 m is expressed by the well-known "EdF equation" 5.5-1, introduced by researchers of the Electricité de France (EdF) (Gallet et al. 1975).

$$V_{50,crit,Rod-Plane} = \frac{3400}{1+\frac{8}{L}} \qquad 5.5\text{-}1$$

V_{50} is expressed in kV and the gap length, L, in m. The equation is valid for standard atmospheric conditions of relative air density, δ, and absolute humidity, h: δ = 1 and h = 11 g/m³.

Taking advantage of more available data, researchers at the Japanese laboratory CRIEPI improved the EdF formula, and developed Equation 5.5-2, which is valid for gap lengths between 1 and 25 m (Kishizima et al. 1984).

$$V_{50,crit,Rod-Plane} = 1080 \cdot \ln(0.46 \cdot L + 1) \qquad 5.5\text{-}2$$

A slightly different expression for the 50% flashover voltage of rod-plane gaps was developed on the basis of a model of continuous leader inception and breakdown of long gaps with critical times-to-crest (Rizk 1989). For gap lengths L > 4 m, the critical 50% flashover voltage of rod-plane gaps in standard atmospheric conditions is given by Equation 5.5-3.

$$V_{50,crit,Rod-Plane} = \frac{1830 + 59 \cdot L}{1+\frac{3.89}{L}} + 92 \qquad 5.5\text{-}3$$

The critical 50% flashover voltages of rod-plane obtained with Equations 5.5-1,5.5-2, and 5.5-3 are plotted versus gap spacing in Figure 5.5-1. A fundamental difference between the empirical EdF formula expressed by Equation 5.5-1 and the CRIEPI's and Rizk's Equations 5.5-2 and 5.5-3, is that the EdF formula predicts saturation of the crit-

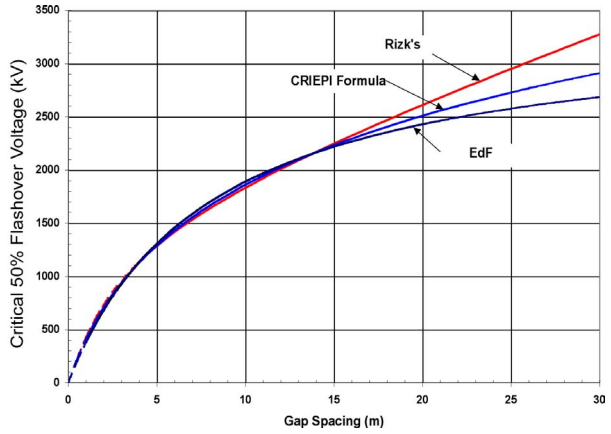

Figure 5.5-1 Critical 50% flashover voltage of rod-plane gaps versus gap length for standard atmospheric conditions.

ical 50% flashover voltage at 3400 kV. Rizk's model predicts saturation of the continuous leader inception voltage but not of the voltage drop along the leader, which will continue to increase with gap length. The differences between the critical 50% flashover voltages obtained with the three equations are small in the practical range of gap lengths but become significant for lengths greater than 17 m. The CRIEPI equation (5.5-2) has gained legitimacy from IEC, which is using it to define the gap factor of other gaps.

Rain does not affect the strength of rod-plane gaps. The effect of relative air density and absolute humidity are discussed in Section 5.11.

The critical time-to-crest is a function of gap length and humidity, as shown in Figure 5.5-2.

The standard deviation of rod-plane gaps depends on the time-to-crest. For critical times-to-crest, it is of the order of 4.5%.

5.5.2 Vertical Rod-Rod

Figure 5.5-3 shows the critical 50% flashover voltage versus gap length for different vertical rod-rod geometries characterized by different ratios between the height, H, of the grounded rod and the gap length, L. The lowest curve of Figure 5.5-3 is for rod-plane, which is a special case of rod-rod when the grounded rod height is zero. Figure 5.5-3 clearly shows the dramatic effect of geometry. As H/L is increased, the 50% flashover voltage of a given gap length increases. For positive polarity, the greatest strength is achieved by the ideal rod-rod gap, with the ground plane removed, corresponding to $H/L = \infty$. For this ideal rod-rod, the positive polarity and the negative polarity strengths coincide. This is the condition corresponding to the lowest negative polarity strength. The negative polarity strength

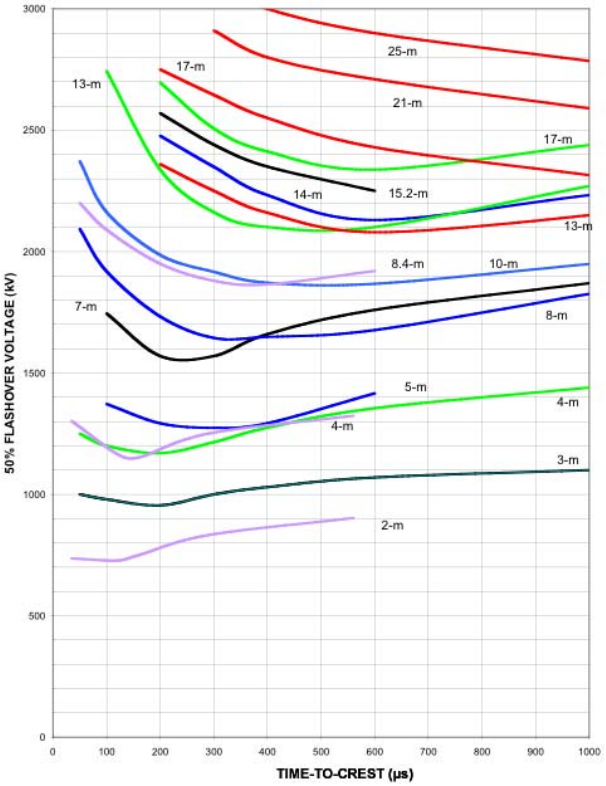

Figure 5.5-2 50% flashover voltage of rod-plane gaps versus time-to-crest. Data from CRIEPI (2, 4, and 8.4 m), Project EHV-UHV (3, 7, and 15.2 m), CESI-ENEL (4, 13, and 17 m), Renardieres (5, 8, 10, and 14 m), AEP/OB (13, 17, 21, and 25 m).

increases with decreasing H/L. The highest negative polarity strength is obtained for $H = 0$ (rod-plane).

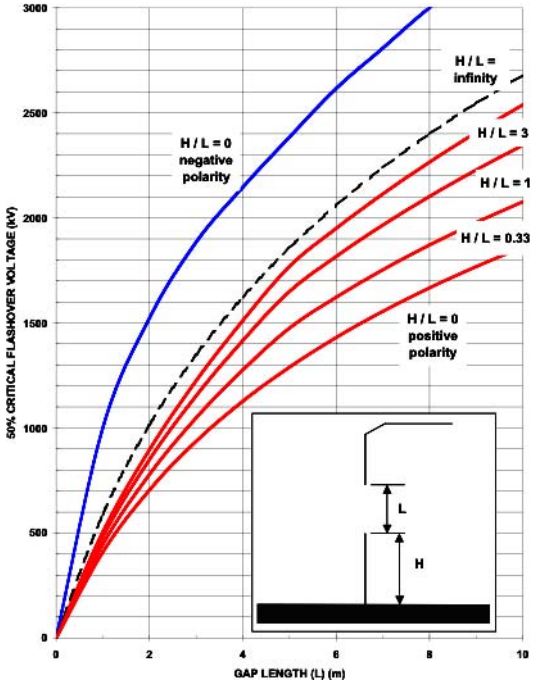

Figure 5.5-3 Critical 50% flashover voltage of vertical rod-rod gaps versus gap length.

This gap behavior demonstrates the critical importance of the positive polarity electrode and of the electric field near it. The presence of the ground plane, or of a massive structure at ground potential, enhances the electric field at the positive rod and decreases the switching impulse strength. When a negative polarity is applied to a rod-plane gap, the positive electrode is the ground plane, which has a much lower electric field. In most gap arrangements, the electric field at the energized electrode is greater than the electric field at the grounded electrode. In these cases the positive polarity switching surge strength is lower than the negative polarity strength. In some exceptional cases, however, the opposite may occur, such as, for instance, for the gap between a large bundle conductor and a tall pointed object at ground potential (conductor-rod).

The proximity effect of ground may be illustrated in another manner, as shown in Figure 5.5-4. The critical 50% flashover voltage of vertical rod-rod gaps is plotted versus the height, $H + L$, above ground of the upper rod. When the height of the rod above ground is small, less than about one-third of the total gap ($H/L \leq 0.5$), the rod has little effect on the positive polarity strength. In this case, flashovers, which start from the positive rod, may reach the ground plane, rather than the grounded rod.

5.5.3 Horizontal Rod-Rod

The critical 50% flashover voltage of horizontal rod-rod gaps is shown in Figure 5.5-5. The strength is practically independent of the height above ground, provided the height is greater than twice the gap length (Kachler et al. 1971).

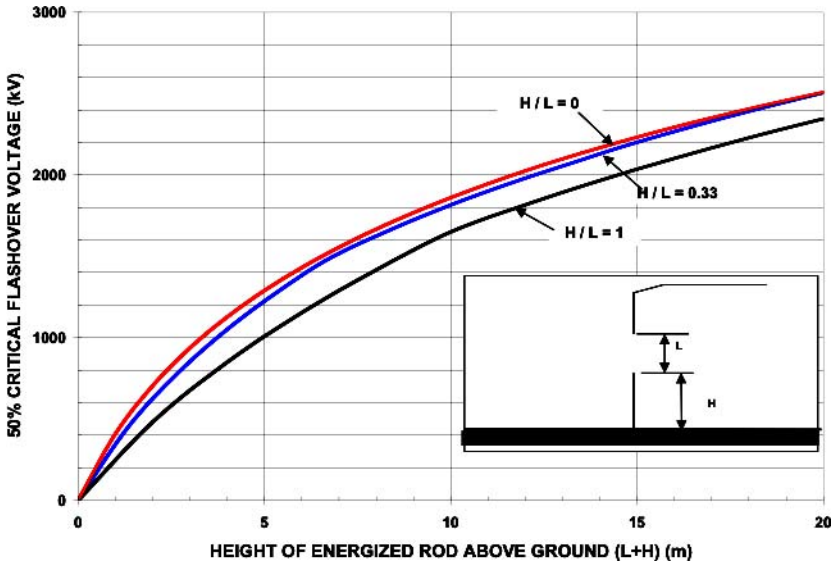

Figure 5.5-4 Critical 50% flashover voltage (positive polarity) of vertical rod-rod gaps versus height of the energized rod above ground.

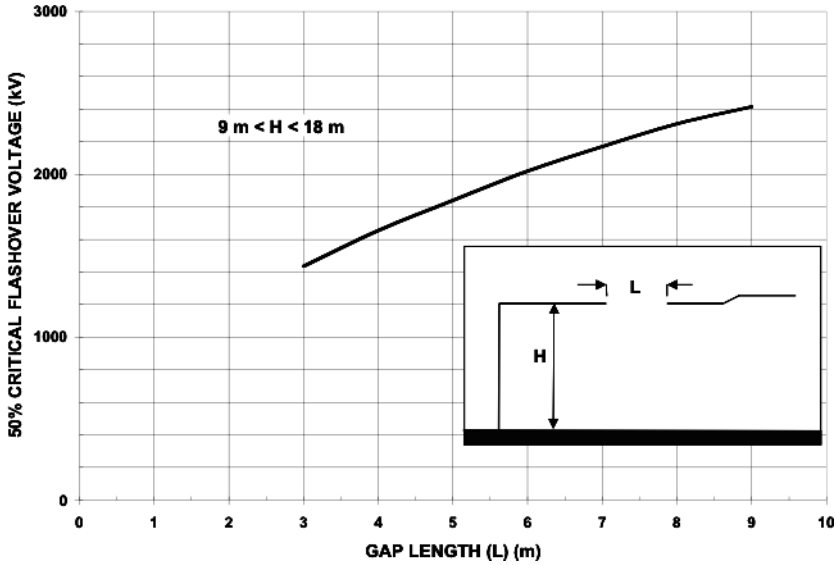

Figure 5.5-5 Critical 50% flashover voltage of horizontal rod-rod gaps versus gap length.

The horizontal rod-rod also shows a significant polarity effect, even for small gap lengths. For instance, for a height above ground of 9 m, the negative 50% flashover voltage of a 4.6 m gap was found to be 1.52 times greater than the positive, and that of a 0.9 m gap was found to be 1.28 times greater than the positive.

If the grounded electrode is a tower structure instead of a rod, the critical 50% flashover voltage may be significantly lower, by 20% or more, depending on the massiveness of the structure.

5.5.4 Sphere-Plane

The 50% flashover voltage for a 0.5-m diameter sphere-plane gap under dry conditions is shown in Figure 5.5-6 as a function of time-to-crest, for gap lengths from 1 to 5 m. For the 1-m gap, there is no dependence of the 50% flashover voltage on time-to-crest. As the gap length is increased, a more or less gradual transition occurs to U-curves. The 50% flashover voltage of sphere-plane gaps is greater or equal to that of rod-plane gaps, the difference between the two types of gap depending on the diameter of the sphere. For spheres of 0.5-m diameter, the sphere-to-plane 50% flashover voltage is twice that of the rod-plane for a 1-m gap, is about 10% greater for a 3-m gap, and is about the same for a 5-m gap.

The 50% flashover voltage for a 1-m diameter sphere-plane gap under dry conditions is shown in Figure 5.5-7 as a function of the time-to-crest. For this larger diameter sphere, the dependence of time-to-crest is not apparent up to 10-m gap lengths. The strength is always much greater than that of a rod-plane with the same gap spacing.

The critical 50% flashover voltages for rod-plane and different diameter sphere-plane gaps are compared in Figure 5.5-8. For each gap there is a critical sphere diameter, below which the sphere-plane gap has the same switching impulse strength as the rod-plane. This result has also been confirmed by physical considerations made during the study of the switching impulse flashover mechanism (Carrara and Thione 1976; Rizk 1989b). As the sphere diameter becomes larger than the critical, the U-curve that characterizes the dependence of the 50% flashover voltage on time-to-crest becomes flatter.

The data presented in Figures 5.5-6 to 5.5-8 refer to spheres with a smooth surface. Such spheres are only of theoretical interest. Practical spherical electrodes may be obtained as the envelope of many small diameter tubes. A sphere of this type with a diameter of 2.5 m has about the same strength as a smooth-surface sphere with half the diameter.

While the 50% flashover voltage of large electrodes is not much dependent on the time-to-crest when the electrodes are dry, it exhibits a significant U-curve when the electrodes are wet. For critical waveshape, rain reduces the switching impulse strength of large sphere-to-plane gaps to that of a rod-plane gap (Rizk 1976).

5.6 SWITCHING IMPULSE STRENGTH OF LINE INSULATION

5.6.1 Tower Window

The gap between conductor and tower is of great importance for tower design. The tower window, in which the tower structure completely surrounds the conductor, is generally the weakest and most important line insulation element.

Test Results

The critical 50% flashover voltage for tower window gaps is presented in Figure 5.6-1, which was derived from the work of many investigators (Rohlfs et al. 1963; Kalb 1963;

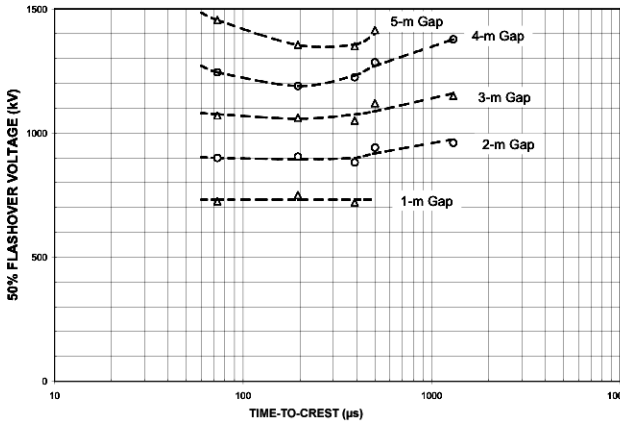

Figure 5.5-6 50% flashover voltage versus time-to-crest for 0.5-m diameter sphere-plane gaps in dry conditions.

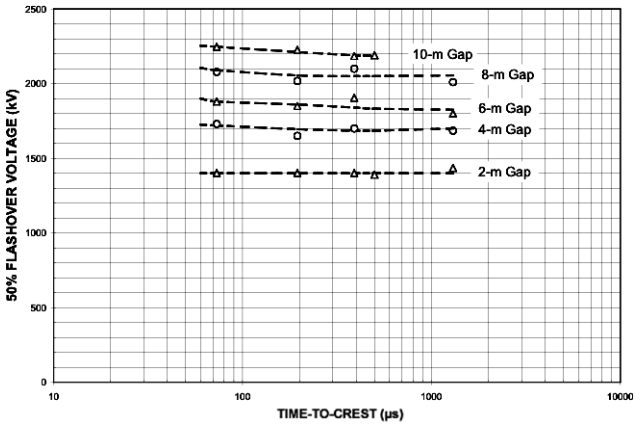

Figure 5.5-7 50% flashover voltage versus time-to-crest for 1-m diameter sphere-plane gaps in dry conditions.

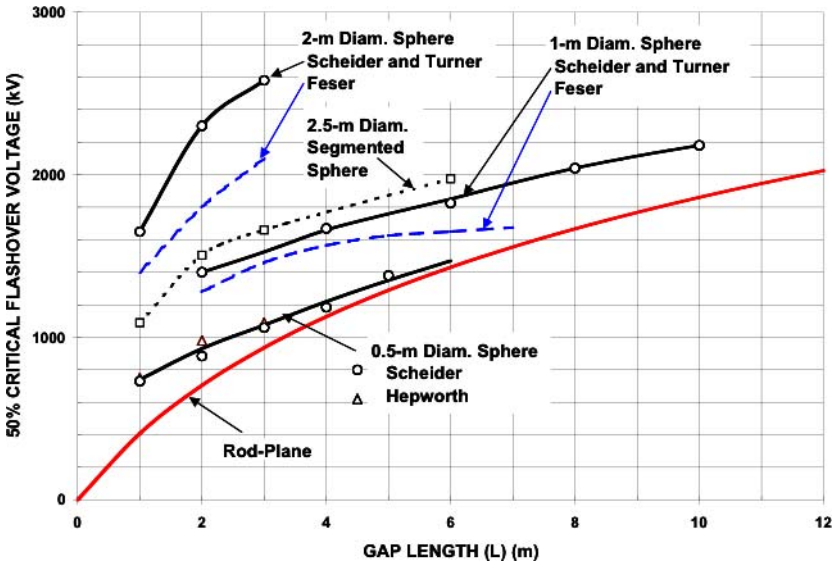

Figure 5.5-8 50% flashover voltage versus gap length for sphere-plane gaps for different sphere diameters. (Feser 1971; Hepworth et al. 1972; Schneider and Turner 1975).

Johnson et al. 1963; Rawls et al. 1964; Atwood et al. 1965; Aubin et al. 1966; Guyker et al. 1966; Armstrong and Miller 1967; Paris 1967; Saruyama et al. 1967; Hauspurg et al. 1969; Kachler et al. 1970; Dillard and Hileman 1970; Annerstrand et al. 1971; Kachler et al. 1971b; Carrara and Zaffanella 1972; Menemenlis and Harbec 1974; Pokorny and Flugum 1975; Young et al. 1980; Lloyd and Zaffanella 1981; Cortina et al. 1985; Yasui and Muruoke 1988; Kim et al. 2000).

Because test conditions (tower shape, tower width, height above ground, time-to-crest, and atmospheric conditions) were not identical, the results are quite scattered. The continuous curve of Figure 5.6-1 represents the best estimate of the results for a square window, tower width equal to 1.2 m, height of conductor above ground greater than twice the gap spacing, critical time-to-crest, relative air density = 1, and absolute humidity equal to 11 g/m^3. The test data were obtained with V-insulators with an insulator length as large as possible, so that the insulators would not affect the positive polarity switching impulse strength, in both dry and wet conditions. For comparison, Figure 5.6-1 reports the critical 50% flashover voltage curves of rod-plane (CRIEPI formula) and horizontal rod-rod gaps. The switching impulse strength of a tower window is intermediate to that of a rod-plane and a horizontal rod-rod with the same gap length.

The critical 50% flashover voltage of tower windows expressed by the continuous curve of Figure 5.6-1 may be expressed in terms of the critical 50% flashover voltage of rod-plane gaps through the gap factor, defined in Section 5.2.4. Tower windows gaps have a gap factor of approximately 1.2. The equation that fits the curve is:

$$V_{50,crit} = 1.2 \cdot \left[1080 \cdot \ln(0.46 \cdot L + 1)\right] \qquad 5.6\text{-}1$$

The height above ground of the conductor has little effect on the switching impulse strength of practical tower window gaps. In general, the critical 50% flashover voltage is minimally influenced by the conductor height above ground when the gap length is less than one-half the height.

Effect of Grading Rings

The gap spacing of a tower window gap is the minimum distance between the conductor and the tower. When there are grading rings, the continuous curve of Figure 5.6-1 still

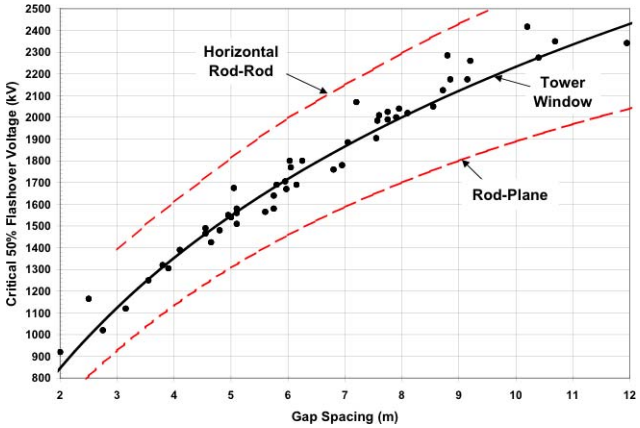

Figure 5.6-1 Critical 50% flashover voltage of tower windows. Continuous curve for square windows, tower width = 1.2 m, standard atmospheric conditions.

applies, provided that the gap length is taken as the minimum distance between the rings and the tower (Kachler et al. 1971b).

Effect of Length of V-Insulators

The effect of the length of the V-insulators, between the suspension hardware at the conductor and the hangers connected to the tower is shown in Figure 5.6-2 (Kachler et al. 1970). The data in this figure show that the critical 50% flashover voltage is reduced when the gap length across the insulators becomes less than the gap length conductor-to-tower. The insulator length is generally considerably greater than the gap length and, therefore, the presence of V-insulators does not affect the switching impulse strength.

Effect of Atmospheric Conditions

The effects of relative air density and absolute humidity are discussed in Section 5.11.

Rain does not affect the switching impulse strength of tower windows, except when the insulator length becomes comparable to, or less than, the gap length. In this case, rain and other wet weather conditions, such as fog, drizzle, wet snow, and high humidity, may, depending on the type of insulators, further reduce the switching impulse strength (see Section 5.12).

Effect of Time-to-Crest

The critical time-to-crest is a function of gap length and humidity, as for rod-plane gaps with the same gap length. The shape of the U-curve may be derived from the discussion in Section 5.10.

Standard Deviation

The standard deviation of the flashover probability function is discussed in Section 5.9.

Effect of Window Shape

The tower window shape may depart considerably from that of a square window, and its strength may be very difficult to predict. Some guidance may be obtained from test results on similar geometry or by exercising Rizk's flashover model (see Appendix 5.2 and Applet S-1). Whenever the geometry departs significantly from a simple known configuration, reliable strength data can be obtained only by performing switching impulse tests on full-scale models in an outdoor high-voltage laboratory.

The tower window results expressed by the continuous curve of Figure 5.6-1 and by Equation 5.6-1 apply to a square window, where the gaps to the top and bottom truss and to the tower legs have the same length. Tests on rectangular windows of various sizes and tower width equal to 1.2 m have shown that a variation, ΔX, in the distance to the top truss is equivalent to a variation equal to $0.6 \cdot \Delta X$ in the length of all the four gaps of a square window (Annerstrand et al. 1971). From this simple rule, it is possible to derive the correction factor to apply to the critical 50% flashover voltage of a square window in order to obtain that of a rectangular window. The correction factor is shown in Figure 5.6-3. For example, consider a rectangular window with a conductor-to-top truss gap length $X = 7$ m and conductor-to-tower leg gaps $Y = 8$ m. The 50% flashover voltage of this window is the same as that of a square window with a gap length equal to $8 - 0.6 \cdot (8 - 7) = 7.4$ m, which is equal to 1961 kV (from Equation 5.6-1). The same result is obtained from Figure 5.6-3. The correction factor for $X = 7$ m and $Y/X = 8/7 = 1.14$ is 1.03. This factor is to be applied to the critical 50% flashover voltage of a square window with a gap length $X = 7$ m, which is 1904 kV. Therefore, the critical 50% flashover voltage of the rectangular window is $1904 \cdot 1.03 = 1961$.

Effect of Conductor Size

Varying the size of the phase conductors, from single-conductor to 4-conductor bundles with a bundle diameter of 65 cm, does not significantly affect the flashover strength if the same gap length is maintained between the conductor and the tower. As the bundle diameter is increased further,

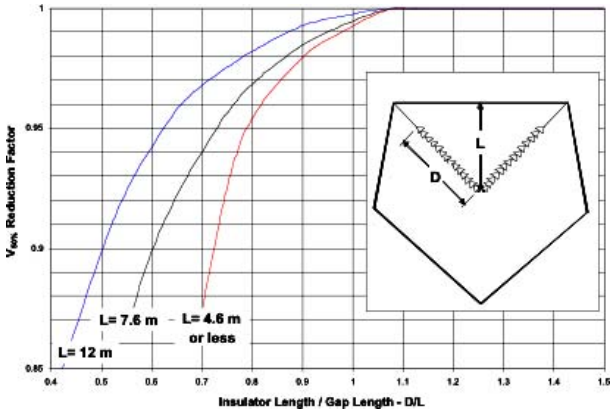

Figure 5.6-2 Effect of V-insulator length on the switching impulse strength of tower windows.

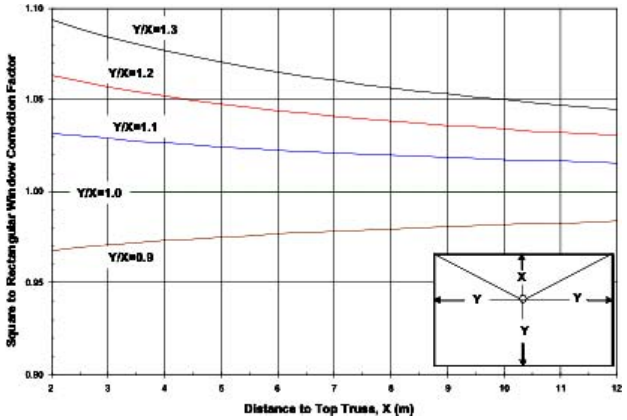

Figure 5.6-3 Voltage correction factor for rectangular window.

the strength may increase for the same gap length but remains practically constant or decreases for the same distance between the center of the bundle and the tower (Lloyd and Zaffanella 1981).

Effect of Entrance Angle

The entrance angle of the conductor to the tower face plays a role in determining the flashover path, but has only a slight effect on the critical 50% flashover voltage, as shown in the example of Figure 5.6-4 (Annerstrand et al. 1971). For instance, for an entrance angle of -7˚, the flashover voltage is only 1% lower than the maximum value, which occurs for an angle of +1.5˚. The data of Figure 5.6-4 were obtained for a tower window gap of 4.6 m; they can be tentatively applied to other gap lengths and also to outside phase gaps.

5.6.2 Outside Phase

The switching impulse strength of outside phase tower gaps with V-insulators is generally stronger than that of tower windows with the same gap length. The increase in strength depends on the geometry, particularly the dimensions of the tower arm and of the tower body and the horizontal distance to the tower body. If the outside phase conductor has the same distance to the tower arm and to the tower body, and if the tower arm and body have the same width of those of a square window, the outside phase strength is about 6% greater than that of the tower window for gap lengths less than 5 m. For gap lengths of 7 m or more, the outside phase strength is only slightly (2~3%) greater than that of the tower window.

As for the tower window, the outside phase is a complex geometry that is very difficult to predict. Some guidance may be obtained from test results on similar geometry or by exercising Rizk's flashover model (see Appendix 5.2 and Applet S-1). Whenever the geometry departs significantly from a simple known configuration, reliable strength data can be obtained only by performing switching impulse tests on full-scale models in an outdoor high-voltage laboratory.

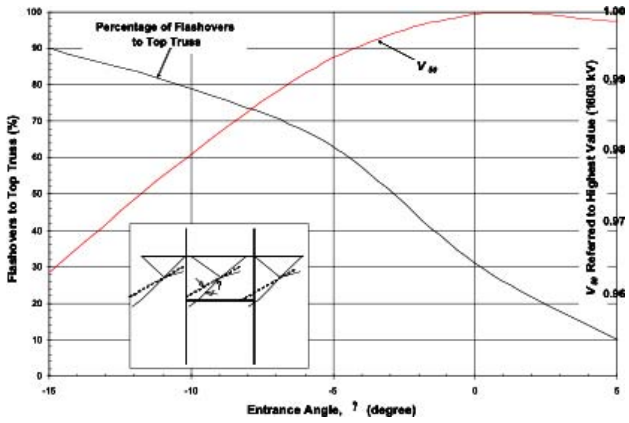

Figure 5.6-4 Percentage of flashovers to top truss and 50% flashover voltage versus entrance angle of the conductor at the tower. Data for 4.6-m tower window gap, 350-μs time-to-crest. The voltage is referred to the highest value (1603 kV).

5.6.3 Insulator Strings

Insulators affect the switching impulse strength of air gaps differently, depending on the type of gap. For positive polarity, the strength in fair weather is the same as the strength of the gap without insulators, provided the insulators are not placed directly along the possible flashover path. For instance, V-insulators in a tower window where flashovers occur from conductor to upper truss do not affect the tower window strength.

The positive dry switching impulse strength is reduced by up to 5% when the insulators are placed along the shortest gap distance, such as vertical insulators in a tower window or in an outside phase, or horizontal insulators in a dead-end structure.

Foul weather does not affect the positive polarity strength of gaps with insulators when the insulators are not placed directly along the possible flashover path. If the insulators are placed along the possible flashover path, the switching impulse strength may be significantly reduced in wet weather conditions (rain, fog, drizzle, and high humidity). The reduction depends on the type of insulators and on the degree of contamination. In clean areas, a 5% reduction over fair weather data should be considered. In areas with very light or light contamination, the suggested reduction is 10-20% (EPRI 1982). In these areas, however, the choice of the types of insulators may be determined by consideration of power frequency strength (see Chapter 4), and antifog or other special types of insulators may be considered. For these insulators, the reduction in positive-polarity strength caused by wet weather may be assumed equal to 5%, even for light degrees of contamination.

For negative polarity, the strength in fair weather is usually much higher than the positive-polarity strength. Some exceptions occur for insulators placed between a large energized electrode and a small, grounded element, such as the insulators shown on the right side of Figure 5.6-5. For these configurations, the negative polarity switching impulse strength may be equal or lower than the positive polarity strength. The negative polarity strength is generally significantly reduced by foul weather. Of concern are the situations where the negative polarity wet switching impulse strength becomes lower than the positive polarity strength. This is the case for the two arrangements on the right side of Figure 5.6-5. The data of Figure 5.6-5 are for clean insulators. For very light or light contamination, a

10-20% reduction is suggested. In these cases, and if the switching impulse strength becomes a limiting factor in line design, the use of antifog or other special types of insulators is recommended.

5.6.4 Conductor-to-Tower Leg

The 50% flashover voltage for the horizontal air gap between a conductor and a tower leg is shown in Figure 5.6-6 for a tower width of 1.2 m and a time-to-crest of 350 μs (Kachler et al. 1971a). Empirical rules were given to obtain the 50% flashover voltage for different values of the tower width (EPRI 1982). These rules, however, are quite cumbersome and unreliable. The conductor-to-tower leg strength may be very difficult to predict for complicated geometry. Some guidance may be obtained by exercising Rizk's flashover model (see Appendix 5.2 and Applet S-1). Whenever the geometry departs significantly from a simple known configuration, reliable strength data can be obtained only by performing switching impulse tests on full-scale models in an outdoor high-voltage laboratory.

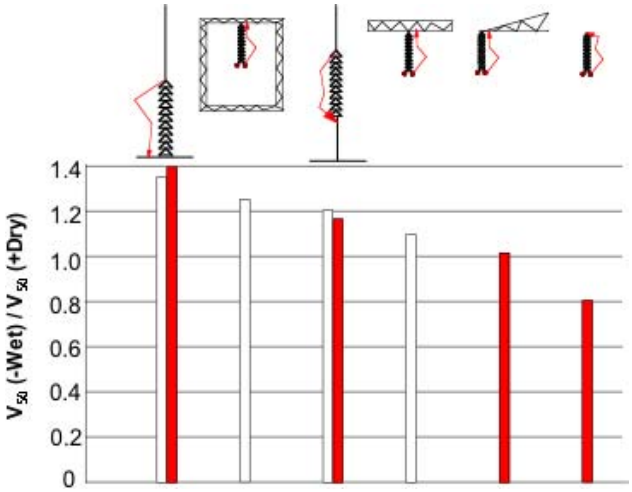

Figure 5.6-5 Ratio V_{50} (negative wet) to V_{50} (positive dry) for vertical insulator strings in different gaps.

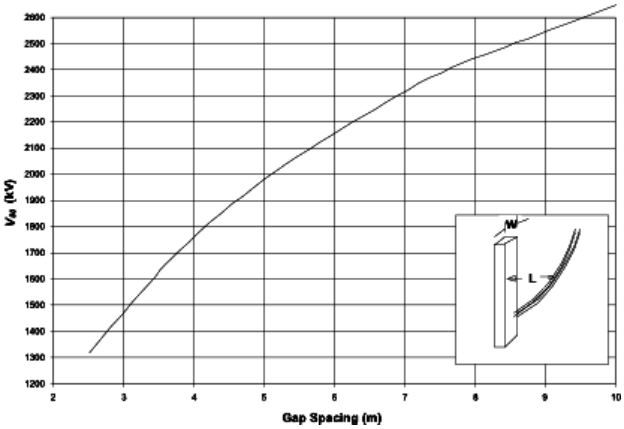

Figure 5.6-6 Switching impulse strength of conductor-to-tower gaps.

5.6.5 Conductor-to-Grounded Objects at Midspan

Minimum clearances of transmission-line conductors to ground are recommended by national standards, such as the National Electrical Safety Code in the U.S., which are based on, among other factors, the requirement that the gap between conductor and grounded objects should withstand switching surges with a high degree of reliability. Figure 5.6-7 shows the 50% flashover voltage of the gap between the conductor and the ground plane. These results were obtained with gap lengths up to 15 m and times-to-crest of 350 μs (Kachler et al. 1971a). Tests on an 11-m conductor to ground gap using one span of a test line and times-to-crest greater than 1000 μs have shown about the same results as the data obtained with 350 μs (Lloyd and Zaffanella 1981). The effect of time-to-crest on conductor-to-ground gaps, in fact, has been found much smaller than for rod-plane gaps (Gallet et al. 1976).

Figure 5.6-7 shows also the 50% flashover voltage of the gap between a conductor and a grounded structure (2.4-m wide and 15.3-m long) simulating a vehicle underneath the line (Lloyd and Zaffanella 1981).

A protrusion from the conductors, such as a broken spacer, reduces the flashover voltage only slightly, and the strength of the gap remains much higher than that of a rod-plane gap with the same length (Kachler et al. 1971a).

5.6.6 Anomalous Flashovers

During switching impulse tests with positive polarity, several investigators have noted anomalous flashovers, so called because they occurred over distances considerably longer than the gap under test. These flashovers are really not anomalous at all (Shindo and Suzuki 1995). They are caused by the breakdown characteristics of long gaps that resemble the rod-plane configuration. These flashovers occur more frequently when impulses with long times-to-

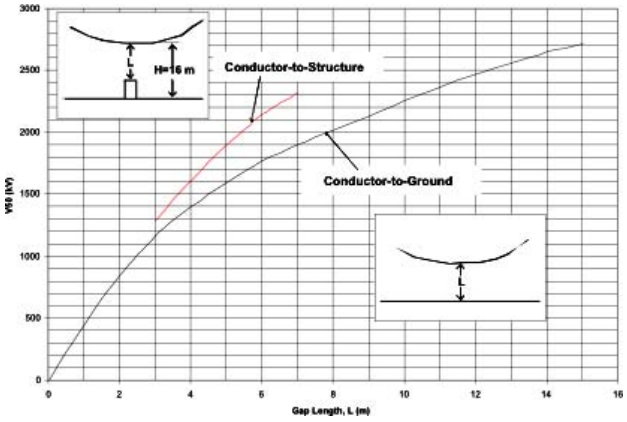

Figure 5.6-7 Switching impulse strength of conductor-to-ground and conductor-to-structure gaps.

crest are applied, because these correspond to the critical waveform for very long gaps (Lloyd and Zaffanella 1981). Because of the existence of this type of flashover, rod-plane data (Equation 5.5-1 plus some safety margin) should be used to determine the clearances between any energized part of a line (or a laboratory circuit) and grounded structures near locations where absolutely no flashover should occur.

5.7 SWITCHING IMPULSE STRENGTH OF STATION INSULATION

5.7.1 Introduction

Insulation elements of many different shapes may be encountered in a substation. Their treatment would exceed the scope of this book, which is about transmission lines. Some insulation elements such as horizontal insulator strings and station posts are encountered in a substation at the entrance of overhead lines and may be considered to also belong to the line. The switching impulse strength data for these elements are given in this section. Station posts have received the greatest attention (Killian and Moran 1964; Hertig and Kelly 1966; Moran and Alton 1968; Moran 1969; Hileman and Askins 1973; Boyd et al. 1974). For a discussion focused on station insulation, the reader may consult other work on the subject (Udo 1966; Menemenlis et al. 1981; Menemenlis et al. 1989).

5.7.2 Horizontal Insulator Strings

An important insulation element common in substations and also found at transmission strain towers is the horizontal gap containing insulator strings between the end of a conductor and the supporting tower face. Horizontal gaps in substations are generally weaker than those at transmission-line strain towers, because they may not have jumper loops, and they are generally closer to ground and to grounded structures.

The 50% flashover voltage of horizontal insulator strings is shown in Figure 5.7-1 (Boyd et al. 1974; Lloyd and Zaffanella 1981). The inset of this figure illustrates the gap geometry.

The results show the significant influence of the shield dimensions. Without a shield, the configuration approaches a rod-plane gap. The presence of large shields causes an increase in strength that is particularly large at shorter gaps. This is an effect similar to that of spheres (see Section 5.5). The effect of shields becomes smaller for larger gaps.

The 50% flashover voltage decreases as the dimensions of the grounded structure increase: the difference between a small truss (1.2 m) and a large truss (3.35 m) is of the order of 4%.

The insulators in the gap have a minor influence on the switching impulse strength, provided they cover more than two-thirds of the gap. Even with half of the gap short-circuited by a metallic connection, the 50% flashover voltage is reduced by only 10%.

5.7.3 Station Post Insulators

The positive polarity switching impulse strength of post insulators is shown in Figure 5.7-2, which summarizes results from several sources (Killian and Moran 1964; Hertig and Kelly 1966; Moran and Alton 1968; Moran 1969; Hileman and Askins 1973; Boyd et al. 1974). The data are for gap length (L) from 4.6 to 12.2 m.

The data shown in the figure are for a platform width of 1.21 m. Increasing the size, W, of the support structure to 3.7 m decreases the strength by 6% for a platform height, B, equal to the gap length, L. Decreasing W to essentially zero increases the strength by about 10% for B/L = 0.8 (Hileman and Askins 1973). Equation 5.7-1 is an empirical formula that provides correction factors (multipliers) to the V_{50} values of the curve for B/L = 1, which are valid for $0 \le W \le 3.7$ m (EPRI 1982).

$$Post\ \ Factor = 0.88 + 0.28 \cdot \frac{B}{L(W+1)} \qquad 5.7\text{-}1$$

For example, if B/L= 0.5, W = 1.22 m, and L = 7.5 m, the *Post Factor* from Equation 5.7-1 would be equal to 0.94. The V_{50} value from the curve for B/L = 1 in Figure 5.7-2 is 2275 kV. Therefore the corrected V_{50} is 2275 × 0.94 = 2139 kV.

The values reported in Figure 5.7-2 are for positive polarity switching impulses and fair-weather conditions. The values of V_{50} for positive polarity and wet weather are essentially

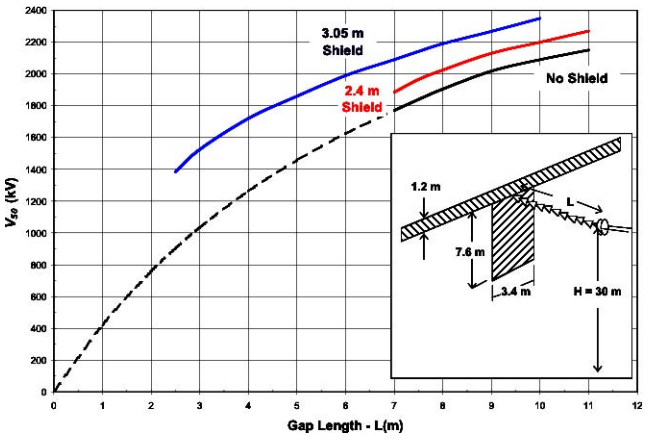

Figure 5.7-1 50% flashover voltage for horizontal insulator strings. Time-to-crest: 350 μs for no shield and 2.4-m shield, 1000 μs for 3.05-m shield.

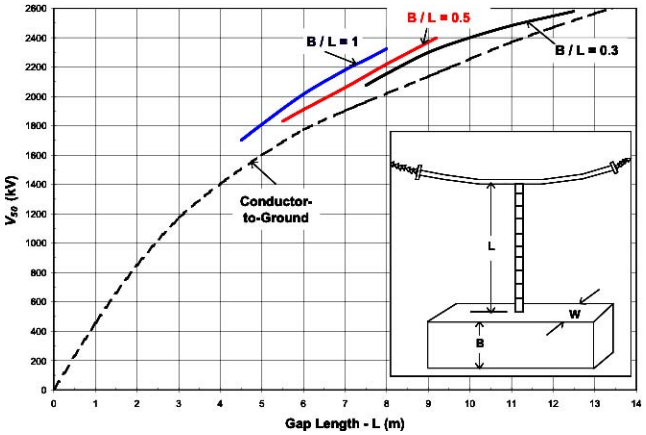

Figure 5.7-2 50% flashover voltage for post insulators for constant ratios between base height and gap length. Time-to-crest: 350 μs.

the same as those for fair weather (Boyd et al. 1974). For negative polarity, in both fair and wet weather, V_{50} is higher than for positive polarity.

5.8 PHASE-TO-PHASE SWITCHING SURGE STRENGTH

5.8.1 Introduction

A switching operation applies a stress not only to the insulation between each phase and ground or objects at ground potential, but also to the insulation between phases. The stress applied between two phases is more complex than that between one phase and ground because of the varying proportions of surges that may appear on the individual phases. For example, a positive-polarity switching surge of 2.0 per unit (i.e., twice the line-to-ground reference crest voltage) may appear on one phase simultaneously with a negative-polarity switching surge of 1.0 per unit on the adjacent phase. The phase-to-phase surge is referred to the same reference voltage as the phase-to-ground surges. The reference voltage is the peak power frequency phase-to-ground voltage immediately prior to a switching operation or to a switching cycle. In the previous example, if the two crests occur simultaneously, the amplitude of the surge between phases would be 3.0 per unit.

The strength of phase-to-phase insulation is a function not only of the surge between phases, but also of the relative proportion between the two phase-to-ground surges. In fact, the phase-to-phase insulation must be considered a system of two independently energized electrodes (the two phases) and objects at ground potential (including the ground). Actually a more accurate representation of a three-phase system should include also the third phase. For practical design purposes only two phase-to-phase insulation systems may be considered even when the system is actually three-phase. For example, the system of Figure 5.8-1 may be considered as the combination of three phase-to-ground insulations (A-G, B-G, and C-G) and two phase-to-phase insulations (A-B and B-C). The phase-to-phase insulation between electrodes A and C is not considered. It is generally assumed that the strength of the insulation between electrodes A and B does not depend on the voltage on electrode C. This is acceptable because the design of the insulation between A and B is based on the largest phase-to-phase surges occurring between A and B, V_{AB}. The voltage on C at the moment of the largest V_{AB} is generally sufficiently low to have no effect. However, this simplification is not possible for insulation systems such as that shown in Figure 5.8-2, which may be the case for some compact lines. Very little research of this case has been done.

An example of switching surges between phases is shown in Figure 5.8-3. The voltage between phases A and B, v_{AB}, is the difference between the voltage between phase A and ground, v_A, and the voltage between phase B and ground,

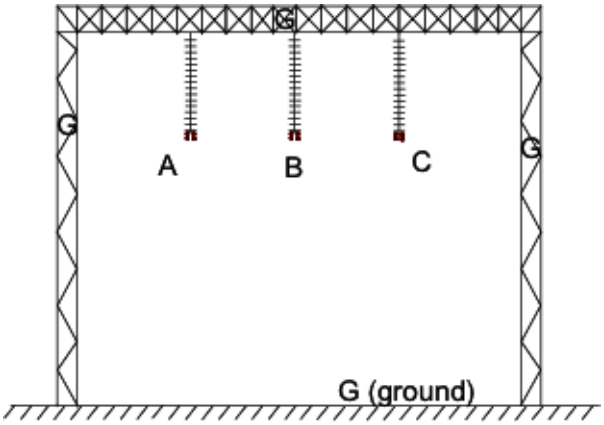

Figure 5.8-1 System of three phase-to-ground insulations (A-G, B-G, and C-G) and two phase-to-phase insulations (A-B and B-C).

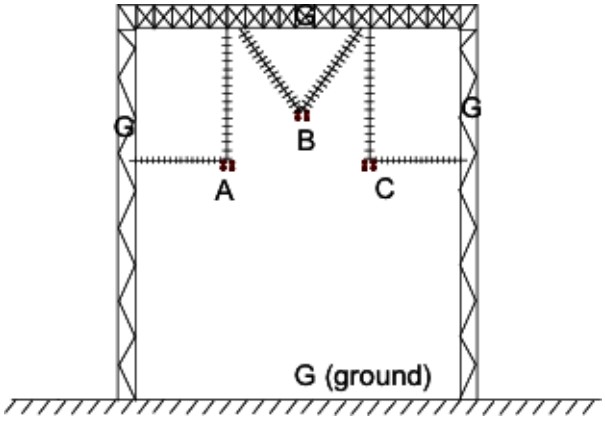

Figure 5.8-2 System of three phase-to-ground insulations (A-G, B-G, and C-G) and a complex phase-to-phase insulation system (A-B-C).

v_B. In Figure 5.8-3, at the instant of maximum phase-to-phase voltage, V_{AB}, the voltage of phase A is positive and that of phase B is negative. The parameters characterizing the phase-to-phase surge are: the crest voltages, V_A and V_B, of the phase-to-ground surges, the crest voltage, V_{AB}, of the phase-to-phase surge, the voltages to ground, V^+ and V^-, of the two phases at the instant of the maximum phase-to-phase voltage (V_{AB}), the voltage, v^-, on the negative phase at the instant of the maximum positive surge (V_A), the interval, ΔT, between the negative and the positive crests, and the equivalent times-to-crest of the surges, $t_{cr,eq.,A}$, $t_{cr,eq.,B}$, and $t_{cr,eq.,AB}$, which are characterized by the times above 70%, $t_{0.7,A}$, $t_{0.7,B}$, and $t_{0.7,AB}$ ($t_{0.7} = 0.69\ t_{cr,eq.}$, see Section 5.2).

Several experimental investigations were performed to determine the effect of each of the parameters described in Figure 5.8-3. The first phase-to-phase switching impulse tests were performed applying positive and negative polarity switching impulses having the same waveshape and simultaneous crests (i.e., $\Delta T = 0$) and varying the ratio between positive and negative crests, $\alpha = V^- / V_{AB}$ (Udo 1966a; Zaffanella et al. 1966). Two impulse generators were used for these tests. Previous testing of phase-to-phase insulation was performed with one phase energized and the other grounded ($\alpha = 0$) (Hertig and Kelly 1966).

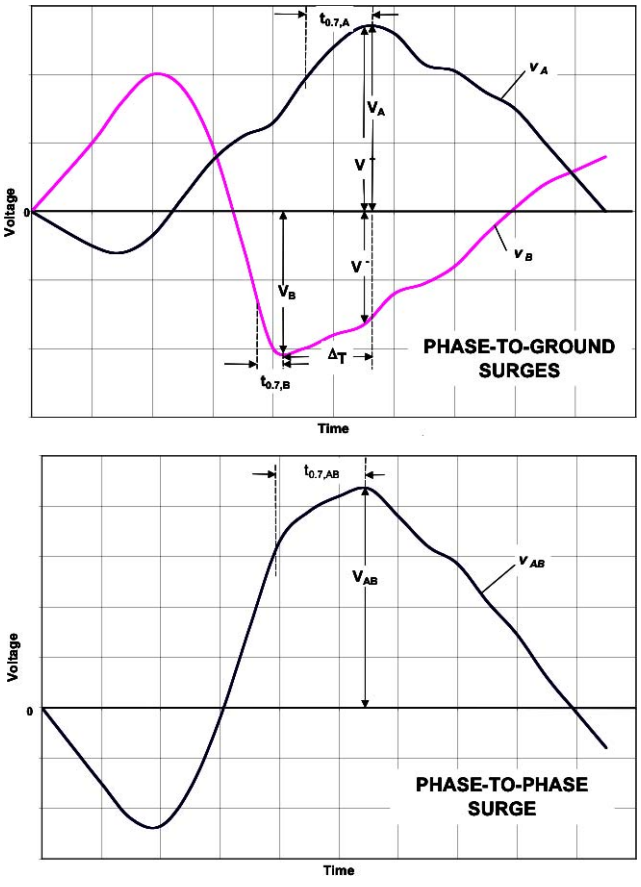

Figure 5.8-3 Example of a phase-to-phase surge.

The shape of the negative surge, which can be characterized by the time above 70%, $t_{0.7,B}$, was found to have little effect on the strength. For this reason, it is possible to test phase-to-phase insulation using an ordinary impulse generator for the positive electrode and a test transformer generating a power frequency voltage for the negative electrode (Dellera and Zaffanella, 1967), or using long-fronted transformer-generated impulses of negative polarity (Boyd et al. 1974; CIGRE 1973a).

The shape of the positive surge has a significant effect on phase-to-phase strength. Phase-to-phase tests have shown a dependence on the time-to-crest of the positive impulses characterized by u-curves that are similar to, but with a much less clearly defined minimum, those found for phase-to-ground insulation (CIGRE 1973a). Minimum phase-to-phase flashover voltages occur for times-to-crest of 50~60 μs for a 2-m rod-rod gap and 250~300 μs for a 10-m rod-rod gap. These times-to-crest are shorter than those for phase-to-ground insulation with the same gap length. Times-to-crest of 1000 μs or greater correspond to 10 to 15% greater strength. For conductor-to-conductor gaps, the effect of time-to-crest is even less pronounced.

The time interval, ΔT, between the negative and the positive surge crests has little effect on the phase-to-phase strength, if the stress is characterized by the maximum phase-to-phase voltage, V_{AB}, and by the positive and negative voltages, V^+ and V^-, of the two phases at the instant of the maximum phase-to-phase voltage (Boyd et al. 1974). On the other hand, if the stress is characterized by the sum, $V_A + V_B$, of the absolute values of the two crest values of the phase-to-ground surges, the influence of ΔT becomes significant. The minimum strength is reached for $\Delta T = 0$, in which case V_{AB} coincides with $V_A + V_B$ (CIGRE 1973a). The highest phase-to-phase voltage stresses recorded during system studies occur when the positive and negative peaks are synchronized (Cortina et al. 1970). The effect of ΔT, therefore, has mainly a theoretical value (Menemenlis et al. 1976; Koszaluk et al. 1981).

When switching surges between phases are being recorded using either a TNA or digital methods, only the highest peak value of a surge between phases is considered. Subsequent peaks occurring during the same switching event, even if they have about the same magnitude, do not constitute a greater stress and are not taken into account (CIGRE 1979b).

When both phase-to-ground surges are positive, or both are negative, the phase-to-phase voltages do not achieve sufficiently high values to be of concern.

The preceding observations justify the use of considerable simplifications in reproducing the switching surge stress between phases using switching impulses in the laboratory. The surge described in Figure 5.8-3 can be reproduced with the impulses shown in Figure 5.8-4. The strength is a function of the crest value of the phase-to-phase voltage $V_{p\text{-}p} = V^+ + V^-$, of the ratio $\alpha = V^-/ V_{p\text{-}p}$, and of the time-to-crest of the positive waveform. The results of laboratory tests on phase-to-phase insulation systems will be described in terms of these parameters.

5.8.2 Phase-to-Phase Strength for a Horizontal Rod-Rod

The horizontal rod-rod configuration is the geometry most tested to study the strength of phase-to-phase insulation (Udo 1966; Zaffanella et al. 1966; Dellera and Zaffanella 1967; Sforzini and Taschini 1970; CIGRE 1973a; Gallet et al. 1978). The rod-rod configuration has the advantage of being symmetric with respect to polarity; the results do not change by changing the positive with the negative electrode. A horizontal rod-rod is characterized by two geometrical parameters: the gap length and the height above ground. The data from the technical literature are summarized in Figures 5.8-5, 5.8-6, and 5.8-7.

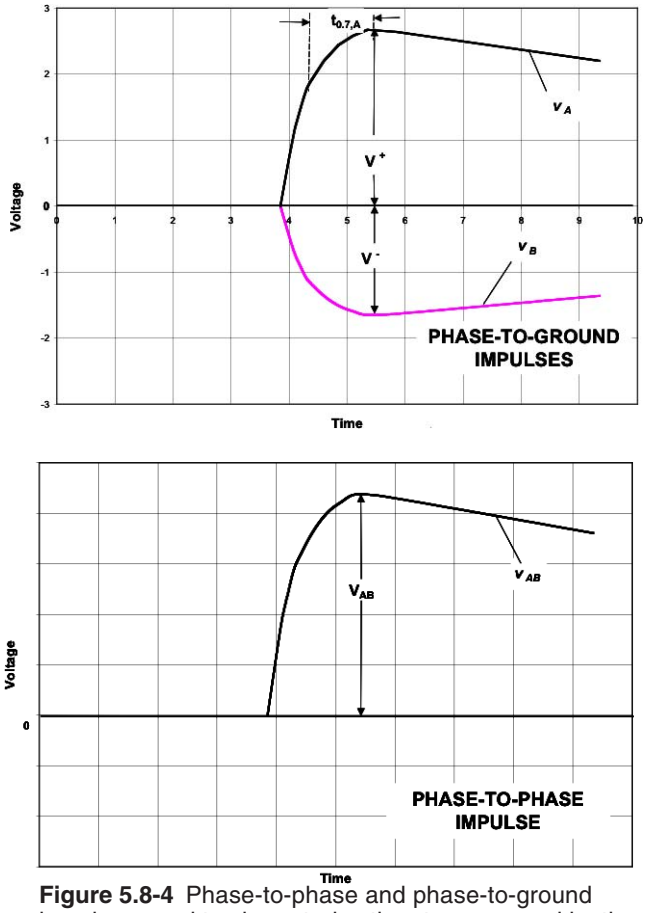

Figure 5.8-4 Phase-to-phase and phase-to-ground impulses used to characterize the stress caused by the switching surge described in Figure 5.8-3.

Figure 5.8-5 shows how the critical 50% flashover voltage varies with the parameter α. The lowest phase-to-phase flashover voltage is obtained when a positive voltage is applied to an electrode and the other is grounded. The highest flashover voltage is obtained when a negative voltage is applied to an electrode with the other grounded. The slope of the curves of Figure 5.8-5 depends on the height above ground. Ideally, for an infinitely large height, the strength of the gap is a function of the total voltage only and not of its components to ground, and the slope of the curves becomes zero.

Figure 5.8-6 shows the effect of the time-to-crest of the positive impulse.

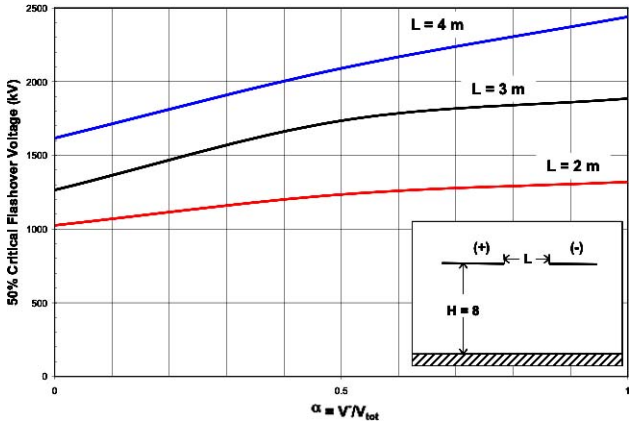

Figure 5.8-5 Phase-to-phase 50% critical flashover voltage for horizontal rod gaps. Effect of the ratio, α, between voltage applied to negative electrode and total phase-to-phase voltage.

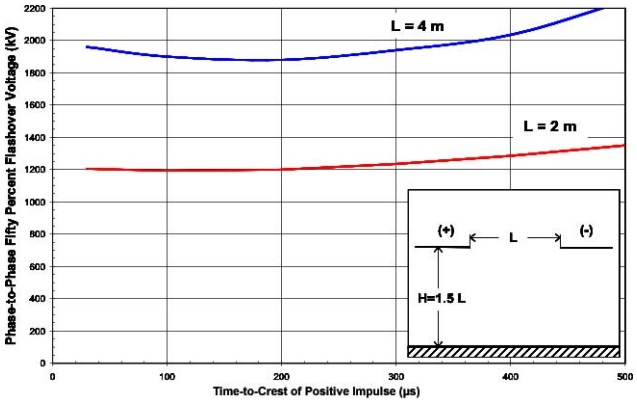

Figure 5.8-6 Effect of time-to-crest of positive impulse on phase-to-phase 50% flashover voltage. α = 0.5.

Figure 5.8-7 shows the effect of the height above ground. The curves of Figure 5.8-7 are for $\alpha = 0$ (positive polarity to a rod with the other grounded), $\alpha = 0.5$ (positive polarity to a rod and negative polarity of equal magnitude to the other), and $\alpha = 1$(negative polarity to a rod with the other grounded). The three curves will converge to the same value for an infinitely large height. For $\alpha = 0.5$, the phase-to-phase strength is only moderately affected by the height above ground.

5.8.3 Phase-to-Phase Strength of the Air Gap Between Conductors

The most important phase-to-phase insulation is the air gap between conductors. The issue is of particular importance for transmission lines because the strength decreases with increasing length of the conductors between which a surge is applied.

The technical literature reports results of tests on short sections of conductors, applicable to station insulation or to individual situations that may be encountered on a transmission line (Hertig and Kelly 1966; Cortina et al. 1970; Boyd et al. 1974; Gallet et al. 1978; CIGRE 1979b; EPRI 1982; Kishizima et al. 1984; Miyake et al. 1987). The data from the technical literature are summarized in Figures 5.8-8 and 5.8-9. The results are qualitatively similar to those obtained for horizontal rod-rod gaps.

The technical literature also reports results of tests on long sections of conductors, usually one or more spans of a test line (CIGRE 1979b; Paulson and Grant 1981; EPRI 1982; EPRI 1983; Vaisman et al. 1993). Equations 5.8-1 and 5.8-2 that give the phase-to-phase 50% flashover voltage were provided by (EPRI 1982) and (Vaisman et al. 1993), respectively. The curves corresponding to these equations are plotted in Figure 5.8-10.

$$\begin{aligned} V_{50} &= 1708 + 532\cdot(\alpha - 0.33) \\ &\quad +40.4\cdot(\alpha - 0.33)^2 \\ &\quad +269\cdot(L-4) - 9.81\cdot(L-4)^2 \\ &\quad +139\cdot(\alpha - 0.33)\cdot(L-4) \end{aligned} \qquad 5.8\text{-}1$$

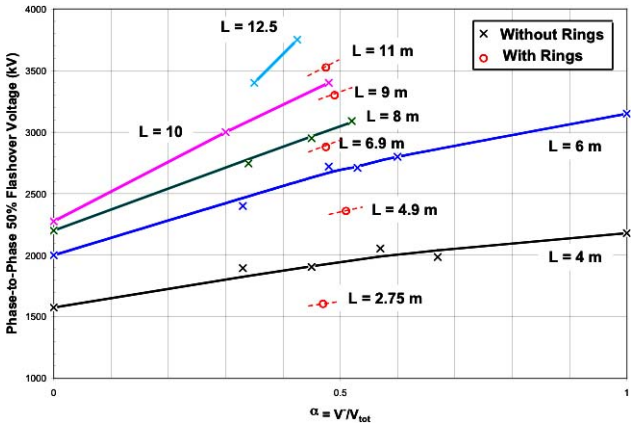

Figure 5.8-8 Phase-to-phase 50% flashover voltage conductor-to-conductor gaps. Conductor length is 12 m. Results for different gap lengths. Effect of the ratio, α, between voltage applied to negative electrode and total phase-to-phase voltage. Results for different phase-to-phase distances. Circles indicate results of tests with 2.1-m diameter toroids simulating corona rings protruding from the conductors.

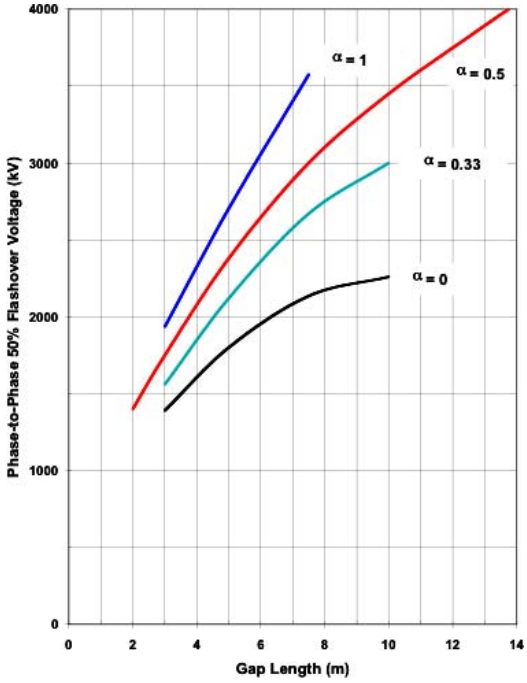

Figure 5.8-9 Phase-to-phase 50% flashover voltage of 12-m conductor sections for different phase-to-ground voltage combinations. Time-to-crest of positive impulse: 350 μs.

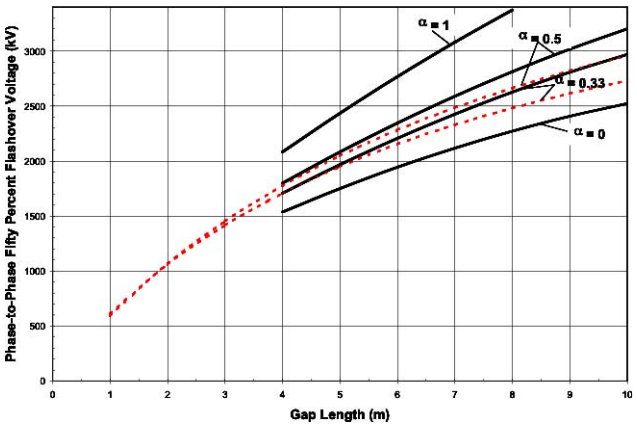

Figure 5.8-10 Conductor-to-conductor 50% flashover voltage versus gap length. Data for a 360-m span and average height above ground of 26 m. Solid curves: Equivalent time-to-crest = 1000 μs, 8-conductor bundles with subconductor diameter = 5.5 cm and bundle diameter = 1.22 m (EPRI 1982). Dashed curves: Time-to-crest = 250 μs, single and 4-conductor bundles with bundle diameter = 0.42 m (Vaisman et al. 1993).

V_{50} is in kV, L is the gap length in meters, and α is the ratio between the negative impulse crest and the phase-to-phase voltage. Data are for standard atmospheric conditions.

$$V_{50} = K_1 \cdot \left(2.17 \cdot (L/H)^{-0.15} \cdot (0.5-\alpha) + 3.24 \cdot \alpha\right) \cdot \frac{3400}{1+8/L} \qquad 5.8\text{-}2$$

V_{50} is in kV, L is the gap length in meters, α is the ratio between the negative impulse crest and the phase-to-phase voltage, H is the average height above ground, and K_1 is a correction factor for conductor length, given in Equation 5.8-3. Data are for standard atmospheric conditions.

$$K_1 = (1 - n \cdot \sigma) \quad ,$$
$$n = 0 \text{ for a conductor length, } S = 75 \text{ m}, \qquad 5.8\text{-}3$$
$$\text{otherwise } n = f(S/75)$$

σ = 0.04 for α = 0 and S= 0.033 for 0.33 ≤ α ≤ 0.5. The function $f(S/75)$ is calculated considering that a span, S, is equivalent to a number, $N_S = S/75$, of 75-m sections energized in parallel. A flashover probability of 50% for the span S corresponds to a flashover probability, p_{75}, of the 75-m section equal to $p_{75} = 1 - 0.5^{1/N_S}$. This probability corresponds to n standard deviations below the 50% value of the 75-m section. Assuming a Gaussian distribution of the flashover probability of a 75-m section, the value n can be derived from Table 5.13-1.

The curves from (EPRI 1982) and (Vaisman et al. 1993) have been plotted in Figure 5.8-10 for the same average height above ground (H = 26 m) and for the same span length (S = 360 m). The EPRI flashover data are higher because of the longer time-to-crest (1000 μs instead of 250 μs) and much larger conductors (8-conductor bundle instead of single or 4-conductor bundles).

Effect of Time-to-Crest

The critical time-to-crest for conductor-to-conductor configurations is proportional to the gap length and is approximately 25 μs per meter. For 0.33 ≤ α ≤ 0.5, the 50% flashover voltage for times-to-crest two times greater than critical is about 3.5% higher than the critical; for times-to-crest four times greater than critical, the increase is about 8%; and for times-to-crest 10 times greater than critical, the increase is about 10%.

Effect of Bundle Size

Very little (~ 1%) difference was found between a single conductor and a bundle of four conductors (Vaisman et al. 1993), as long as the gap length is intended as the minimum clearance between the phases and not as the distance between the two centers. The same conclusion was reached on the basis of theoretical considerations (Rizk 1996). It should be noted, however, that an increase in strength is reached when the conductor to which the positive impulse is applied is larger than a critical size, which is a function of the gap length (see Section 5.3 and Appendix 5.2).

The presence of an insulator string between phases does not appreciably alter the phase-to-phase switching impulse strength in fair weather, while a 5-10% reduction in wet weather should be expected.

5.8.4 Phase-to-Phase Strength of Other Insulation Geometries

The technical literature reports data on the switching impulse strength of several different types of geometrical configurations involving a phase-to-phase gap. These include data on vertical rod-rod (Udo 1966), conductor-to-conductor, stacked vertically (Kishizima et al. 1984), bus-to-orthogonal bus (Boyd et al. 1974, Menemenlis et al. 1981), ring-to-bus (Menemenlis et al. 1981), and ring-to-ring (Paris et al. 1973; CIGRE 1979).

5.8.5 Phase-to-Phase Insulation Stress

Most measurements of actual switching surge amplitudes and waveshapes have concentrated on phase-to-ground switching surges. Only a few data on phase-to-phase switching are available, as discussed in Chapter 3. The procedure outlined in Section 3.2.3 yields the 2% (S_2) and 50% (S_{50}) values of phase-to-phase surges and the standard deviation (σ_s) of the surge amplitude distribution that should be used for phase-to-phase gap length design.

5.8.6 Design of Phase-to-Phase Gap Length

Air distances to withstand phase-to-phase switching surges are designed by combining the strength data of Sections

5.8-2 to 5.8-4 with the stress data described in Section 3.2. The procedure is illustrated in the following example in which the minimum phase-to-phase distance of a 765-kV line is calculated. Assume the following conditions:

- Maximum system voltage: 800 kV.
- Stress distribution with 50% value, S = 2.47 p.u. and σ_S = 2.4 %.
- Strength: CFO data of Figure 5.8-10 for α = 0.5, continuous curve.
- Standard deviation of flashover voltage, σ_F = 3 %.
- Number of objects (spans) in parallel: 1000
- Desired probability of phase-to-phase flashover: less than one in a thousand switching operations.

The stress distribution is constructed using the maxima of the three phase-to-phase surges (A-B, B-C, and A-C). Assuming a configuration as the one shown in Figure 5.8-1, one-third of the switching operations produce maximum surges between nonadjacent phases (A-C) and are not of concern. Therefore, the flashover probability to consider is p = 1 / (1000 · 2/3) = 1/666.

The phase-to-phase flashover probability of the transmission line is a function of the strength/stress ratio defined in Section 5.13:

$$R = V_{50} / S_2 \qquad 5.8\text{-}4$$

S_2 is the statistical maximum switching surge. S_2 = 2.47 + 2 · (0.024 2.47) = 2.59.

The value of R may be determined from Figure 5.13-3. For N = 1000, σ_S = 2.4 %, and σ_F = 3 %, the value R = 1.13 is found. From Equation 5.8-4, V_{50} = 1.13 · 2.59 = 2.93 per unit. The maximum phase-to-ground voltage of an 800-kV line is $800\frac{\sqrt{2}}{\sqrt{3}}$ = 653 kV. Therefore, V_{50} = 2.93 · 653 = 1914 kV. From Figure 5.8-10 or Equation 5.8-1 for α = 0.5, the phase-to-phase distance, L = 4.4 m, is determined.

Minimum phase-to-phase distances between conductors of transmission lines were calculated using the data in Figures 3.2-5 and 3.2-6, N = 500 spans, Equation 5.8-1 for α = 0.5, and σ = 3 %. The results are shown in Table 5.8-1. The phase-to-phase distances are shown in Table 5.8-2. It is apparent that phase-to-phase distances of existing lines are very conservative. In general, corona phenomena are a more severe constraint on phase-to-phase design than switching surges.

Table 5.8-1 Expected Per-Unit Values of Statistical Maximum Phase-to-Phase Switching Surges and Required 50% Flashover Voltage

2% Phase-to-Ground Surge	2% Phase-to-Phase Surge	Standard Deviation, σ_S	σ = 3 %, N = 500, p = 1/10,000

5.9 VARIATION OF FLASHOVER PROBABILITY WITH VOLTAGE

The result of an application of a switching impulse to an external insulation system, such as the insulation between a conductor and a tower, is either a withstand or a flashover. The probability of obtaining a flashover increases with the crest voltage of the applied impulse. Laboratory tests are usually designed to derive with adequate accuracy the 50% flashover voltage, which is the crest voltage of the impulse corresponding to a probability of flashover equal to 50%. For application to line design, however, of great interest are the voltages corresponding to a very low flashover probability—i.e., a very high probability of withstand. Numerous investigations were made to determine the shape of the flashover probability distribution. Tests were performed at Project EHV (Edison Electric Institute 1968), at the CESI laboratory in Italy, and in Japan (Suzuki et al. 1969) on many identical test objects electrically connected so they would be identically stressed by an applied switching impulse. Many switching impulses of the same crest values were applied to such setups in order to determine

the voltages corresponding to extremely low probabilities of flashover. For instance, consider N equal test objects and apply M consecutive switching impulses having the same crest voltage V. If F flashovers (and M-F withstands) are obtained, the voltage V corresponds to a flashover probability equal to: $p = 1 - (1\text{-}F/M)^{1/N}$. For example, for 20 test objects and a series of 40 switching impulse applications, if only one flashover is obtained ($F = 1$), the best estimate of the flashover probability is $p = 0.00063$. By applying several series of impulses with different crest voltages, it is possible to assess the shape of the flashover probability distributions corresponding to relatively low flashover probabilities. The investigations have reached the conclusion that the flashover probability distribution in the low flashover probability region may be assumed Gaussian down to at least 4 standard deviations below the 50% flashover voltage. The assumption of a Gaussian distribution, in other words, cannot be refuted, although the actual shape of the distribution may never be known. Since the Gaussian distribution is relatively simple to express in mathematical terms, it has become normal practice to express the switching impulse strength of an object using two parameters, the 50% flashover voltage and the standard deviation, σ.

On a normal probability paper, a straight line, as shown in Figure 5.4-5, represents a Gaussian distribution. The flashover probability versus voltage can be calculated knowing the 50% flashover voltage and the standard deviation from Equations 5.13-2 to 5.13-4 and Table 5.13-1.

5.9.1 Withstand Voltage Level

With the assumption that the flashover probability distribution is Gaussian, there is no voltage level, however small, at which there is a sure withstand. This is not practical. Following the desire to define a withstand voltage level, V_{WS}, at which the probability of flashover is so low to be practically zero, the withstand voltage is defined as in Equation 5.9-1. At three standard deviations below the 50% flashover voltage, in fact, the flashover probability is less than 0.14%.

$$V_{WS} = (1 - 3\sigma) \cdot V_{50} \text{ (σ in per unit)} \qquad 5.9\text{-}1$$

5.10 EFFECT OF WAVESHAPE ON SWITCHING IMPULSE STRENGTH

The qualitative dependence of the 50% flashover voltage shown in Figure 5.2-2 cannot be easily generalized to all gap types. An attempt was made for line insulation as follows. The dependence of the switching impulse strength on the time-to-crest may be expressed by the function,

$$\frac{V_{50}}{V_{50,crit}} = f\left(\frac{T_f}{T_{f,crit}}\right)$$ where V_{50} is the 50% flashover voltage and T_f the time-to-crest of the actual wave and $V_{50,crit}$ and $T_{f,crit}$ are the corresponding values for the critical wave. A composite of data from different sources was used to derive the curve of Figure 5.10-1 (EPRI 1982; Yasui and Murooka 1988). The data for different gap factors, may be derived from those for rod-plane gaps (gap factor, $K = 1$), by considering that for the same gap length the critical time-to-crest and the increase in voltage caused by changing the time-to-crest are the same, independently of the gap factor. These considerations lead to Equation 5.10-1, which is valid for any gap factor, K.

$$\frac{V_{50}}{V_{50,crit}} = 1 + \frac{1}{K} \cdot \left[f_0\left(\frac{T_f}{T_{f,crit}}\right) - 1 \right] \qquad 5.10\text{-}1$$

f_0 applies to rod-plane ($K = 1$) and is given by the solid curve of Figure 5.10.-1.

The gap factor, K, is given by Equation 5.10-2

$$K = \frac{V_{50,crit}}{1080 \cdot \ln(0.46 \cdot L + 1)} \qquad 5.10\text{-}2$$

where L is the gap length in meters, and $V_{50,crit}$ is the critical 50% flashover voltage in kV.

The critical time-to-crest for double exponential impulses is given by Equation 5.10-3.

$$T_{f,crit} = A \cdot L + B \qquad 5.10\text{-}3$$

L is the gap length (in meters) and A and B are constants, $A = 35$ μs/m and $B = 40$ μs for $1 \le L \le 5$ m according to (Harada et al. 1973) or $A = 54$ μs/m and $B = -60$ μs for $5 \le L \le 15$ m according to (EPRI 1982). The critical time-to-crest increases significantly with increasing humidity. Equation 5.10-3 is approximately valid for standard absolute humidity (11 g/m^3).

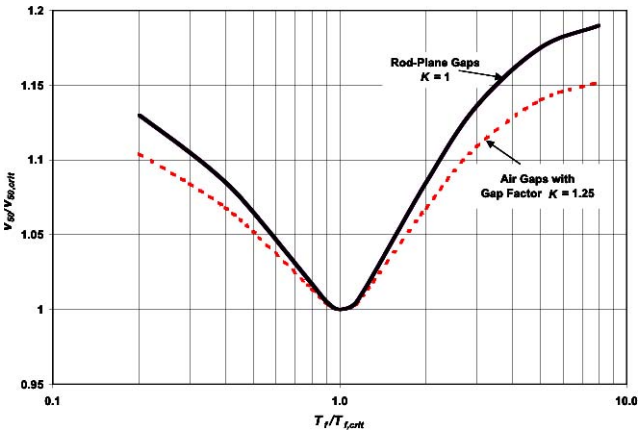

Figure 5.10-1 Influence of time-to-crest on switching impulse strength of air gaps.

5.11 EFFECT OF AIR DENSITY AND HUMIDITY ON SWITCHING IMPULSE STRENGTH: CORRECTION TO STANDARD CONDITIONS

5.11.1 Introduction

The strength of external insulation depends on the atmospheric conditions. Usually the strength increases when either the air density or the humidity increases. An exception may occur for high humidity conditions if the flashover develops close to insulator surfaces. This, however, rarely occurs for switching surges, especially those with positive polarity, which represent the most severe stress.

The effect of air density is particularly important for the design of transmission lines at high altitude, where the air density is low. In this respect, switching surges are particularly limiting because the switching impulse strength was found to decrease with altitude much more rapidly than the lightning impulse strength (Philips et al. 1967). This early finding stimulated much research based on switching impulse tests at laboratories located at different altitudes above sea level (Harada et al. 1970; Pigini et al. 1985; Ramirez et al. 1990) and based on studies of the flashover mechanism (Feser and Pigini 1987; Rizk 1992).

Although less important for switching surge design, the effect of humidity has also been the subject of experimental and theoretical studies (Kucera and Fiklik 1970; Kachler et al. 1971; Harada et al. 1971; Harada et al. 1973; Hahn et al. 1976; Busch 1978; CIGRE 1991).

5.11.2 Standard Air Density and Humidity Conditions

When high-voltage tests are performed on a specific insulation system that involves a possible flashover path in air, the air density and humidity at the time of the tests are recorded together with the test result. The result is corrected to standard atmospheric conditions—i.e., the operator calculates the value that would have been obtained for well-defined (standard) air density and humidity values. The calculations are made using correction factors derived from research or recommended by standardizing organizations (IEC 60-1 1989; IEEE Std 4 1995).

The standard atmospheric conditions are:

- Air density corresponding to a temperature, t_0, of 20°C and a pressure, b_0, of 760 mm Hg, corresponding to 101.3 kPa (1013 mbar)
- Absolute humidity, h_0, of 11 g/m^3

The air density is referred to the air density in standard conditions by using the relative air density, δ_r, which can be calculated for different temperatures, t, and pressures, b, using Equation 5.11-1.

$$\delta_r = \frac{b}{b_0} \cdot \frac{(273 + t_0)}{(273 + t)} \qquad 5.11\text{-}1$$

The absolute humidity, h, may not be directly known. Rather, the relative humidity, h_r (%), and the temperature, t, may be known. The absolute humidity may then be derived from the curves of Figure 5.11-1. When a high-voltage test is performed, the operator measures the air temperature and the temperature of a wet bulb thermometer and derives the absolute humidity using the curves of Figure 5.11-1.

5.11.3 Effect of Air Density

The effect of air density on the dielectric strength of air has long been known. It is based on Paschen law, which states that the breakdown voltage in a uniform electric field depends on the product of gas pressure and gap length. Figure 5.11-2 shows this effect for air (Loeb 1939). This figure applies to air gaps where the electric field is uniform and to very small distances. It is interesting to note that for points far to the right of the minimum, the steepness of the curve is one to one—i.e., the dc flashover strength becomes proportional to the product of gas pressure and gap length. For constant gap length, the strength is directly proportional to the air pressure, which, for constant temperature translates into a direct proportionality with δ_r. Indeed the effect of altitude on power frequency flashover strength of various types of insulators was taken into account by considering the flashover voltage proportional to the relative

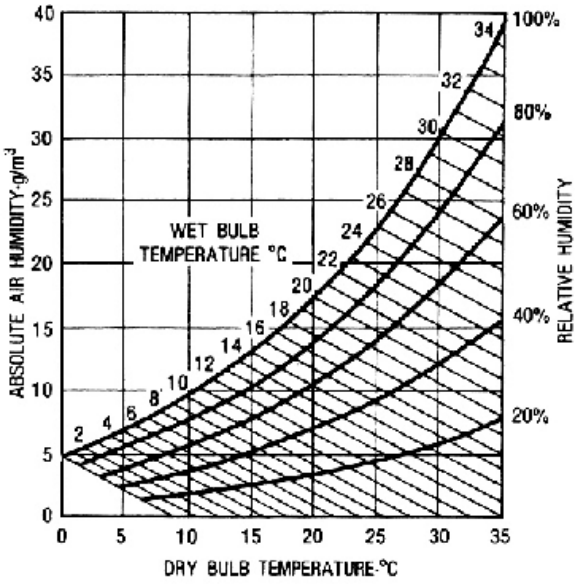

Figure 5.11-1 Absolute humidity of air as a function of relative humidity and temperature or of dry and wet bulb temperatures.

air density (Peek 1914). This behavior was confirmed for lightning impulses.

Nonlinear Air Density Effect on Switching Impulse Strength

The lightning impulse strength is proportional to the air density. A quite different behavior was found for switching impulses by different investigators who performed tests on identical gaps at two different altitudes, one close to sea level and the other at high altitude: at 3200 m at Leadville, Colorado, USA (Philips et al. 1967), at 1850 m on the top of Mount Nyugasa, Japan (Harada et al. 1970), at 1540 m at Apollo, South Africa and at 1800 m at Irapuato, Mexico (Pigini et al. 1985), and at 3000 m at Topilejo, Mexico (Ramirez et al. 1990).

Tests at different altitudes with switching impulses of positive polarity have shown that the flashover voltage is less than proportional to the air density. This effect is shown in Figure 5.11-3, which compares the curves of critical 50% flashover voltage versus gap spacing for rod-plane gaps at two different relative air densities: 1 and 0.8. For all types of air gaps, the effect of air density diminishes with increasing gap length and increasing proximity of the high-voltage electrode to ground. At the time when experimental results were available only for voltages up to about 1100 kV, it was thought possible to simplify the air density effect by applying a correction to the gap length rather than to the voltage. The effect of a reduced air density is assumed to be equivalent to a geometrical adjustment. Accordingly, two gaps with gap length in inverse proportion to the relative air density would have the same critical 50% flashover voltage (Zaffanella 1967). The dashed curve SC of Figure 5.11-3 shows that the gap length correction gives results in closer agreement to experimental result than a straight voltage correction (dashed curve VC). This gap length correction approach was recommended in the previous edition of this reference book (EPRI 1982).

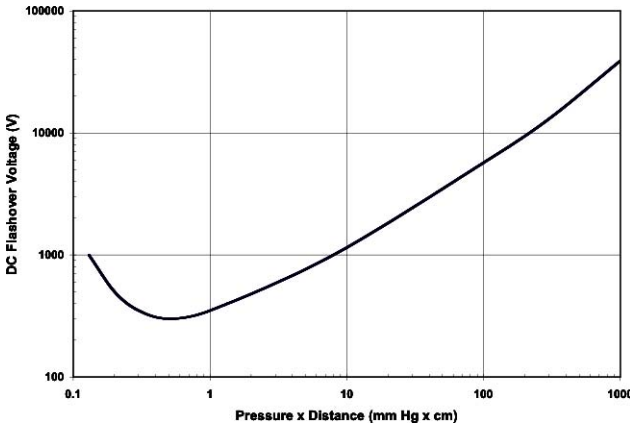

Figure 5.11-2 Dc flashover voltage as a function of pressure and spacing.

Air Density Correction Factor Recommended for High-Voltage Testing

The results of a gap length correction are not satisfactory for higher voltages, as shown by data obtained after 1967. Furthermore, a gap length correction is difficult to implement when an insulation system with given dimensions is tested. As a result, the latest IEEE standard for high-voltage testing recommends a complex procedure (IEEE Std 4 1995).

A measured 50% flashover voltage, V_{TEST}, may be converted to the value, V_{STD}, that would have been obtained under standard conditions ($\delta_r = 1$) by dividing by an air density correction factor k_δ.

$$V_{STD} = \frac{V_{TEST}}{k_\delta} = \frac{V_{TEST}}{\delta_r^n} \qquad 5.11\text{-}2$$

The exponent n is a function of the parameter G_0 given by Equation 5.11-3. The function relating n to G_0 is shown by Equation 5.11-4.

$$G_0 = \frac{V_{STD}}{500 \cdot L} \qquad 5.11\text{-}3$$

$$n = \frac{G_0(G_0 - 0.2)}{0.8} \text{ for } G_0 < 1 \qquad n = 1 \text{ for } G_0 \geq 1 \qquad 5.11\text{-}4$$

V_{STD} is in kV and must be estimated in order to calculate G_0, L is the gap length in meter.

Apart from being cumbersome, the air density correction method in the IEEE standards has serious limitations. For example, a 10-m rod-plane gap at a relative air density of 0.8 and an absolute humidity of 11 g/m^3 has a flashover voltage of 1720 kV. The parameter G_0 (from Equation

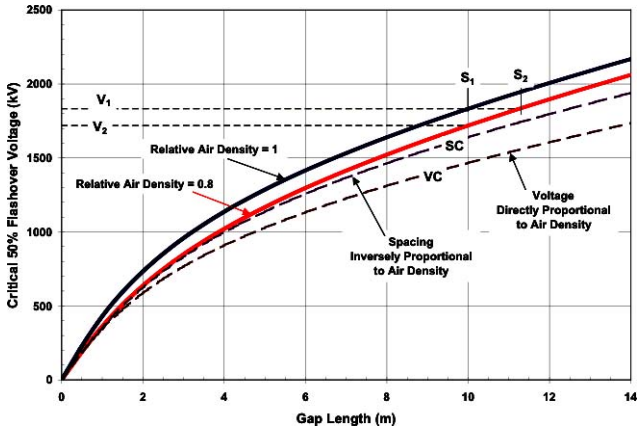

Figure 5.11-3 Critical 50% flashover voltage of rod-plane gaps. Top curve for $\delta_r = 1$. Bottom curve for $\delta_r = 0.8$.

5.11-3, using an estimated V_{STD} = 1830 kV) is equal to 0.37 and the exponent n (from Equation 5.11-4) is equal to 0.08. The correction factor is $k_1 = 0.8^{0.08} = 0.98$ and $V_{STD} = \frac{V_{TEST}}{k_1} = \frac{1720}{0.98} = 1750\,\text{kV}$. This result does not compare well with the value of flashover voltage expected for a 10-m rod plane gap at standard air density (1830 kV).

A closer value (1790 kV) is obtained applying the IEC correction factor, which is described by Equations 5.11-5 to 5.11-7.

$$G_0 = \frac{V_{STD}}{500 \cdot L \cdot [1 + (K-1)/3]} \quad 5.11\text{-}5$$

where K is the gap factor (see Table 5.13.-2) and V_{STD} must be estimated.

$$T = 1.4 \cdot \frac{1 - 0.8 \cdot G_0}{1 - 0.2 \cdot G_0} \cdot K^{1.6} \quad 5.11\text{-}6$$

$$k_\delta = \frac{0.8 \cdot [1 + T \cdot (1 - \delta_r)] \cdot (\delta_r - 0.2 \cdot G_0)}{1 - 0.2 \cdot G_0} + 0.2 \quad 5.11\text{-}7$$

Approach Based on Physical Model

An approach based on a physical model of the flashover mechanism was successfully developed and currently offers the best approach to the design of transmission lines at high altitude (Rizk 1992). The model accounts for the effect of air density on two key quantities that affect the flashover voltage: the continuous leader inception voltage and the leader length at the moment of the final jump. These parameters are described in Section 5.3 and Appendix 5.2. The effect of air density on the continuous leader inception voltage, V_{lc}, is described by Equation 5.11-8.

$$V_{lc} = \frac{V_{c\infty}}{1 + \frac{A}{\delta_r R}} \quad 5.11\text{-}8$$

$V_{c\infty}$, A, and R are parameters described in Appendix 5.2.

The leader length, l, at the moment of the final jump is:

$$l = d - \frac{V_{lc}}{\delta_r E_s} \quad 5.11\text{-}9$$

d is the gap length and E_s is the streamer gradient given by Equation 5.11-15 with h = 11 g/m^3.

The voltage drop, ΔV_l, along the leader is given by Equation 5.11-10:

$$\Delta V_l = 50 \cdot l + 37.5 \cdot \ln(8 - 7 \cdot e^{-1.33 \cdot l}) \quad 5.11\text{-}10$$

The 50% flashover voltage, V_{50}, is equal to:

$$V_{50} = \frac{V_{lc} + \Delta V_l}{1 - 3\sigma} \quad 5.11\text{-}11$$

σ is the standard deviation, which is taken as 0.05, although tests at high altitude show a tendency of the standard deviation to decrease with a decrease in air density (Philips et al. 1967; Pigini et al. 1985).

5.11.4 Effect of Humidity

The moisture content of the air has an influence on the breakdown strength of air gaps and insulators. The breakdown strength of air gaps increases with increasing humidity. This effect is caused by the tendency of water molecules to attract free electrons, thus causing an increase in the electric field necessary to cause ionization. The behavior of insulators with changing humidity is complicated by the condition of the insulator surfaces, whose conductivity depends on humidity. However, for positive polarity switching surges, which are the most limiting for insulation design, the possible flashover path develops mostly in air away from the insulator surface, and surface conductivity plays a negligible role.

The influence of humidity on positive polarity switching impulse breakdown is quite complicated. The previous edition of this reference book recommended a humidity correction factor equal to $\frac{1}{(H_0)}n$, where $1/H_0$ is the basic correction factor for short gaps, and the exponent n is equal to one for short gaps and decreases with increasing gap length. The exponent n was the same as that used for air density correction. Both H_0 and n were based on experimental data and depended on the waveform. The advancement in knowledge of the physical phenomena governing the switching impulse flashover mechanism (see Section 5.3), together with experimental data from different laboratories, has provided a more solid foundation to an improved correction procedure (CIGRE 1991).

Humidity Correction Factor Recommended for High-Voltage Testing

A measured flashover voltage may be corrected to the value that would have been obtained under standard conditions (h = 11 g/m^3) by dividing by the humidity correction factor k_h.

$$V_{STD} = \frac{V_{TEST}}{k_h} = \frac{V_{TEST}}{(K_0)^w} \quad 5.11\text{-}12$$

K_0, given by Equation 5.11-13, represents the basic correction factor applicable to short gaps. K_0 is the inverse of the factor H_0 previously employed. It must be noted that K_0 is

also a function of air density. It is expressed as a function of h/δ because an absolute humidity corresponds to a constant partial pressure of water vapor, which is independent of the changes in the partial pressure of air that occur when air density changes. This effect becomes important at high altitude

$$K_0 = 1 + 0.0095 \cdot (h / \delta_r - 11) \qquad 5.11\text{-}13$$

h is the absolute humidity expressed in g/m^3.

The exponent w is a function only of the parameter G_0 given by Equation 5.11-3, irrespective of electrode configuration and the type of stress (lightning or switching impulses). The function relating w to G_0 is shown by Equations 5.11-14.

$$\begin{aligned} &\text{For } G_0 < 1 && w = \frac{G_0 \cdot (G_0 - 0.2)}{0.8} \\ &\text{For } 1 < G_0 < 1.2 && w = 1 \\ &\text{For } 1.2 < G_0 < 2 && w = \frac{(2 - G_0)}{0.66\, G_0} \\ &\text{For } G_0 > 2 && w = 0 \end{aligned} \qquad 5.11\text{-}14$$

For $G_0 < 1$, the exponent w has the same value as the exponent n used for relative air density.

Effect of Humidity on the Physical Aspects of the Flashover Mechanism

The most significant humidity effect is the increase in streamer gradient with increasing humidity. This effect is expressed by Equation 5.11-15, which shows the effect of humidity on the breakdown of short gaps.

$$E_s = E_{s,0}(1 + 0.0095 \cdot (h / \delta_r - 11) \qquad 5.11\text{-}15$$

$E_{s,0}$ is the streamer gradient with standard humidity (h = 11 g/m^3) and relative air density (δ_r = 1). $E_{s,0}$ = 400 kV/m.

Contrary to the significant effect on streamer gradient, humidity has little effect on the gradient of the leader. The leader length becomes increasingly important as the gap length increases. This explains why humidity effects decrease with increasing gap length.

Humidity affects the net space charge injected by the first streamer corona. As humidity increases, the net space charge is reduced. This reduces the shielding effect of this space charge and facilitates the transition from streamers to leader. This phenomenon is dependent on the ratio h/δ_r. Humidity also affects the leader velocity, which increases with increasing humidity. The two effects of increasing humidity, more rapid leader formation and greater leader velocity, result in a reduction of the time from first corona to breakdown. Test results have shown that the critical

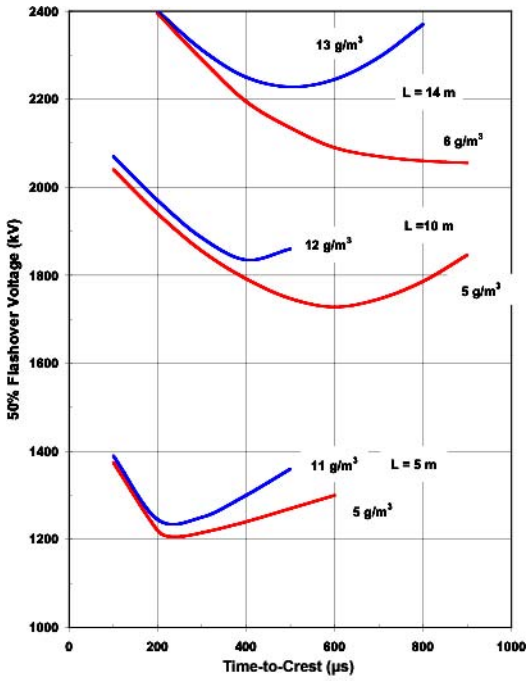

Figure 5.11-4 50% Flashover voltage of rod-plane gaps versus time-to-crest for different humidity.

time-to-crest decreases with increasing humidity (Kachler et al. 1971; Busch 1978; Aihara et al. 1983). This phenomenon is shown by the curves of Figure 5.11-4 (Busch 1978). The figure shows that different humidity effects can be found using different times-to-crest. Large humidity effects were found with waves having equivalent times-to-crest greater than 1000 µs (Lloyd and Zaffanella 1981; EPRI 1982).

5.12 EFFECT OF RAIN AND OTHER WET WEATHER CONDITIONS ON SWITCHING IMPULSE STRENGTH

5.12.1 Air Gaps and Clean Insulators

A significant amount of research has addressed the issue of how the switching impulse strength of transmission-line insulation systems is affected by rain and various types of wet-weather conditions (Udo 1966b; Armstrong and Miller 1967; Paris 1967; Malaguti and Zaffanella 1968; Paris and Cortina 1968; Hauspurg et al. 1969; Kachler et al. 1970; Kachler et al. 1971a; Kachler et al. 1971b; CIGRE 1979c; Riu et al. 1988).

Rain, drizzle, fog, snow, and any other type of precipitation do not affect the strength of air gaps. An exception occurs when the energized electrode is smooth and is larger than a critical size. The critical size is given by Equation 5.12-1 for spheres, and by Equation 5.12-2 for cylinders.

Critical radius of sphere for sphere-to-plane gaps:

$$R_c = 0.38(1 - e^{-L/L_0})(m) \quad 5.12\text{-}1$$

L is the gap length, $L_0 \approx 3.8$ m (EPRI 1982) or $L_0 \approx 5$ m (Carrara and Thione 1976)

Critical radius of cylinder for cylinder-to-plane gaps:

$$R_c = 0.0037 \cdot \ln(1 + L) \text{ (Rc and L in m)} \quad 5.12\text{-}2$$

When the energized electrode size is greater than the critical, rain, drizzle, snow, and other weather conditions that cause water drop or particle formation on the electrode surface, cause a reduction in switching impulse strength to values corresponding to electrode sizes below critical (Carrara and Thione 1976; Rizk 1978; Rizk 1989a). Efforts to improve switching surge performance by designing smooth electrodes are successful only in fair-weather conditions (Commellini 1971).

When insulators are present, the effect of wet weather depends on how much the flashover path develops along the insulator surface. For most transmission-line insulation systems, the positive polarity switching impulse strength is not affected by wet weather because flashover paths are in air away from insulators. Vertical insulator strings supporting a transmission-line conductor from a tower crossarm may be an exception, especially if the crossarm is slender. In these cases, the positive polarity flashover strength is quite high when the insulators are dry. The flashover develops close to the insulator string. When the insulators are wet, surface conductivity for some types of insulators in rain, drizzle, fog, wet snow, and even high humidity will increase significantly and will affect the flashover process. The positive polarity switching impulse strength may be reduced by a few percent, with a 5% reduction being a reasonably conservative value. The same behavior is shown by horizontal or V strings when the flashover path is along the insulators. As an approximate rule, the positive polarity strength is affected by wet weather when the gap factor of the insulator string gap is greater than 1.65. When the gap factor is 1.9, the reduction in switching impulse strength due to wetness of the insulators may reach 10%. For instance, assume that a 2-m-long insulator string is a part of an insulation system having a critical 50% flashover voltage of 1240 kV with flashovers along the insulator string. According to Equation 5.5-2, the critical 50% flashover voltage for a 2-m rod plane is 705 kV. The gap factor is 1240/705 = 1.76. The estimated reduction due to wet weather is 4.5%. The reduction depends on the type of insulators and on the insulator profile. The insulators that have a good performance in contaminated conditions under ac stress perform also better under switching surges. For instance, the switching impulse strength of insulation systems with nonceramic insulators is little affected by wet weather.

Switching impulse tests with artificial rain with the very high intensity (between 1 and 1.5 mm/min) prescribed by IEC (IEC 60-1 1989) have a poor reproducibility because of the difficulty in generating a consistent water spray and because of the random nature of the water cascading along the insulators (Riu et al. 1988).

The negative polarity strength of insulation systems with insulator strings is significantly affected by wet weather. This is consistent with the observation that negative polarity flashovers develop close to insulator surfaces. The reduction in negative polarity strength is of little concern regarding line performance, because negative polarity strength in dry conditions is generally much higher than the positive polarity strength. However, when the gap factor is high (1.8 ~ 1.9), the negative polarity wet strength may be as low as the positive polarity wet strength. It has also been observed that the reduction in negative polarity strength caused by insulator wetness increases as the time-to-crest increases. For long fronts (e.g., times-to-crest greater than 1000 μs), the negative polarity wet strength of insulator strings may be considered the same as the positive polarity wet strength.

Snow does not affect the insulation strength of insulation system, unless it succeeds in wetting the surfaces of the insulators along which flashovers may develop. This is not the case for dry snow or for wet snow and vertical or V-strings, but it may be the case for horizontal strings and wet snow. The design of insulator strings covered with ice or snow is based on power frequency voltage. Insulators designed to withstand the power frequency voltage when covered with ice or snow will also withstand switching impulses with crest values of at least 2.5 per unit (Yasui and Murooka 1988). This conclusion was reached on the basis of tests carried out in Japan (Watanabe 1978; Fujimura et al. 1979).

The standard deviation of the flashover voltage of air gaps and insulators is not affected by wet weather. The same value of 5% used for dry conditions may also be used for wet conditions.

5.12.2 Switching Impulse Strength of Contaminated Insulators

When insulators are contaminated and dry, the switching impulse strength is the same as for insulators clean and dry. When the insulator surface becomes conductive because of contamination and high humidity or fog, the switching impulse strength may be reduced (Okada and Koga 1970; Macchiaroli and Turner 1970; EPRI 1982). Insulators for

contaminated conditions are designed to withstand the power frequency voltage. If different contaminated insulators are ranked according to their behavior, the same ranking is obtained for switching surges and for power frequency (Macchiaroli and Turner 1970). Tests on strings with 10-25 standard insulator units and times-to-crest that were critical for the gaps in dry conditions have shown that the ratio of switching impulse to power frequency crest value for the same flashover probability is 1.9 to 2.5, depending on the severity of contamination and the type of insulation (Macchiaroli and Turner 1970). Tests with switching impulses having times-to-crest longer than 1000 μs applied to 4.4-m-long insulator strings have resulted in a ratio between switching impulse and power frequency crest for the same flashover probability equal to 1.7 for very light contamination and 1.2 for moderate degrees of contamination. Apparently the flashover process on contaminated insulators requires a much longer time than in air, and times to flashover are greater than 1000 μs. Therefore it would appear that serious insulation problems could occur if contaminated insulators, severe wetting conditions, and long- fronted switching surges were to occur simultaneously. The probability of simultaneous occurrence of these circumstances is very low, except perhaps for switching surges that may result from a line reclosure after a power frequency insulator flashover due to insulator contamination. In these circumstances, it may be difficult to re-energize the line. Therefore the design of insulators for contaminated conditions should be based on withstanding the power-frequency voltage (see Chapter 4).

5.13 RISK OF FAILURE OF PHASE-TO-GROUND INSULATION

5.13.1 Introduction

The behavior of transmission-line insulation when stressed by switching surges is dependent on a large number of parameters: crest value, polarity and shape of the surges, variation of the crest value of the surges along the line, number of insulation elements simultaneously stressed by the same surge, geometry of each insulation element, probability of flashover of each insulation element for each crest voltage and each waveshape, air density, humidity, rain, and wind.

The effect of these parameters and often the value of the parameters themselves are known with some degree of uncertainty. A design of transmission-line insulation based on the simultaneous occurrence of the worst estimated value of each parameter would be unnecessarily conservative. The use of statistical methods is necessary to deal with the complexity of the problem and optimize the design in an effective way (Anderson and Barthold 1964; McElroy and Charkow 1967; Barthold and Paris 1970; IEEE Std 4 1975; Kassakian and Otten 1975; Elovaara 1978; Brown 1978, Papadias 1979).

The behavior of transmission-line insulation can be defined by the *risk of failure*, which is the probability of an unwanted flashover of any insulation element of the transmission line when a switching operation that may create a voltage surge occurs.

This section discusses the determination of the risk of failure of phase-to-ground insulation. Phase-to-phase risk of failure is discussed in Section 3.2. In general, the risk of phase-to-phase failure is much lower than that of phase-to-ground.

5.13.2 Distribution of Switching Surges on Transmission Lines

Chapter 3 discusses methods to determine the distribution of switching surges on transmission lines. The amplitude and shape of a surge are determined by simulating several system conditions such as circuit breaker pole-closing characteristics, energizing versus reclosing, pre-insertion resistors, presence and behavior of surge arresters, line length, location along the line, and network configuration. By randomly varying each of the system conditions within their possible range, an infinite-sample distribution of switching surges is obtained. This distribution can be characterized by a function *F(V),* which expresses the probability that a switching surge crest voltage exceeds the value *V.*

Because of the physical nature of the system, or because of limitations caused by surge arresters, there will be a maximum switching surge level that cannot be exceeded, and the function *F(V)* will be truncated at its maximum value.

Switching Surge Amplitude and Waveshape Distribution

The switching surge amplitude distribution is characterized by the surge value, S_2, corresponding to 2% probability of occurrence, by the standard deviation, σ_s, and by the value of the probability of the truncation point (see Chapter 3). Chapter 3 discusses how the surge amplitude may vary along a transmission line and the variability of the surge waveshape, which has a significant effect on the stress applied to the line insulation (see Section 5.10).

5.13.3 Parameters Affecting Risk of Failure Caused by Switching Surges

The risk of failure of a transmission line is affected by the parameters of the surge distribution (S_2, σ_s, truncation point, variation of surge amplitude along the line, distribution of waveshapes) and by the strength characteristics of all line elements. Calculations can be performed with Applet S-2.

Vertical insulators are often free to swing because of wind. The gap between conductor and tower is reduced depend-

ing on wind speed and direction. The calculation of the swing angle is discussed in Appendix 5.1. The analysis of this situation involves also the assessment of the probability that any given swing angle will coincide with a switching surge. In general, this analysis shows that the worst stress is caused by the ever-present power frequency voltage, and that a design that avoids a flashover at power frequency in the highest expected wind conditions, would also be adequate for withstanding randomly occurring switching surges.

5.13.4 Simplified Design Procedure

A thorough design procedure requires the detailed knowledge of several parameters related to line insulation characteristics, switching surges, and weather conditions. This procedure is described in Applet S-2. A simplified procedure can be used if the following assumptions can be made:

- The switching surge amplitude distribution is considered Gaussian without a truncation point, and is defined by the statistical maximum surge (2% level), S_2, and by the standard deviation of the surge distribution, σ_s.
- The surge level is constant along the line.
- All surges are assumed to have the critical time-to-crest.
- All insulating elements have the same strength, defined by the value of V_{50}.
- The distribution of flashover probabilities is assumed Gaussian with a standard deviation, σ_F.
- There are N insulation elements per phase simultaneously subjected to a switching surge.

The probability of flashover of one insulation element subject to a surge of crest voltage, V, is expressed by Equation 5.13-1.

$$P(V) = \frac{1}{\sigma_F \sqrt{2\pi}} \int_{-\infty}^{V} e^{-\frac{1}{2}\left(\frac{x - V_{50}}{\sigma_F}\right)^2} dx \qquad 5.13\text{-}1$$

Introducing the parameter $z = \dfrac{x - V_{50}}{\sigma_F}$, Equation 5.13.1 may be written:

$$P(V) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{Y} e^{-\frac{z^2}{2}} dz = f(Y) \qquad 5.13\text{-}2$$

$$Y = \frac{V - V_{50}}{\sigma_F} \qquad 5.13\text{-}3$$

Equation 5.13-2 expresses the flashover probability of an insulation element as a function of the number of standard deviations by which V_{50} differs from the surge crest, V. A tabulation of the probability $P(V)$ versus Y is shown in Table 5.13.1 for values of Y from 0 to –4.4. If Y is positive, the probability of flashover is greater than 0.5 and may be calculated as $1 - f(-Y)$ using the same table. For extremely low values of flashover probability ($Y < -4$), Equation 5.13-4 gives sufficiently accurate results.

$$P(V) \approx -\frac{e^{-Y^2/2}}{Y \cdot \sqrt{2\pi}} \qquad 5.13\text{-}4$$

For example, if the 50% flashover voltage of a gap is 1500 kV with a standard deviation of 5%, and a surge with a crest voltage equal to 1260 kV is applied, the flashover probability is calculated as follows: $Y = (1260 - 1500)/(0.05 \cdot 1500) = -3.2$ and, from Table 5.13-1, $P(V) = 6.87 \cdot 10^{-4}$.

The probability of flashover of one insulation element subjected to a switching surge of a given family depends on the probability of occurrence of a surge, expressed by the switching surge amplitude distribution density, $F(V)$, which expresses the probability, $F(V) \cdot dV$ that the crest value of a switching surge is between V and $V + dV$. $F(V)$ is assumed Gaussian, and is expressed by Equation 5.13-5:

$$F(V) = \frac{1}{\sigma_S \cdot \sqrt{2\pi}} \cdot e^{-\frac{1}{2}\left(\frac{V - S}{\sigma_S}\right)^2} \qquad 5.13\text{-}5$$

where $S = \dfrac{S_2}{1 + 2.05 \cdot \sigma_S}$

If a surge of the switching surge family characterized by $F(V)$ is applied to an insulation element characterized by V_{50} and σ_F, the probability of flashover can be calculated

Table 5.13-1 Flashover Probability P(V) versus the Variable Y = (V – V_{50}) / σ_F.

Y	P(V)	Y	P(V)	Y	P(V)
0	0.5	-1.5	0.0668	-3.0	0.00135

-0.5	0.309	-2.0	0.0228	-3.5	0.000233
-0.6	0.274	-2.1	0.0179	-3.6	0.000159
-0.7	0.242	-2.2	0.0139	-3.7	0.000108
-0.8	0.212	-2.3	0.0107	-3.8	0.000072
-0.9	0.184	-2.4	0.00820	-3.9	0.000048
-1.0	0.159	-2.5	0.00621	-4.0	0.000032
-1.1	0.136	-2.6	0.00446	-4.1	0.000021
-1.2	0.115	-2.7	0.00347	-4.2	0.000013
-1.3	0.0968	-2.8	0.00256	-4.3	0.000009
-1.4	0.0808	-2.9	0.00187	-4.4	0.000005

combining Equations 5.13-2 and 5.13-5, with the following result:

$$P = \frac{1}{\sqrt{2\pi}} \cdot \int_{-\infty}^{Y} e^{-\frac{z^2}{2}} dz = f(Y) \qquad 5.13\text{-}6$$

$$\text{where } Y = \frac{(S - V_{50})}{\sqrt{(\sigma_F \cdot V_{50})^2 + (\sigma_S \cdot S)^2}} \qquad 5.13\text{-}7$$

For example, assume S_2 = 1.8 p.u., σ_S = 10%, V_{50} = 2.2 p.u., and σ_F = 5%. It will be: S = 1.8 / (1+2.05 · 0.10) = 1.49 p.u. and $Y = \frac{(1.49 - 2.2)}{\sqrt{(0.05 \cdot 2.2)^2 + (0.10 \cdot 1.49)^2}} = -3.83$.

From Table 5.13-1, in correspondence to Y = -3.83, the flashover probability is $P(V) = 6.5 \cdot 10^{-5}$.

It must be noted that the surge distribution contains positive and negative surges in equal proportion, as is ordinarily the case for surge distributions derived with the TNA or with digital methods. The flashover probability derived with Equation 5.13-6 should be divided by 2, because it is assumed that negative polarity surges do not significantly stress the insulation.

The flashover probability of N identical insulation elements subjected to a switching surge of crest value, V, is given by Equation 5.13-8, which expresses the probability that at least one of the N elements will flash over.

$$P(N,V) = 1 - \left[1 - P(V)\right]^N \qquad 5.13\text{-}8$$

P*(V)* is given by Equation 5.13-1. *P(N, V)* is the stress distribution on N insulating elements. If *P(V)* is Gaussian, *P(N, V)* is not. An example of the stress distribution for a single insulation element and for a set of 100 elements is shown in Figure 5.13-1. Using the previous example with V = 1260 kV, V_{50} = 1500 kV, and σ_F = 75 kV, we obtain: $P(100, 1260\text{ kV}) = 1 - (1 - 6.5 \cdot 10^{-5})^{100} = 6.5 \cdot 10^{-3}$.

The probability of flashover of the set of 100 insulation elements becomes significant, even when the probability of flashover of a single element is negligible. Unfortunately, the accuracy with which *P(N, V)* is calculated is poor because *P(V)* is not well known at low flashover probabilities. Hence the value of σ_F and the assumption that *P(V)* is Gaussian become critical. Nevertheless, the Gaussian assumption still appears to be a good working assumption and conservative values of σ_F, 5% for a phase-to-ground insulation element and 3% for the phase-to-phase insulation of a transmission line span, are recommended.

The probability of flashover of a system of N identical insulation elements subjected to a switching surge of a given family is given by Equation 5.1-9.

$$P = \int_0^{\infty} F(V) \cdot \left\{1 - \left[1 - P(V)\right]^N\right\} \cdot dV \qquad 5.13\text{-}9$$

F(V) is given by Equation 5.13-5, and *P(V)* is given by Equation 5.13-1. When N = 1, Equation 5.13.9 becomes Equation 5.13-7.

The individual factors (stress density *F(V)* and strength of N insulation elements) appearing in the integrand of Equation 5.13-9 are plotted separately for a specific set of parameters in Figure 5.13-1. The product of the stress and strength curves, which is the integrand in the equation, is also plotted.

To facilitate the application of Equation 5.13.9, calculations were made for different combinations of the parameters N, σ_F, σ_S, and the strength to stress ratio, R defined by

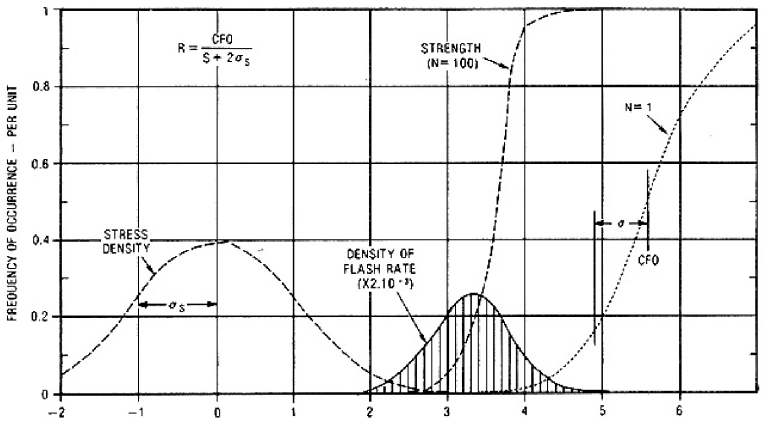

Figure 5.13-1 Stress density distribution and cumulative flashover probability (strength) distribution. Flashover rate per surge is given by the area under the flashover density distribution.

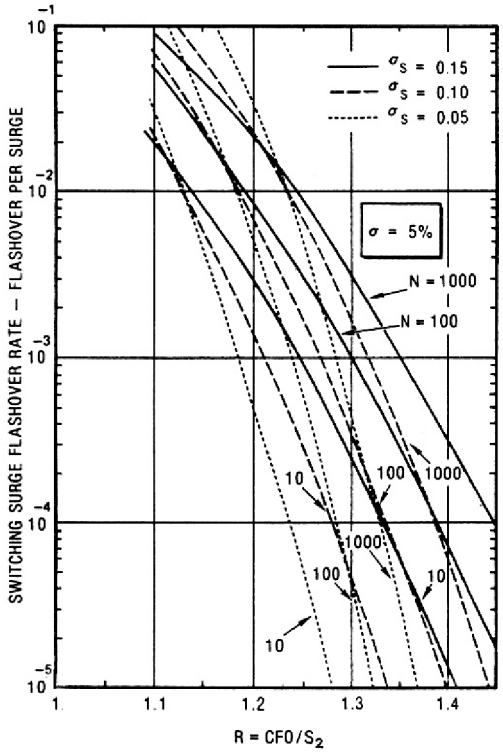

Figure 5.13-2 Flashover rate versus strength-to-stress ratio for different values of N and $\sigma_S \cdot \sigma_F$ = 5%.

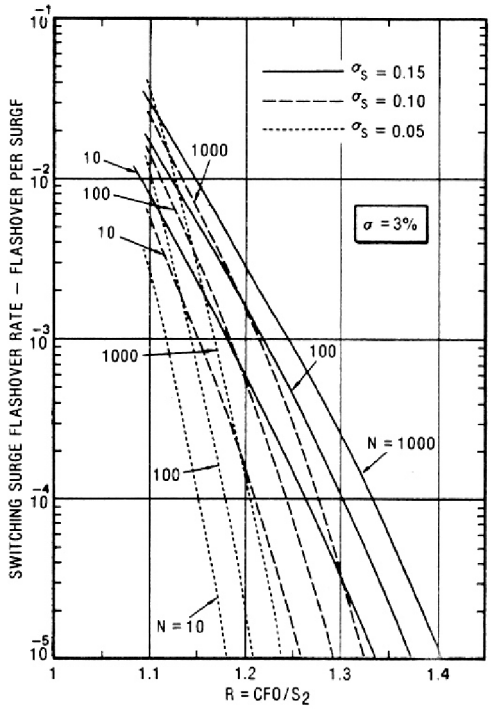

Figure 5.13-3 Flashover rate versus strength-to-stress ratio for different values of N and $\sigma_S \cdot \sigma_F$ = 3%.

Equation 5.13-10. The results are shown in Figures 5.13-2 and 5.13-3.

$$R = \frac{V_{50}}{S_2} \qquad 5.13\text{-}10$$

The use of R is justified by the common use of the statistical maximum surge to characterize the stress and by the convenient use of the 50% flashover voltage to characterize the insulation strength.

To illustrate the use of the curves of Figures 5.13-2 and 5.13-3, assume that a line with 1000 towers is subjected to switching surges having a statistical maximum S_2 of 1.75 per unit with a standard deviation σ_S of 10%. Further assume that the desired risk of failure rate is no more than one flashover every 10,000 switching operations. Ignoring the negative surges, the failure rate becomes $0.5 \cdot 10^{-4}$. Figure 5.13-2 for N = 1000, σ_F = 10%, and σ_S = 5% gives R = 1.385. Therefore, the design value of V_{50} corresponds to $1.75 \cdot 1.385 = 2.42$ per unit. For an 800-kV maximum system voltage, $V_{50} = 2.42 \cdot 800 \cdot \frac{\sqrt{2}}{\sqrt{3}} = 1580\ kV$. This is the minimum strength required by tower insulation in order to satisfy the desired failure rate requirement.

5.14 CONSIDERATION OF SWITCHING SURGES DURING LIVE-LINE MAINTENANCE

5.14.1 Introduction

The selection of tools, equipment, and work procedures for live-line maintenance are described in Chapter 13. In this section only the aspects of live-line maintenance that are affected by switching surges are discussed. Switching surges are indeed the major concern during live-line maintenance, since this is performed in fair weather when the possibility of lightning is remote, but the possibility of a switching operation exists.

Recommended minimum approach distances have been based on switching surge considerations (see Chapter 13). The insulation strength of individual live-line tools is normally estimated from the switching impulse strength of rod gaps with a safety margin. Live-line maintenance methods, however, may consist of complex tools, ladders, and lineman configurations where the critical gap distance cannot be easily defined. Furthermore, the presence of live-line tools may lower considerably the strength of an insulator string in some gap configurations. Therefore, switching surge tests are carried out for methods used on 220-kV lines and above (Reichman 1981; ESMOL 2002a).

In order to minimize the risk factor of a work method, the use of protective gaps has been promoted. These are special portable gaps that are installed on towers adjacent to that where live-line work must be carried out. These gaps are designed so that they will flashover whenever a surge of any shape exceeds a magnitude that may cause unacceptable risk at the work tower (Gela, Lux et al. 1996; ESMOL 2001).

Maintenance work can be performed with linemen at ground potential handling insulating tools or by placing linemen on the high-voltage conductor. During the transition between ground and line potential, a lineman is placed at a floating potential. This is the case of a lineman in a protective suit climbing an insulating ladder, or inside a work platform being raised to the conductor from ground, or a helicopter hovering near the conductor, or a robotic device being installed on the conductors. All these situations must be tested with switching impulses to determine the conditions leading to the lowest strength (ESMOL 2002a). Testing may be rationalized using analytical tools based on physical understanding of switching impulse flashover phenomena (Rizk 1995).

5.14.2 Minimum Number of Insulators to Withstand Switching Surges

The ability of a string of insulators to withstand a switching impulse depends on the number of defective units and their position in the string. A defective insulator is one that has lost some or all of its dielectric strength. Defective units may be shorted (all the dielectric strength is lost), broken (a portion of the porcelain or glass is missing), or punctured (with a visible hole). A healthy insulator is one that has retained all its dielectric strength.

The number and shape of the insulator units of a healthy string depend on line design criteria, such as limiting the line outage rate. Insulators either do not affect the strength of the gaps where they are placed (e.g., V-strings) or, if they do (e.g., vertical strings on an outside phase), the lowest strength occurs in wet weather. Therefore, the outage rate depends on the insulator design and on the contamination conditions of the area traversed by the line. No flashover due to healthy insulators is expected in dry conditions when live working is performed. In fact, the dry insulator performance is so much better than the wet performance that the insulator string can withstand the highest expected surge even when some insulator units are shorted.

Two methods are considered to determine the minimum number of healthy insulator units that can be accepted in a string during live line work (ESMOL 2002b). The first method is based on a formula that indicates the reduction in strength caused by defective units. The second method is a simplified approach based on an average withstand voltage of 55 kV for a single 146 mm × 254 mm (5 " × 10") insulator.

Method Based on the Reduction in Strength Due to Defective Units

The 50% flashover voltage, $V_{50,d}$, of an insulator string with N_d defective units is:

$$V_{50,d} = V_{50,0} \cdot (1 - 0.8 \frac{N_d}{N_0} \cdot k) \qquad 5.14\text{-}1$$

$V_{50,0}$ is the 50% flashover voltage with all healthy units,
N_0 is the total number of units in the string,
k is an empirical coefficient that characterizes the average dielectric strength of the defective units.

Broken glass insulators are considered shorted, therefore $k = 1$. Broken porcelain units may retain some strength; it is recommended to use $k = 0.75$, which is a conservative value.

Equation 5.14-1 assumes that the broken units are all in the worst location within the string—i.e., at the energized end of the string. The least reduction in strength occurs when the broken units are near the center of the string.

Simplified Method

The simplified method assumes that the healthy units have a withstand dielectric strength of 55 kV regardless of the insulator unit type. Tests have shown this to be a conservative value when an insulator string is subjected to switching impulses. The number of healthy units is derived by dividing the crest value (in kV) of the maximum expected surge by 55.

5.14.3 Performance of Portable Protective Gaps

Portable Protective Air Gaps (PPAG) are used as a live-line tool to control the maximum surge that can stress the insulation systems at the work site. The worker's minimum approach distance is a function of the flashover voltage of the PPAG. These devices and their use are described in Chapter 13.

PPAG are essentially rod-rod gaps that vary in length from about 0.5 to 1.04 m for applications in the range of voltages from 220 kV to 500 kV. These represent rather short gaps, where corona-starting voltage plays an important role in the flashover strength. The shape of the electrode must be carefully controlled to assure a consistent performance.

The performance of such gaps is greatly influenced by the proximity to either grounded parts or to the conductor. To assure a predictable behavior, the gap must be installed away from the conductor in a consistent way for which test data are available. In this case the lower strength is

obtained with positive polarity, which is desirable since that is the critical polarity for line insulation that is protected by the gap. The switching impulse strength depends very little on the waveshape.

5.14.4 Effect of Floating Objects

At any time a worker is in the air gap between conductor and grounded structures, he is considered a "floating object." The switching impulse flashover voltage of a gap with a floating object has been studied experimentally (Hutzler 1987) and theoretically (Rizk 1995). Because of the importance to worker safety, switching impulse tests using the exact dimensions and procedures of actual working methods should be performed. Rules governing the distance to be maintained by the worker in all the phases of the transitions between ground and conductor have been developed (ESMOL 2002a).

APPENDIX 5.1 COMPUTATION OF THE SWING ANGLE DISTRIBUTION

The calculation of the magnitude and frequency of the swing angle of free-swinging insulator strings requires information concerning wind statistics and the magnitude of the swing angle as a function of the wind velocity.

The method illustrated in this appendix was developed for switching surge performance calculations (EPRI 1982), not for mechanical design. The relation between swing angle and wind speed was derived from the results of the Hornisgrinde test project in Schwarzwald, Germany (Mors 1956a; Mors 1956b; Leibfried and Mors 1960). The wind speed distribution must be constructed on the basis of data available from stations such as those of the U.S. Weather Bureau.

Swing Angle as a Function of Wind Speed

The swing angle of free-swinging insulator strings is a function of the parameter:

$$K = \frac{D}{W} \cdot \frac{H}{V} \qquad \text{A5.1-1}$$

D is the diameter of the conductor (mm), W is the weight per unit of length of the conductor (kg/m), H is the horizontal span (m), and V is the vertical span (m).

The meaning of the parameters H and V is shown in Figure A5.1-1.

The swing angle versus the mean wind speed along the spans adjacent to the insulator strings is shown in Figure A5.1-2 for different values of the parameter K shown in Equation A5.1-1. All the curves are for single conductors. The wind is assumed normal to the line. Data for two- and four-conductor bundles show lower swing angles, especially at lower wind speed. It is conservative to use for bundles the same data as for single conductors. The curves are based on a span length of 300 m. Longer spans may have slightly lower swing angles, and shorter spans may have slightly higher swing angles. However, the difference is not significant for spans longer than 150 m. The data are based on the experience at a site with wind that is probably more uniform and has wider and longer lasting gusts than most other locations. For this reason, the data may be conservative.

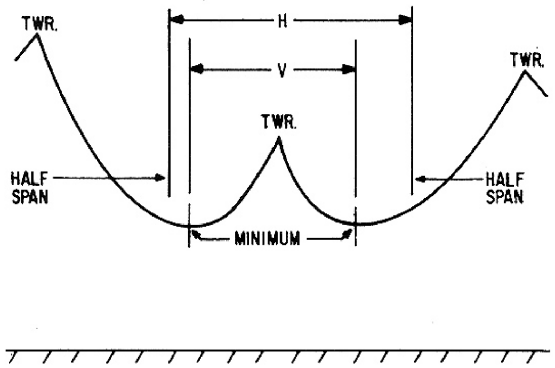

Figure A5.1-1 Illustration of the horizontal and vertical spans.

Wind Speed Statistics

Wind speed data from first-order U.S. Weather Bureau stations are housed at the National Climatic Data Center in Ashville, North Carolina. Hourly records of 2-minute-average wind speeds are available, as well as the daily peak 2-3 second gust (5-second gust for more recent records). The 2-minute hourly means may reasonably be used as hourly averages for statistical analyses. If this raw data is used for analysis, proper consideration must be made of the anemometer height and exposure, length of record, sampling error, averaging times, statistical analysis model, and height and exposure of the line under consideration.

For assessment of insulator swing angles, a recurrence interval wind speed (for example, 50-year recurrence means that the wind speed will occur every 50 years on average, or with a probability of 0.02 per year) should be used that is consistent with other design issues on the line. Recurrence interval gust wind speeds are available in ASCE 2003 (50-year nominal speeds are in maps, and tables can be used to convert to other recurrence intervals). The wind speed can be converted to a static load equivalent

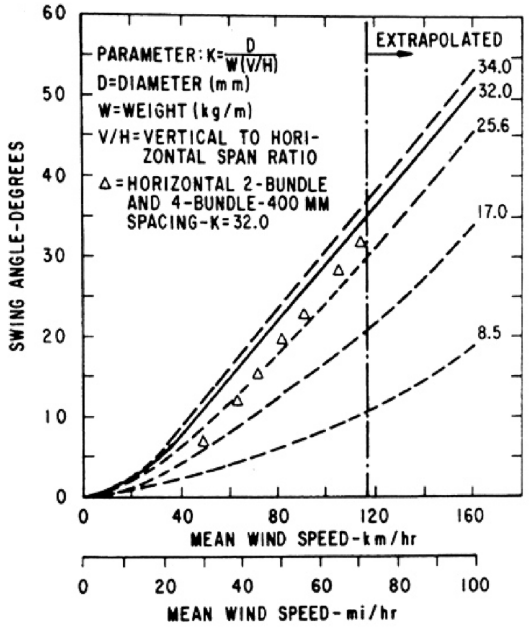

Figure A5.1-2 Swing angle as a function of mean wind speed. Curves are for single conductors. Data points for bundles of two and four conductors.

to an effective gust load for swing angle calculation using ASCE Manual of Practice (ASCE 1991). The 1991 version of this manual is based on older "fastest mile of wind" map that is obsolete. For use in this model, peak gust values from ASCE 7 can be converted to a "fastest mile" wind speed using Table A5.1-1.

Table A5.1-1 Conversion of Gust Wind Speed to Fastest Mile Wind Speed

Gust Speed (mph)	85	90	100	110	120	130	140	150	160
Fastest Mile Speed (mph)	70	75	80	90	100	110	120	130	140

APPENDIX 5.2 MODEL FOR THE CALCULATION OF SWITCHING IMPULSE STRENGTH OF AIR GAPS

Among the various models of the flashover process with positive switching impulses (see Section 5.3), the model proposed by Carrara and Thione (Carrara and Thione 1976) and later perfected by Rizk (Rizk 1989a, 1989b) appears to be the most practical and amenable to provide satisfactory results when applied to a variety of geometrical configurations. It should be emphasized that, while this model provides satisfactory results for most common situations, full-scale tests in outdoor high-voltage laboratories will provide more reliable results for an unusual situation or tower geometry and should be preferred.

The objective of the model is to calculate the critical 50% flashover voltage of air gaps with any given geometry. The model applies to positive polarity switching impulses with critical times-to-crest. It is based on the experimental observations regarding the various phases of the flashover process made by the Les Renardieres Group (Les Renardieres Group 1972, 1974, 1977, 1987).

The flashover process involves various phases: first corona, leader inception, leader propagation, and final jump (see Section 5.3). First corona is very difficult to assess; it is very dependent on the detailed shape of the high voltage electrode, and does not have a direct impact on the flashover voltage. For critical times-to-crest (corresponding to the lowest possible flashover voltage), the leader advances in the gap in a more or less straight fashion and in a continuous way (without sudden stops, dark periods, and re-illuminations) until, with a sudden final jump, the discharge reaches the grounded electrode. The initiation and propagation of the *continuous leader* are the two most important aspects of the model. Continuous leader inception appears to be dependent on the type of high-voltage electrode (for instance, conductor rather than rod), but less on the detailed shape of the electrode (conductor diameter or shape of rod tip). The model is based on the following assumptions:

1. The continuous leader starts when the streamer discharge activity at the high-voltage electrode has reached a critical stage, defined by the size and shape of the streamer space charge and by a critical electric field, E_c, at the tip of the streamers' stem, where the continuous leader initiates.
2. The stem of the streamers is assumed conductive, and its tip at the same voltage as the high-voltage electrode. The field, E_c, may be assessed assuming that the stem's tip is equivalent to a sphere with very small radius, r_{eq}, at the conductor voltage and located at a short distance from the electrode surface. The field, E_c, is then the sum of three components.

$$E_c = E_{lc} - E_a + E_b \qquad \text{A5.2-1}$$

E_{lc} is the field at the surface of the small sphere if there were no space charge; this field is proportional to the voltage and depends only on r_{eq}.

$$E_{lc} = \frac{V_{lc}}{4\pi\varepsilon r_{eq}} \qquad \text{A5.2-2}$$

E_a is the field at the surface of the small sphere caused by the space charge and by the image of the space charge in the high-voltage electrode. This field is of opposite direction to the electrostatic field, as the space charge tends to shield the streamer's stem. It is assumed that, at the critical stage, the value and location of the space charge are such that E_a is proportional to the voltage. This is a key assumption, based on experimental evidence.

$$E_a = \frac{V_a}{4\pi\varepsilon r_{eq}} = \frac{Q_0 / X}{4\pi\varepsilon r_{eq}} = \frac{c \cdot V_{lc} / X}{4\pi\varepsilon r_{eq}} \qquad \text{A5.2-3}$$

V_a is the space potential at the stem's tip caused by the space charge, Q_0, and by the image of Q_0 in the high-voltage electrode. The quantity X is a distance, function of the geometry of the high-voltage electrode, of the distribution of the space charge, and of the location of the small sphere. The parameter c, which has the dimension of capacitance, is the ratio between Q_0 and V_{lc} and will assume a certain value when the streamer discharge activity reaches the critical stage. It is not necessary to know the values of c and X, but only to realize that the electric field E_a depends only on the continuous leader inception voltage and on quantities related to the geometry of the high-voltage electrode and to the space charge at the critical stage.

E_b is the field at the surface of the small sphere caused by the image of the critical space charge in the grounded electrode. For calculating this field, the space charge may be assumed lumped at a point near the high-voltage conductor. It follows that, in addition to the small sphere

radius, E_b depends on the value of the critical space charge, and on the gap geometry.

$$E_b = \frac{V_b}{4\pi\varepsilon r_{eq}} = \frac{Q_0 / R}{4\pi\varepsilon r_{eq}} \qquad \text{A5.2-4}$$

V_b is the space potential at the stem's tip caused by the image of Q_0 in the grounded electrode. The quantity R is a distance, a function of the gap geometry. For instance, when the grounded electrode consists of the ground plane, $R = 2L$ (L is the gap length). R can be evaluated even for complex geometries of the grounded electrode, using the charge simulation method applied to 3-D configurations (Applet S-1).

3. The continuous leader inception voltage, V_{lc}, of a given air gap geometry with a given type of high-voltage electrode (conductor or rod), but a grounded electrode different from a plane is calculated by requiring that the critical electric field, E_c, at the tip of the streamers' stem is the same as that of an electrode (conductor or rod)-plane configuration with the same critical space charge: $E_c = E_{c,plane}$.

$$\begin{aligned} E_c &= E_{lc} - E_a + E_b \\ &= \frac{V_{lc}}{4\pi\varepsilon r_{eq}} - \frac{V_{lc}}{4\pi\varepsilon r_{eq}} \cdot \frac{c}{X} + \frac{Q_0}{4\pi\varepsilon r_{eq}} \cdot \frac{1}{R} \end{aligned}$$

$$\begin{aligned} E_{c,plane} &= E_{lc,plane} - E_{a,plane} + E_{b,plane} \\ &= \frac{V_{lc}}{4\pi\varepsilon r_{eq}} - \frac{V_{lc}}{4\pi\varepsilon r_{eq}} \cdot \frac{c}{X} + \frac{Q_0}{4\pi\varepsilon r_{eq}} \cdot \frac{1}{2L_{plane}} \end{aligned} \qquad \text{A5.2-5}$$

L_{plane} is the gap length of the electrode-plane configuration that produces the same continuous leader inception voltage and critical space charge. This occurs when

$$\frac{1}{R} = \frac{1}{2L_{plane}} \quad i.e. \quad L_{plane} = R/2 \qquad \text{A5.2-6}$$

Therefore, the continuous leader inception voltage of an air gap with any geometry of the grounded electrode is equal to the continuous leader inception voltage of the energized electrode-plane geometry with a gap length equal to $R/2$.

4. The continuous leader inception voltage for conductor-plane is given by Equation A5.2-7 and for rod-plane by Equation A5.2-8. The general forms of these equations were based on theoretical considerations, and the coefficients were derived from experimental data (Rizk 1989a, 1989b).

$$V_{lc} = \frac{2247}{1 + \dfrac{5.15 - 5.49 \cdot \ln(r)}{L \cdot \ln \dfrac{2L}{r}}} \text{ for conductor – plane} \qquad \text{A5.2-7}$$

$$V_{lc} = \frac{1556}{1 + \dfrac{3.89}{L}} \text{ for rod – plane} \qquad \text{A5.2-8}$$

V_{lc} is the continuous leader inception voltage in kV, L is the gap length in meters, r is the radius of the conductor in meters.

5. Equation A5.2-7 applies to cylinders with a radius smaller than a critical value, and Equation A5.2-8 applies to rods or spheres with a radius smaller than a critical value. For clean and dry electrodes with radius of curvature greater than a critical radius, the continuous leader inception voltage coincides with the first corona inception voltage. Critical radii for spheres and for cylinders are given by Equations A5.2-9 and A5.2-10, respectively. The first corona inception gradient is given by Figure A5.2-1 for cylinders and by Equation A5.2-11 for spheres.

$$R_c = 3.7 \cdot \ln(1 + L) \text{ for cylinders} \qquad \text{A5.2-9}$$

$$R_c \cdot \left(1 + \frac{0.224}{R_c^{0.37}}\right) = \frac{0.667}{1 + \dfrac{3.89}{L}} \text{ for spheres} \qquad \text{A5.2-10}$$

$$E_i = 2400\left(1 + 0.0113 / \sqrt{R} + 0.213 / \sqrt{R}\right) \text{ for spheres} \qquad \text{A5.2-11}$$

L, R_c, and R are in meters; E_i is in kV/cm

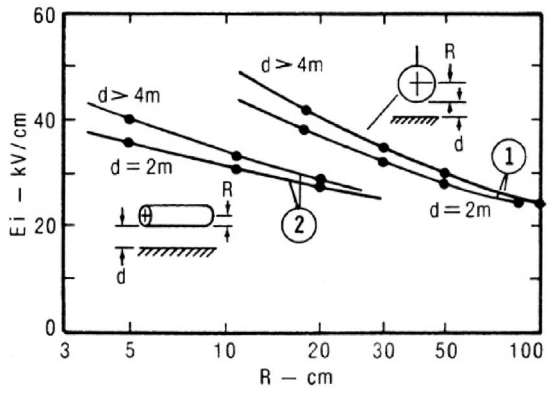

Figure A5.2-1 First corona inception gradient versus radius for cylinders.

6. The continuous leader propagates into the gap by maintaining a constant potential at its tip—i.e., the potential at the tip of the leader is always equal to the leader inception voltage, V_{lc}.
7. The continuous leader propagates toward the grounded electrode along the direction of highest electric field at a constant velocity v = 1.5 cm/μs.
8. The electric field along the continuous leader is E_i = 400 kV/m for a newly formed leader section. The electric field in a leader section decays to E_∞= 50 kV/m with a time constant θ = 50 μs (corresponding to $x_0 = v \cdot \theta$ = 75 cm of leader propagation).
9. The final jump occurs when the average electric field between the tip of the leader and the grounded electrode reaches a value, E_s = 400 kV/m when the grounded electrode is a plane or a structure and E_s = 500 kV/m when the grounded electrode is a rod.
10. The final jump occurs at great speed, and its duration may be considered zero.
11. The above criteria apply to the minimum flashover voltage, which is defined as $V_B = V_{50} / (1 + 3\sigma / 100)$. The standard deviation, σ, is taken as 3% when the high-voltage electrode is of conductor type and 5% when it is of rod type.

From items 6, 10, and 11, it is concluded that:

$$V_{50} = \frac{V_B}{1 + 3\sigma / 100} = \frac{V_{lc} + \Delta V}{1 + 3\sigma / 100} \qquad \text{A5.2-12}$$

ΔV is the voltage drop along the leader.

From items 6 and 9, the height, H, of the final jump is related to the leader inception voltage by:

$$H = \frac{V_{lc}}{E_s} \qquad \text{A5.2-13}$$

The length of the continuous leader at the instant of the final jump is:

$$L_{lc} = L - H = L - \frac{V_{lc}}{H} \qquad \text{A5.2-14}$$

Knowing the length of the continuous leader and considering items 7 and 8, Equation A5.2-15 is derived:

$$\Delta V = L_{lc} \cdot E_\infty + x_0 \cdot E_\infty \cdot \ln\left[\frac{E_i}{E_\infty} - \frac{E_i - E_\infty}{E_\infty} \cdot e^{-L_{lz} / x_0}\right] \qquad \text{A5.2-15}$$

The steps for the calculation of the 50% flashover voltage of an air gap subjected to a switching impulse of positive polarity and critical waveshape are shown in Figure A5.2-2. The calculation algorithms are implemented in Applet S-1.

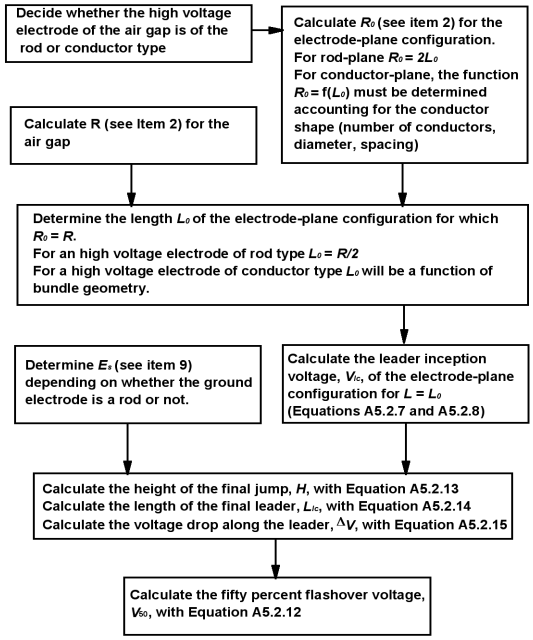

Figure A5.2-2 Steps for the calculation of the 50% flashover voltage of an air gap subjected to a switching impulse of positive polarity and critical waveshape.

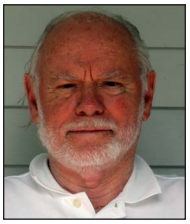
CHAPTER 6

Lightning and Grounding



William A. Chisholm
John G. Anderson

This chapter describes the mechanisms of lightning flash, the effects of those mechanisms on transmission-line equipment, and the methods for mitigation of effects. Included are descriptions of measurement and detection systems, surge impedance effects, calculation methods for insulation strength and shielding failures, initiation of flashovers, and transmission-line grounding measurement techniques and tools.

Dr. William A. Chisholm is an internationally acknowledged expert in lightning protection, insulation, and thermal rating of power systems. He is a Senior Research Project Manager in the Transmission and Distribution Technologies group of Kinectrics, the former Research Division of Ontario Hydro, now a division of AEA Technologies PLC. In this capacity he has completed research contract and project work for more than 40 electric utilities, manufacturers and research organizations.

Dr. Chisholm was recognized as the editor of the "Best Standard" award in 1999 for the IEEE Standard 1243, *Guide to Improving the Lightning Performance of Overhead Transmission Lines.* He is a corresponding member of CIGRÉ Study Committee 33 working groups on lightning and insulator icing test methods. He is the chairman of the IEEE Power Engineering Society Lightning and Insulator Subcommittee and a member of the PES Editorial Board.

John G. Anderson is one of the original authors of the *EPRI Transmission Line Reference Book,* including the chapter on line lightning performance. He has had more than 50 years of high-voltage engineering experience, and is a Life Fellow of the IEEE and an elected member of the National Academy of Engineering. He is a former manager of the General Electric High Voltage Laboratory and served as a consulting engineer for General Electric and also as a senior consultant for Power Technologies, Inc. He was one of the original researchers at the Lenox, Massachusetts EPRI Project EHV and later Project UHV, and also carried out lightning research at the Empire State Building in New York City. He is the author/coauthor of more than 40 technical papers and coauthor of three books concerned with high-voltage transmission, lightning, and insulation performance.

6.1 INTRODUCTION

Lightning flashes occur many times over the design life of a transmission line. The initiation of a flashover across line insulation may occur in response to a severe flash. This flashover process involves poorly defined gas discharge physics, fast-changing electromagnetic fields relative to the structure size, time-dependent nonlinear effects of corona development, and time- and current-dependent impedance of the earth electrodes. The problem must be evaluated in the context of large uncertainties in the lightning parameters and smaller, but significant, uncertainties in the line description.

6.1.1 Historical Context

Depictions of lightning exist on Akkadian clay roll seals as far back as 2200 BC and in Leviticus (Golde 1977), and "thunder magic" was common in early cultures. However, it was not until the 18th century that the electrical nature of lightning was recognized by Franklin and others (Schonland 1964). The first physicist to be killed carrying out electrical experiments on lightning was G.W. Richmann in St. Petersburg, Russia. In 1752, he was duplicating Franklin's sentry-box experiment, a variation of Franklin's kite experiment, and was killed by a direct flash to his equipment.

The invention of the Boys camera (Boys 1926), in which photographic film was moved at high speed by an open lens at night, provided the first resolution of the initial downward leader velocity and the multiple return strokes that followed. This photographic technique has been used since that time to dissect all those characteristics of the lightning sequence that involve light, much of the early research being done by Schonland in South Africa (Schonland 1956), although now it is usually replaced by electronically-triggered streak or fast frame-rate pixel cameras.

In 1939 and later, direct stroke measurements were made at the Empire State Building, New York City, (McEachron 1939, Hagenguth and Anderson 1952) and by McCann (McCann 1944) in Pittsburgh. Such work was continued after World War II by many investigators, of which the researches by Berger at Mount San Salvatore in Switzerland from 1947 to 1975 were particularly outstanding (Berger et al. 1975). The widespread application of practical lightning location systems started in the late 1970s, with the theoretical and experimental work of Krider, Noggle, and Uman (Krider et al. 1976), combined with advancements in telecommunications to make real-time lightning detection economically feasible.

6.1.2 Lightning Protection of Transmission Lines

The use of overhead catenary wires for lightning protection started early in the electric power utility industry. Original design blueprints for the first power lines from Niagara Falls show intended mounting locations for overhead ground wires above each phase conductor, for a total of seven overhead groundwires per tower. The industry quickly established that a single wire, located several meters above the phases and acting as a horizontal lightning air terminal, gives nearly perfect protection at much lower cost. However, the true role of overhead groundwires in lightning protection was not fully described until the 1930s, after photographic methods led to a proper understanding of the lightning progression mechanism.

The 1930s were particularly fruitful in transmission-line lightning research, driven by a need to ameliorate plagues of serious lightning damage to transmission lines and station equipment occurring at that time. This period included some of the first direct measurements of lightning currents and resolutions of stroke current waveshapes, polarities, and magnitudes. This period also led to major advances in surge arrester design, insulator development, and the understanding of interactions between incoming transmission-line lightning transients and transformer windings.

In North America and many other parts of the world, lightning still remains the primary cause of transmission-line outages, momentary interruptions, and reliability and maintenance problems. On a multi-circuit line, simultaneous flashovers by lightning of two or more circuits can cause particularly severe disruptions to service, and 40-60% of flashovers on double-circuit towers can usually be expected to involve both circuits. A lightning strike can generate millions of volts across line insulators, sometimes leading to insulator tracking, punctures, and shed damage. Power frequency arcs triggered by lightning flashovers are then a major source of melting, burning, and pitting of wires, corona shields, and supporting hardware. High-voltage traveling waves injected onto phase conductors by tower flashovers or by shielding failures can travel for long distances to enter substations and present severe challenges to transformers, circuit breakers, and other components. The strong electromagnetic fields created by a flash to earth can induce enough voltage on a distribution or subtransmission line to flash over the line, even though the flash does not contact the line directly. Tower-mounted communications equipment and overhead shield wires with encased optical fibers are also vulnerable unless properly protected.

6.1.3 Simulation of Lightning on Transmission Lines

Lightning in all its complex physics is highly statistical in incidence, magnitudes, charge delivery, and all other electromagnetic effects that initiate line flashovers. In any given geographical area, meteorology dictates that the

number of hits to earth or to lines in the area can vary greatly around the observed averages—by 3:1 or more. Lines can be designed for a flashover return period of once in 20 years, and yet have a flashover the first year. Lines that require a very high reliability can be engineered and be largely successful, but may occasionally deliver a surprise from an unexpected and unusual lightning event. This chapter covers the principal statistics of this process in some detail.

Conversely, very often lightning has been designated as the culprit in a line tripout, when no lightning was actually involved. The recent growth of the North American Lightning Detection Network (NALDN) and similar networks around the world has made extensive data available on ground flash magnitudes, times, and locations. In principle, one can now determine whether a lightning flash at that location at the same time accompanied a line flashover, and—if so— the magnitude of the first stroke current in the flash. This technology provides estimates of stroke current parameters such as polarity, peak amplitude, and multiplicity. These estimates can often flag the root cause of the flashover, whether a shielding failure or a backflashover, so the proper remedial measures can be undertaken.

A wide range of software tools and design equations supplement the real-world laboratory of random stimulus (lightning strokes) and response (time-correlated records of transmission-line breaker operations). In this edition, the authors review some of the software simulation programs available to the reader to model lightning performance and discuss in some detail the advantages and limitations of each. A good simulation program has to handle the statistics of the process as well as the physics of breakdown and the response of the transmission system. Corrective actions for unsatisfactory performance can expend large quantities of money with little actual gain unless the user first determines the actual cause of the failures. Simulation programs can be very helpful in arriving at effective improvement strategies.

In the second edition of this Reference Book (EPRI 1982), a step-by-step, linearized numerical solution was developed to describe the problem in an approach that was developed for hand or programmable calculators. The industry (IEEE 1985, IEEE 1993, IEEE 1997b) found that this simplified method (based on a fixed 2-μs ramp wave, a deterministic volt-time description for insulator strength, simple models for corona effects, and relatively detailed traveling-wave analysis) gave results that were as satisfactory as any sophisticated prediction method. The "Red Book Method" was adapted into the IEEE FLASH program that forms part of IEEE Standard 1243 and formed an important basis for teaching the subject to a generation of graduate students and engineers.

Since the second edition, there has been considerable improvement in the ability to carry out numerical modeling on personal computers. An engineer or student would now use a simple spreadsheet or Internet applet rather than the eight-page schedule of calculations. Statistical and mathematical functions are available directly within these applications and do not require simple approximations. The computer even provides the new ability to visualize the downward and upward development of the leader, the traveling-wave response of the line, or the nonlinear effects of corona envelopes in the air and in the ground.

Hand in hand with this improved capability are improvements in our understanding of the individual components of the lightning problem. The overall level of risk in the second edition was based on the number of thunderstorm days per year, while this third edition makes use of observations from lightning location technologies. The statistics of stroke parameters based on measurements from around the world can be discussed quantitatively. The lightning attachment process no longer needs to rely fully on empirical description, as extrapolation of models for large-gap switching surge breakdown are found to give satisfactory predictions too. The physics of the lightning impulse flashover for typical 1-3 m insulation length has been studied, and improved numerical models have been proposed (CIGRE 1991). Details of tower and ground plane surge impedance have received scrutiny, and the entire subject of grounding has been simplified. Finally, and perhaps most importantly, utilities and researchers have tested the assertion in the second edition that "large negative first strokes cause the majority of transmission line outages" by comparing transmission-line flashover records with lightning location network records to form their own conclusions.

6.1.4 Capital Cost of Lightning Protection for Transmission Systems

The strength, weight, and cost of transmission towers are usually established by the transverse wind loading. The overturning moment on the transmission towers is the sum of traverse wind forces on each wire, multiplied by each wire height at the tower. The overhead groundwires are the tallest conductors, and in cold regions, they accumulate nearly the same ice thickness as phase conductors of larger diameter.

The tower weight needed to withstand traverse forces on conductors can be estimated simply from Equation 6.1-1:

$$W = K_m \sum ht \qquad 6.1\text{-}1$$

Where:

W = the tower weight (kg).
t = an individual traverse force (kg) located at attachment height h (m).
K_m = a coefficient of 0.014 kg/(m-kg) for double-circuit HV and EHV lattice towers.
K_m = a coefficient of 0.013 kg/(m-kg) for single-circuit horizontal EHV towers.
K_m = a coefficient of 0.021 kg/(m-kg) for single-circuit horizontal HV towers.

The coefficient relating tower weight and transverse forces varies depending on utility design practice and has trended downward over time. Good practice calculates the wind pressures on conductors and towers independently, and applies each force at the correct centroid, but for approximate purposes, the ratio of (Total) to (Conductor) overturning moment can be fixed at 1.9. Typical values of overturning moment for a double-circuit 345-kV line would be (t = 410 kg, h = 41 m) for two groundwires, and (t = 950 kg, h = 18 m, 25.5 m, and 33 m) for twelve conductors. The total tower moment from conductors would be 324 Mg-m, and the pressure of the wind on the tower adds 288 Mg-m. The total tower weight would be 8420 kg from Equation 6.1-1. If there were no overhead groundwires to support, the overturning moment would be only 549 Mg-m, and the tower weight would only be 7560 kg, a difference of 860 kg.

Table 6.1-1 shows the additional tower weights needed to support overhead groundwires for eight typical base-case conditions, as found in the appendix describing base cases. With four towers per km and a tower steel cost of $7/kg, the extra cost of supporting overhead groundwires above the 345-kV double-circuit base-case line is $2.4 M for a 100-km line.

6.1.5 Benchmark: Cost of Avoided Momentary Outages

The cost of supplying and supporting overhead groundwires (OHGW) is not the only cost of lightning protection using overhead groundwires. As transmission voltage increases, choices in the electrical layout have increasing influence in the extra costs of generation capacity and energy. Over the 50-year life of an overhead groundwire in areas of moderate lightning activity, there are three substantial costs: capital, peak loss, and energy loss. In an approximation with U.S. dollars in 2003, these costs are:

- **Capital Cost**—the capital cost of OHGW protection. This was established in Section 6.1.4 as $2.4 M per 100 km for the 345-kV double-circuit base-case line.
- **Peak Loss Cost**—the marginal cost of providing peak generation at peak load. As described in Section 7.9.2, and modeled using Applet EMF-8, currents of 92 A are induced in each of two overhead groundwires of the 345-kV double-circuit base case with "superbundle" or ABC/ABC phasing at a typical peak load of 1 A per kcmil of conductor cross-section. The loss at peak load of 2.6 MW per 100 km requires additional installed peak capacity at US_{2003}$ 2 M/MW, with a capital investment of $5.2 M per 100 km of OHGW.
- **Energy Loss Cost**—the present value of the continuous I^2R loss in the OHGW. Typical average loading would be one-third of peak; so continuous loss would be one-ninth of peak (290 kW per 100 km), and the cost of the energy loss at $0.05/kWh would be $120,000 per year per 100 km. This would have a present value of $3.2 M at 3% interest rate over 50 years.

The "superbundle" configuration was deliberately chosen to highlight the cost of energy losses in the overhead groundwires for EHV systems. Consider instead the situation where a low-reactance phasing, ABC/CBA, is used on the same 345-kV double-circuit line.

- Capital cost remains the same at $2.4 M extra per 100 km.
- Induced currents are reduced from 92 A to 11 A with the low-reactance phasing.
- Cost of additional generation capacity and energy are reduced by 98% and can now be neglected.

Table 6.1-1 shows that the control of overhead groundwire-induced currents, using favorable low-inductance phasing, optimal placement, or other methods in Applet EMF-8, becomes increasingly important as system voltage increases.

The load capability, and thus the number of customers affected by a transmission-line lightning outage, increases nearly as the square of line voltage. This results from the use of an increasing number of subconductors, providing greater ampacity. It is possible to compute the cost of an avoided momentary outage, using the difference in outage rate between a protected and an unprotected line. This calculation was carried out for an area of moderate ground flash density, N_g = 1.0 flash per km^2 per year. As an example, again using the 345-kV double-circuit line with 100 km length as a base case:

- The line would serve a summer peak of about 8500 MW, with each customer drawing 24 kW at a normal precontingency load of 3800 MW.
- A momentary outage on one circuit, successfully reclosed, would still introduce a voltage dip exceeding 50% for three cycles for 160,000 customers at the load end.
- Without lightning protection, there would be about 880 direct flashes to the unprotected upper phases over a 50-year exposure, and nearly all would cause phase-to-ground flashovers.

Table 6.1-1 Cost of Avoided Customer Momentary Outages using Overhead Groundwires in Area of Low Ground Flash Density (N_g = 1.0 (flashes/km²)/year)

System	Top Phase Height (m)	Extra Tower Weight (kg each)	Induced Current in OHGW[1] (A)	OHGW Loss /100 km at Peak Load	TOTAL[2] Capital in OHGW ($/ 100 km)	Cost Per Avoided Customer Momentary Outage[3]
230-kV Single Circuit	10.3	570	15.3	0.07 MW	$1.8 M	14¢
345-kV Single Circuit	12.5	710	33.7	0.3 MW	$3.1 M	9¢
500-kV Single Circuit	14.0	860	71.2	1.6 MW	$7.5 M	8¢
765-kV Single Circuit	18.5	1210	138.8	7.3 MW	$27 M	8¢
230-kV Double Circuit	15.3	620	26.7 SB 2.7 LowZ	0.2 MW 0.002 MW	$2.4 M $1.7 M	5¢ 4¢
345-kV Double Circuit	26.5	860	92.1 SB 11.2 LowZ	2.6 MW 0.04 MW	$10.8 M $2.5 M	8¢ 2¢
500-kV Double Circuit	31.0	940	140.8 SB 29.3 LowZ	7.5 MW 0.26 MW	$27 M $3.2 M	8¢ 1¢
765-kV Double Circuit	41.8	1300	262 SB 60.8 LowZ	26 MW 1.1 MW	$88 M $6.0 M	8¢ 1¢

SB = Superbundle phasing (ABC/ABC); LowZ = Low Reactance phasing (ABC/CBA).
1. Assuming 1 A per kcmil of conductor cross section at peak load for cost of capacity.
2. Cost of extra steel in towers, extra capacity at $2000/kW, and present value of energy at $0.05/kWh.
3. Assuming 24 kW per customer near summer peak load with dew point temperature > 25°C.

- With two overhead groundwires, there would be about 1000 direct flashes, and only 2% of these (17 over 50 years) are estimated to cause flashovers at a typical footing resistance.
- The overhead groundwires eliminated a total of (880-17) (160,000) customer momentary outages.
- With an overhead groundwire cost of $10.8 M using a high-loss superbundle configuration, the utility is spending about eight cents to prevent each momentary outage at a customer service entrance.
- The utility could provide the same protection at a cost of one cent per avoided customer momentary if it manages overhead groundwire circulating currents efficiently.

This investment level varies widely with customer and lightning ground flash density. The investment reaches nearly $1.00 per avoided momentary in some systems. The calculation can serve as a benchmark for regulation of other power quality investments, once suitable local values are substituted for the construction, generation, and energy costs; lightning flash density; transmission-line configurations; and number of customers affected by each momentary outage.

The cost of interruption to customers also varies widely, depending on the nature of the load. Table 6.1-2 summarizes costs of momentary outages, expressed as a sum of $US per kW (the momentary component) and $US per kWh (which can be neglected for momentary duration).

Table 6.1-2 Average Cost[1] of Single Interruption for Industrial Plants (IEEE 1997a, Table 2-5)

Industrial plants with <1 MW maximum demand	$15.61/kW + $27.57/kWh
All industrial plants	$6.43/kW + $9.11/kWh
Industrial plants with >1 MW maximum demand	$3.57/kW + $3.20/kWh

1. US$ 1997.

The cost of power interruption to commercial or office buildings is similar to the cost for small (<1 MW) industrial load (IEEE 1997a, Table 2-7). Clearly, from the industrial customer's point of view, utility investment in overhead groundwires and other lightning protection represents good value.

6.1.6 Organization and Contents of the Chapter

Section 6.2 describes the basic mechanisms of the lightning flash and results of recent analysis of these mechanisms. Section 6.3 reviews statistics and data on lightning flashes compiled through common measurement and detection systems. Section 6.4 discusses surge impedance and corona effects of lightning flash for a variety of conductors and tower shapes. Sections 6.5 and 6.6 provide calculation methods for insulation strength and shielding failure. Sections 6.7 through 6.9 explain the initiation mechanisms for backflashover, induced flashovers, and midspan flashovers. Section 6.10 describes tools and measurement methods for transmission line grounding. Appendix 6.1 discusses the disruptive effect algorithm to evaluate impulse failures of insulators. Appendix 6.2 gives some

additional details about the process of estimating lightning current from its distant radiated fields.

Several aspects of lightning can be calculated using simple software applications provided in the electronic version of this book. The user may exercise the following applets:

- L-1: "Transmission Line Lightning Performance." This applet calculates backflashover rate and shielding failure rate for each phase (number per km per year) given the input of line geometry at the tower, sag, phase voltages, insulator lightning impulse strength, span length, ground flash density, tower footing parameters, shield wire surge impedance, constants of the basic equations describing striking distance, and number of strikes to the line.
- L-2: "Stroke Attraction Model." This applet calculates the possible paths of lightning strokes as they descend from the cloud to hit the shield wires, the phase wires, or the ground.
- L-3: "Dynamic Tower Footing Resistance." This applet calculates the resistance of ground rods versus current and versus time, given the number and length of the rods, soil resistivity, soil dielectric strength, current peak value and waveshape.
- L-4: "Tower Lightning Flashover Tutorial." This applet calculates the currents and voltages that characterize the process of tower insulation flashover due to a lightning stroke that hits the tower. The applet is tutorial in nature, because it allows the user to verify in a friendly graphical way the effect of several physical parameters, such as stroke peak current, stroke waveshape, maximum stroke steepness, tower height, tower surge impedance, shield wire surge impedance, tower footing resistance characteristics, location of phase conductor in relation to the ground wire hit by lightning, height of the crossarm to which the insulators are attached, insulator string length, and span length. The applet shows how these parameters affect the current down the tower, the voltage between tower top and earth, the voltage between tower base and earth, the voltage across the phase insulator, and the disruptive effect on the insulators.
- L-5: "Tower Surge Impedance." This applet calculates the equivalent surge impedance of a tower to be used in simple models for lightning flashover calculations (Applet L-1 and Applet L-4) and shows how this surge impedance depends on the geometry of the tower. This applet calculates the response of a transmission tower when a unit current step is injected at the top of the tower and the response to a variety of current waveshapes. The applet shows the tower current, the tower top voltage, the tower base voltage, and the voltage at each crossarm versus time.
- L-6: "Step and Touch Potential." This applet calculates the potential of points on the ground with respect to earth, the step potential, and the maximum touch potential when lightning current flows from tower to earth. The potentials are calculated for the no-ionization case and are expressed as a percentage of the tower base-to-earth voltage. Potentials and step potentials are calculated at any desired point, or along a straight line, or in a rectangular area defined by the user. The applet can provide contour maps of potential and step potential.
- G-2: "World Map of Ground Flash Density and North American Map of Earth Resistivity." This applet provides some basic geophysical data that can be used to evaluate lightning protection in any region.

6.2 THE LIGHTNING FLASH

The following terms have been defined to encourage consistent description of lightning phenomena among engineers and researchers.

- ***Flash***—a term encompassing the entire electrical discharge from cloud to stricken object.
- ***Stroke***—the high-current components in a flash. A single flash contains a first stroke and may contain one or more subsequent strokes.
- ***Flashover***—an electrical discharge completed from an energized conductor to a grounded support. It may clear itself without tripping a circuit breaker.
- ***Backflashover***—an electrical discharge completed from a grounded support to an energized conductor. It may clear itself without tripping a circuit breaker.
- ***Tripout***—a flashover or backflashover of a line that does not clear itself. It must be cleared by momentary operation of a circuit breaker, removing ac power long enough for the flashover arc to extinguish.

6.2.1 Cloud Electrification

Figure 6.2-1 sketches one of the many possible configurations of a thunderhead. It functions much as a gigantic chimney, drawing moist heated air from the land and feeding the air high into the stratosphere, 15,000 m or more. The upward winds can reach speeds of 300 km per hour. The rising moisture, which first super-cools as it rises, finally turns to snow, hail, and ice in the upper regions. There can be severe turbulence in these clouds, which commercial aircraft must avoid. The turbulence—involving intermixing and friction of raindrops, snow, ice, and hail—causes a strong electrification to take place. Cooray (Cooray 2003b) summarizes cloud electrification models, and notes that negative charging occurs in the temperature range from -15 to -30°C (in the middle of the cloud), while positive charging occurs from 0 to -15°C (the bottom of the

cloud) and at temperatures below -30°C (the top of the cloud) (see Figure 6.2-1).

As Figure 6.2-1 shows, the lower regions of the cloud usually become strongly negatively charged, with small pockets of positive charge frequently interspersed. The upper regions of the cloud—at temperatures far below the freezing point of water—have widely distributed positive charges, and often these charges are embedded in an "anvil top" created by the rising air currents. The net negative charge at the base of the cloud induces a similar positive charge on the surface of the earth beneath, and voltages between the base of the cloud and the earth can increase to 100 million volts or more. This charge concentration increases the voltage between cloud and earth until the dielectric strength of the moist air between cloud and ground is overcome, and a spark—the lightning flash—occurs.

6.2.2 The Stroke Mechanism—Negative Downward Leaders

Lightning flashes may have to traverse several kilometers to complete a path to earth. The progression of the lightning channel toward the earth is sketched in Figure 6.2-2 for a typical negative downward leader. As shown in Figure 6.2-2, the leader usually starts from a negative charge pocket in the cloud as a "stepped leader," so called because the discharge proceeds as a series of steps toward the earth. Each step appears as a faint glow discharge whose core may be a few centimeters in diameter and approximately 50 m long, surrounded by a corona envelope a meter or more in diameter. The tip at the bottom end of the leader exhibits some enhanced illumination caused by strong corona activity, and typically appears on a streak camera photograph as a sequence on glowing spots proceeding toward the earth. Each step starts at the lower end of the previous step, zigzagging toward the earth, often accompanied by downward branching.

A time interval of about 50 μs occurs between successive steps, but this time between steps shortens as the leader nears the earth below. The average velocity is in the range of 3 x 10^5 m/s, one-thousandth the velocity of light. The entire stepped leader acts as a conductor carrying a strong distribution of negative charge in its corona sheath as it moves toward the striking point. As the leader progresses, it carries negative charge from the charge pocket from which it began, and this charge distributes along the leader channel in the manner shown in Figures 6.2-3 and 6.2-5.

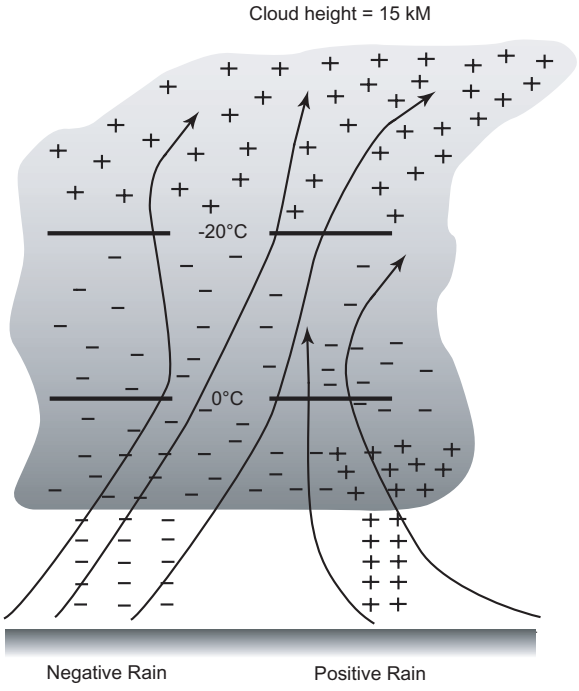


Figure 6.2-1 Electrification of a thunder cloud.

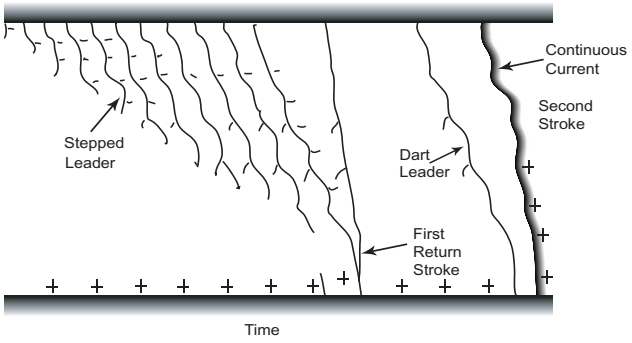

Figure 6.2-2 Progression of the downward leader and formation of the return stroke.

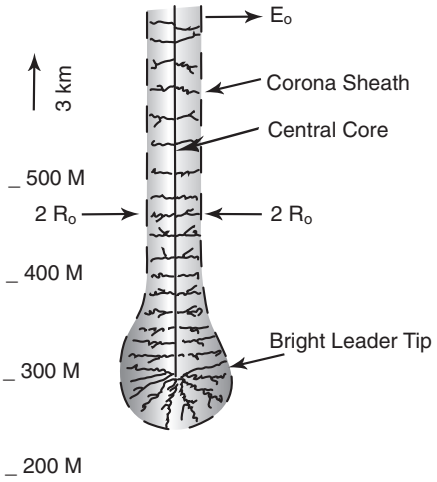

Figure 6.2-3 Storage of space charge in the corona envelope around the leader core (Hileman 1999).

In the stepping action, this charge is continually redistributing itself, feeding the leader tip as it moves and drawing more charge from the cloud charge pocket in what is essentially a progressive electrostatic process. As the leader tip approaches the earth, the leader charge creates a strong electric field at the earth's surface (or on a transmission-line conductor), and a leader is initiated from the earth and/or conductor, which moves upward to intercept the tip of the downward leader. When the two make contact, an electrical connection is created between cloud and earth.

This charge down near the lower end of the leader channel—not the charges in the cloud above—creates the very high and rapidly-changing currents injected into a transmission line. The charge distribution on the downward leader is not uniform. It is continually changing as the leader progresses, but the charge concentrates in the lower reaches of the channel, attracted by image charges in the earth below.

As the leader tip approaches within approximately 100 m of the earth (depending on the charge on the downward moving leader), the earth's electric field builds up to values greater than the dielectric strength of the air around pointed or protruding objects, and a positively charged upward leader rises from the ground or from a protruding object to meet the downward leader (Figure 6.2-2). When the two leaders merge, a current path now exists between cloud and ground. In classical terminology, the negative charges in the leader channel and its corona envelope now move down the completed channel toward the earth as the positive charges on the earth now move up the channel to meet them. The negative charge flowing down through an ammeter creates the same negative deflection as the positive charge flowing up through the other end of the same ammeter, so a powerful negative "return stroke" current moves skyward, eventually discharging most of the negative leader charge along the leader channel. The surge impedance of this return stroke channel is much higher than the impedance of any line conductor or transmission tower, so it can be considered to be a high-impedance current generator.

As shown in Figure 6.2-2, the first stroke can be followed by one or more subsequent strokes. A "dart leader" initiates each subsequent stroke. This dart leader progresses continuously down the ionized channel without stepping, and carries new charge extracted from other charge pockets in the cloud. As each dart leader reaches the ground terminal, it triggers another return stroke. These subsequent strokes tend to have lower magnitudes than the first stroke because the dart leader can move downward along the ionized path with less charge and less gradient at its tip. However, the higher conductivity tends to concentrate more charge per meter near its tip, and this creates a faster rate of rise of current, *dI/dt*. This high *dI/dt* can be an important contributor to the insulator flashover process for towers with high inductance, and is a dominant term in the electromagnetic pulse effects that affect nearby low-voltage or distribution systems. The mean number of strokes in a flash is three, but more than 20 strokes have been reported in unusual conditions.

Many return strokes are followed by continuing current flow of a few hundred amperes, representing a slow depletion of charge in the cloud. Because of its duration of many milliseconds, this low current can deliver more charge than that delivered by the return stroke, a characteristic similar to that of an arc welder. This charge transfer is primarily responsible for burning, melting, and other thermal effects associated with a lightning flash, including ignition of combustible material. Rakov and Uman (2003) estimate about 10% of the 1363 strokes in Florida and New Mexico had a continuing current of more than 40 ms.

6.2.3 The Stroke Mechanism—Upward Positive Leaders

When a tall object such as a river crossing tower, tall building, or mast is located on the earth under the same cloud electrification shown in Figure 6.2-1, a different triggering mechanism can occur. The electric field can build up around the top of grounded object so strongly that an upward leader is initiated from the object and moves toward a negative charge pocket at the base of the cloud, often accompanied by upward branching. This leader eventually completes the circuit, and negative current flows from the cloud to earth as a first stroke, and subsequent strokes can then follow. Analytical models from switching-surge flashover physics can be extrapolated (Rizk 1994) to give relatively simple estimates for the induced potential U_{ic} needed to initiate and propagate an upward positive leader from a vertical tower of height h (in m):

$$U_{ic} = \frac{1556\,kV}{1 + \frac{3.89}{h}} \qquad 6.2\text{-}1$$

One common lightning research strategy takes advantage of this upward initiation by firing small rockets toward a charged cloud with trailing wires attached to a grounded test object (Leteinturier 1990). An upward leader is emitted off the nose of the rocket as it approaches the cloud, completing the current path between the cloud and the ground, and a current flows down the wire. The wire vaporizes, but a complete ionized path then exists between the cloud and the test object for subsequent strokes to follow. This "triggered lightning" has been found to be very useful in simulating lightning hits to or near experimental objects such as

overhead wires, buried cables, arresters, or buildings (Barker et al. 1996; Schnetzer et al. 1995).

Structures having a height of 150 m or more (river crossings, tall masts, etc.) can initiate upward leaders directly without the necessity of an approaching downward leader. For this reason, they tend to collect a disproportionate share of lightning hits per year (Eriksson 1987; Gorin and Shkilev 1984). The 553-m CN Tower in Toronto, Ontario initiates an average of 70 upward flashes per year in an area of moderate ground flash density, some with upward leader development to charge centers more than 10 km away (Janischewskyj et al. 1997a).

6.2.4 The Stroke Mechanism—Positive Flashes

While the majority of lightning flashes deliver negative stroke currents, a small percentage are positive. Positive stroke currents tend to be of higher magnitudes and—although less frequent—can be more severe for surge arrester duty and metal erosion. Measurements from lightning location networks suggest a fairly wide variation of positive flash events over time and space, with a greater number of positive events in the winter, and areas in central North America and the Sea of Japan showing high positive-flash activity.

6.2.5 Charge and Voltage

Mazur and Ruhnke (Mazur and Ruhnke 2001) provide some recent experimental results for 24 low-current return strokes, measured from a lightning-location system. They measured time-correlated field changes associated with the return strokes at two locations. Figure 6.2-4 shows their estimates of leader potentials to earth as a function of leader charge.

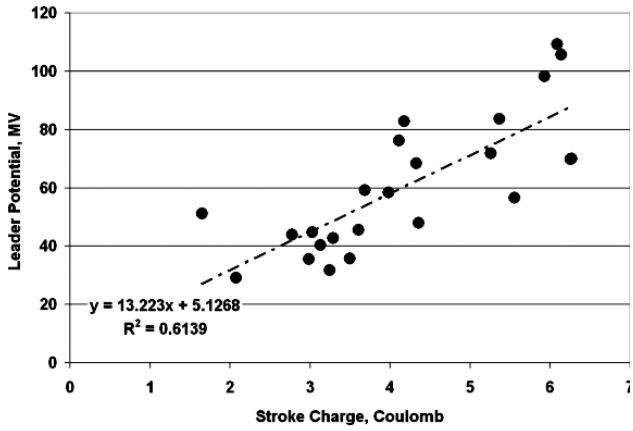

Figure 6.2-4 Experimental estimates of leader potential as a function of leader charge.

The leader potentials reached over 100 MV in two cases, with total charge approximating 6 C. Six coulombs released over a period of 100 ms corresponds to an average current of 60 A, but the same charge released in 100 μs corresponds to an average current of 60 kA.

6.2.6 Leader Diameter, Visibility, and Branching

Streak camera photographs of negative lightning usually show the stepping action as a series of bright dots along the channel, representing the strong ionization occurring at the leader tip at the end of each step. Between these tip discharges, little is to be seen, although ionization is occurring radially outward from the center of the channel as it moves. This radial ionization can extend from the core for a distance of a meter or more, as shown in Figure 6.2-4, and is responsible for the storage of the negative charge that is later swept up by the return stroke. If 31 kA is assumed for the median peak stroke current, and if this current is created by a linear charge moving at one-third the velocity of light, that charge equates to 3.1×10^{-4} C/m. Assuming the outer wall of this radial ionization expands until its gradient is less than a nonuniform field breakdown strength of air of approximately 20 kV/cm, application of Gauss' Law yields an ionization radius R_0 of 2.9 m in which charge is stored. Thus the downward leader can be regarded as a large cylindrical capacitor, which dumps its charge to earth via the return stroke.

In weak strokes, very little branching occurs, but if the downward leader channel contains excessive charge, the leader branches to maintain some kind of equilibrium at its walls. The branches proceed in the same direction at the main channel, usually downward because downward leaders initiate most flashes. If a flash is observed with upward branches, the assumption can usually be made that the flash was triggered by an upward leader emitted from a tall, earthed object. Two or more branches can sometimes reach the earth nearly simultaneously, creating multiple strikes to the earth or to a transmission line.

Both (Kitigawa et al. 1962) and (Rakov and Uman 1990b) report nearly 50% incidence of multiple earth terminations from the same downward leader. In some cases, distance between terminations can be more than 30 km, although most pairs are observed to hit the ground within 5 km of each other. This has led to discussion of whether it is more appropriate to evaluate lightning performance on the basis of ground stroke termination density, which could be as much as 1.7 times the traditional ground flash density. Another possibility is the use of the observed stroke flash density. At present, about 20% of flashes classed as first strokes by lightning location networks are probably the first of several subsequent strokes in events where the first stroke is difficult to observe remotely. Observation and

classification systems are being improved and validated using ground-truth (video) or high-performance Lightning Imaging Detection and Ranging (LIDAR) equipment. Accurate observation of multiple ground terminations and of subsequent stroke movements using lightning location systems may well prove to be of more value than the simple ground flash density values.

6.2.7 Structure and Progression of the Positive Upward Connecting Leader

The positive upward leader emitted from the earth or from a transmission line by induction from the downward leader negative charge (Figure 6.2-2) acts as the link to complete the lightning discharge circuit. The initiation characteristics and velocity of this upward leader play an important role in transmission-line shielding failures. The last step of the downward leader and its junction with the upward leader is frequently labeled the "final jump" or "striking distance," and several mathematical models of this striking distance have been proposed. Young, Clayton, Hileman, Brown, Armstrong and Whitehead proposed early models. The latter noted that this last step could appropriately be described by the switching surge behavior of large air gaps. Their application of the Paris-Cortina switching surge flashover data (CFO = 500 k_g $S^{0.6}$, kV, m) (Paris and Cortina 1968) led to the development of an early electrogeometric model for the shielding of transmission lines.

Later studies by (Dellera and Garbagnati 1990) and (Rizk 1989; Rizk 1994) have applied more comprehensive Leader Progression (LP) models of the switching-surge flashover process to the development of the upward and downward leader. The upward process in this case responds to the downward leader, initiating an upward streamer that, with increasing energy input, "thermalizes" into a leader, which then propagates upward. Rizk (Rizk 1994) defines the two conditions that must be satisfied—one for initiation of the positive upward "counter leader," and another for its stable propagation.

Electric Field Conditions

An upward leader from the earth initiates when the electric field at the earth's surface reaches some critical value. This field is from the combined effect of charges in the leader and in the cloud above it. For air at atmospheric pressure and 20°C, the balance between ionization and recombination occurs in uniform electric field strength of 2600 kV/m. The earth is invariably a nonuniform field electrode with projecting vegetation, rocks, or a variety of geologic features. Estimates of this critical gradient vary widely, depending on surface roughness, and the authors have used a median value of 500 kV/m for many common surfaces. Similarly, an upward leader from a transmission-line conductor initiates when the charge induced on the conductor by the approaching downward leader reaches some critical value, and 1500 kV/m on the wet conductor surface appears to be a workable value. Applet L-2 supplied in this chapter permits the user to experiment with different gradient values and actually observe the progression of the upward and downward leaders associated with one or two transmission lines on a right-of-way.

Structure of the Upward Leader

There are two distinct types of upward leaders: the upward leader initiated by the approach of a downward leader from the cloud, and an upward leader triggered from a tall structure in the absence of a downward leader. For a negatively charged cloud, both types carry positive charge and progress upwards as a continuous discharge without stepping and with an estimated velocity in the range of 0.6 to 1 m/μs, approximately twice the speed of the negative downward leader. The upward leader from a transmission line usually travels without branching since it is carrying a minimal charge, but the leader from a tall structure can display pronounced branching, which is one way of identifying by photography whether a flash to a tall structure was initiated by a downward leader from the cloud or by an upward leader from the structure.

Figure 6.2-5 shows the instantaneous magnitude of negative charge distributed on the leader channel as a downward negative leader approaches the earth. This charge distribution of the return stroke can be modeled with vari-

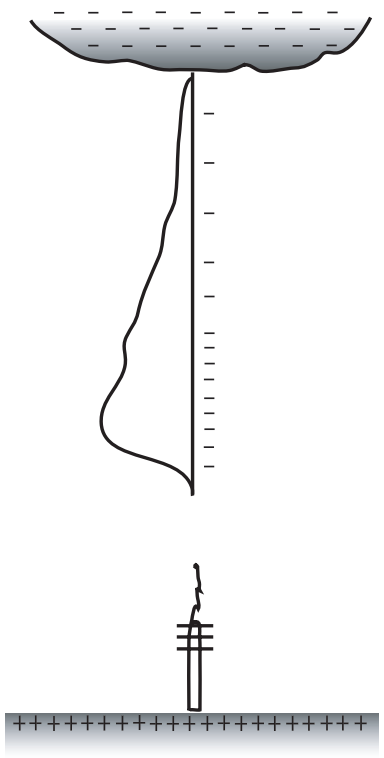

Figure 6.2-5 Distribution of charge on the downward leader.

ous return stroke models as a uniform distribution (Transmission Line, or TL model), a linear decay with height (Modified Transmission Line—Linear, or MTLL model), or an exponential decay with height (Modified Transmission Line—Exponential, or MTLE model) (Uman et al. 1975; Rakov and Dulzon 1991; Nucci et al. 1988 respectively). The peak charge can be 10^{-4} C/m or more. As the upward leader from the earth punches up through this channel charge on its way to the cloud above at approximately one-third the velocity of light (Figure 6.2-2), it can be thought of as an upward-moving grounded wire, collecting the channel charge as it moves. This collected charge moves down the return stroke channel at approximately the velocity of light, and the current waveshape measured at the ground end then replicates the charge distribution on the channel. The front time is greatly influenced by the way the stepping action distributes the charge on the lower end of the channel, as well as by the distribution of charge on the upward leader rising to meet it. This distribution makes the front of the first stroke concave, but subsequent strokes—being much faster—show much less concavity.

Junction with the Downward Leader

Figure 6.2-6, taken from (Anderson and Eriksson 1980), shows the observed "attractive radius" of a structure versus structure height. Attractive radius represents the radius measured outward from the top of a structure such that any downward leader tip within that radius initiates an ultimate strike to that structure. The attractive radius is closely related to "striking distance" in the electrogeometric model, which is the point of discrimination measured outward from the tip of the leader towards any nearby grounded object or line. Both models are partially correct: photographs show that the leaders develop from both ends simultaneously.

Attractive radius is seen to increase with height. Taking an extreme condition, if a wire is 1 cm above the ground, its attractive radius would approach 0, because the ground would reduce the gradient at the conductor surface to a very low value. Nevertheless, many proposed striking distance equations, including that recommended by the IEEE, include no direct conductor height correction. However, the IEEE recommends an indirect correction using a "Beta factor," which varies with line height, as will be discussed in Section 6.6.6.

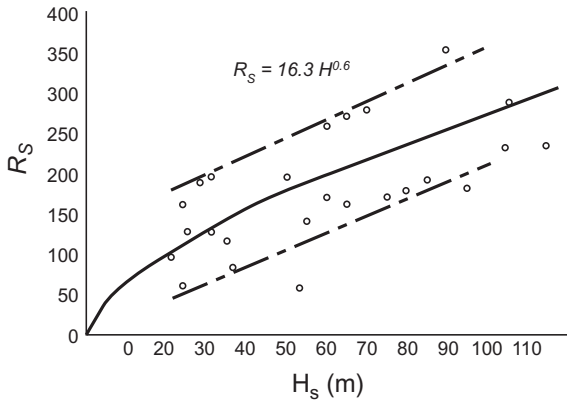

Figure 6.2-6 Observed variations of attractive radius with conductor height.

6.2.8 First Return Stroke Waveshapes

As discussed in Section 6.2.7, the return stroke current waveshape is initially determined by the distribution of charge on the downward leader channel at the moment of contact with the upward leader from a line conductor. The return stroke extracts the downward leader charge as it proceeds upward, and conducts this charge to earth in the form of a high transient current.

Velocity and Channel Charge Neutralization

The charged leader is neutralized by a zero-potential wave that sweeps upward, usually with a velocity that is considerably less than the speed of light. This return stroke velocity can be simulated in the laboratory by distributing multiple, short horizontal stubs at various angles along a vertical conductor, making a cylindrical brush. Each stub diverts and delays a fraction of the total current, and the average path length is increased. Corona streamers around the charged leader are ionized to a high level of conductivity and function nearly as metallic structures in this regard.

Channel Surge Impedance

It is generally assumed that the return stroke channel has a surge impedance much greater that the surge impedance of any transmission tower or line conductor (Wagner and Hileman 1960). Figure 6-2.7 shows observed values of return stroke surge impedance as a function of return stroke current (Mazur and Ruhnke 2001). While the data are widely scattered, in all cases, the impedance is 2000 Ω or higher, which supports the view that the return stroke

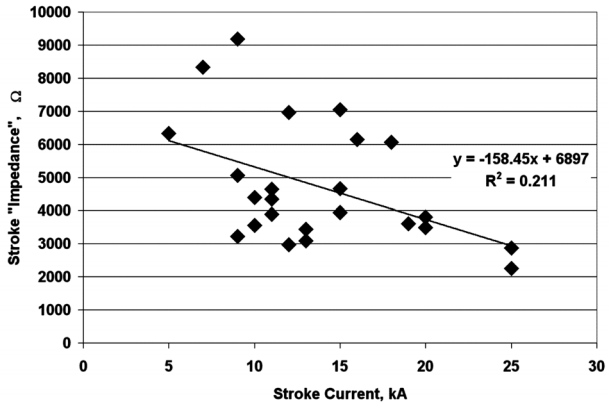

Figure 6.2-7 Return stroke "impedance" (potential / return stroke current) as function of return stroke current (Mazur and Ruhnke 2001).

can be regarded as a current source, not greatly influenced by the impedance of the object at the ground end. This means that the waveshapes and other parameters measured on tall, thin 60-m structures with 300 Ω surge impedance can be used with some confidence on transmission lines with parallel overhead groundwires that present a lower impedance.

Formation of the Surge Current Waveshape

Lightning currents and their corresponding overvoltages are unipolar impulses that may be represented by a waveform shown in Figure 6.2-8. The shape of the impulse consists of a fast-rising front, followed, after reaching a peak value, by a slowly decaying tail. It is usually characterized in terms of the peak value U_m, an equivalent front time t_f extrapolated from the 10 and 90% levels and the time of decay to half of peak voltage on the tail, t_h. The peak values of lightning overvoltage are usually much higher than the corona onset voltage U_0 of the conductor or conductor-bundle used on the transmission line. While the true waveshape has a concave front with relatively slow transition from 10 to 30%, the rise time of standard waves is in the range of 1-2 μs, and the time to half-value is in the range of 40-60 μs. Impulse voltages of this type are usually specified in terms of the peak voltage U_m and t_f/t_h values. The standard lightning impulse voltage, specified in IEEE Standard 4-2000 (IEEE 2000) as 1.2/50 μs, is closest to the lightning current waveshape. When the current is shunted by parallel connections to ground, the tail time reduces as a function of span length and resistance of those paths. Currents measured through nonlinear surge arresters also have longer front times of 4 to 8 μs when a 1.2/50 μs voltage is applied. This has led to the definition of 4/10 μs and 8/20 μs current waves for testing purposes, but these waveshapes do not correspond so well to the original source parameters and should not be used for calculating lightning performance.

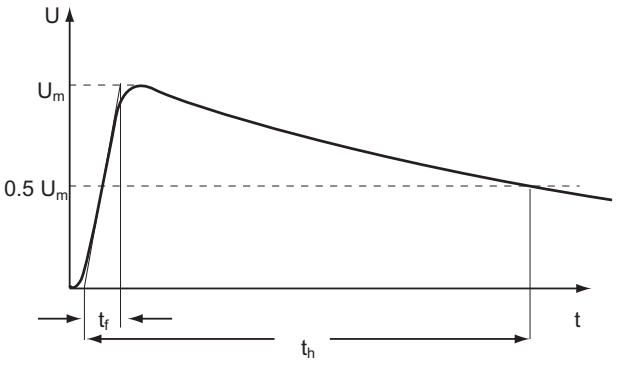

Figure 6.2-8 General voltage waveshape created on transmission lines by return strokes.

Double Exponential Waveshape

Many standards, including IEEE Standard 4, rely on a "double exponential" waveshape described by:

$$I = I_{pk} \cdot K(e^{-t/\tau_1} - e^{-t/\tau_2}) \qquad 6.2\text{-}2$$

For a 1.2 x 50 μs wave, $K = 1.037$, $\tau_1 = 68.5$ μs, $_2 = 0.404$ μs.

The "standard lightning impulse" has a virtual front time (defined as 1.67 times the 30-90% rise time) of 1.2 μs and a virtual time to half value of 50 μs. The current derivative is given analytically by:

$$\frac{dI}{dt} = I_{pk} \cdot K\left(\frac{e^{t/\tau_2}}{\tau_2} - \frac{e^{t/\tau_1}}{\tau_1}\right) \qquad 6.2\text{-}3$$

For the 1.2 x 50 μs wave, the maximum steepness of I_{pk} / 0.392 μs occurs at $t = 0$ (see Figure 6.2-9). The value for a median 31-kA flash would be 79 kA/μs, which is consider-

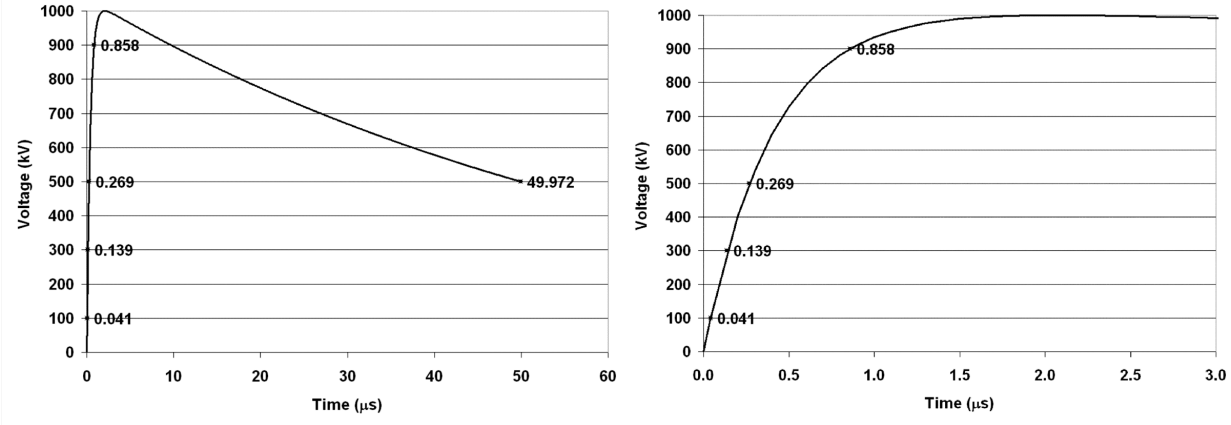

Figure 6.2-9 Front and tail profiles of a standard 1.2 x 50 μs double exponential voltage wave.

ably steeper than the correct 24 kA/μs value, but also occurs when the current is 0, rather than near its maximum. The double-exponential voltage wave is a poor approximation to the lighting stroke current in this regard and, like 4 x 10 μs and 8 x 20 μs current waves, should not be used to describe the input source current in lumped-circuit models.

Heidler Waveshape

Heidler et al. (Heidler et al. 1999) gives a functional form of current *I(t)* as:

$$\eta = e^{(-(\tau_1/\tau_2)(n\tau_2/\tau_1)^{(1/n)})} \quad 6.2\text{-}4$$

$$I(t) = \frac{I_{pk}}{\eta} \frac{\left(\frac{t}{\tau_1}\right)^n}{\left(\frac{t}{\tau_1}\right)^n + 1} e^{(-t/\tau_2)} \quad 6.2\text{-}5$$

Where:

I_{pk} = peak current.
τ_1 = rise time constant.
τ_2 = tail time constant.
n = concave factor (usually n = 5 since this factor mainly introduces delay rather than a change of shape).
η = the peak correction factor.

The Heidler function peak correction factor is valid for concave factors $n > 3$. In contrast, the expressions given in (Feizhou and Shanghe 2002) are valid for all values of n and have the advantage of smoother derivatives in work with Fourier transforms. Figures 6.2-10 and 6.2-11 show the current waveforms for typical waveform parameters.

For a 2 x 50 μs wave, η= 0.9566, τ_1 = 0.244 μs, and τ_2 = 67.5 μs. However, the lower part of the concavity contributes little to the development of severe insulator voltages, and—for this reason—a simple double-exponential current waveshape can be used to create nearly the same current characteristics in the vicinity of the crest of the wave (Figure 6.2-12).

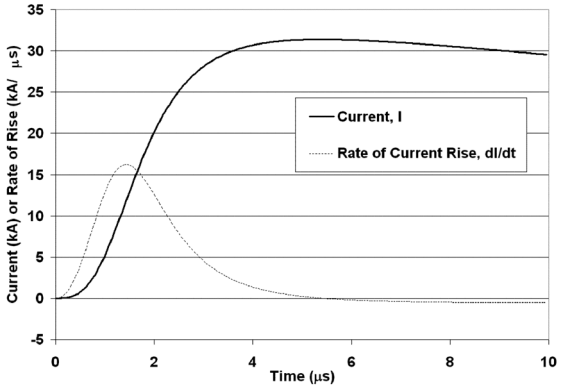

Figure 6.2-10 Heidler waveshape (Heidler et al. 1999).

In both cases, the peak value of *dI/dt* occurs 1.4 μs after the start of the wave, and is still not synchronized with the peak of wave. This feature persists even with high values of *n* and limits the use of either expression for computing the response of the transmission line. Measurements such as those in Figure 6.2-12 show that the peak *dI/dt* occurs at the same time as the current peak, meaning that resistive and inductive voltage rise should be simultaneous.

CIGRE Waveshape

A CIGRE working group has made an extensive analysis of measured stroke current waveshapes, taken mainly from the oscillograph records of Berger (CIGRE 1991). This group defined additional waveform parameters as shown in Figure 6.2-13.

The observed waveshapes (Figure 6.2-13) do not start at zero current, because a minimum current is always required to turn on the measuring equipment. The wavefronts are

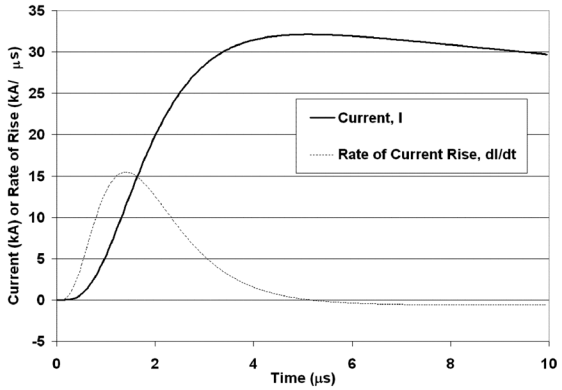

Figure 6.2-11 Feizhou waveshape (Feizhou and Shanghe 2002).

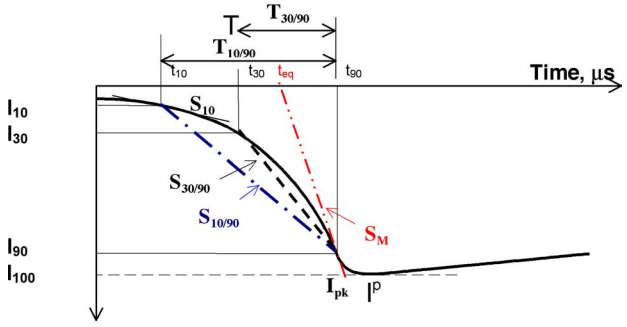

Figure 6.2-12 Crest and front time parameters for a CIGRE current wave.

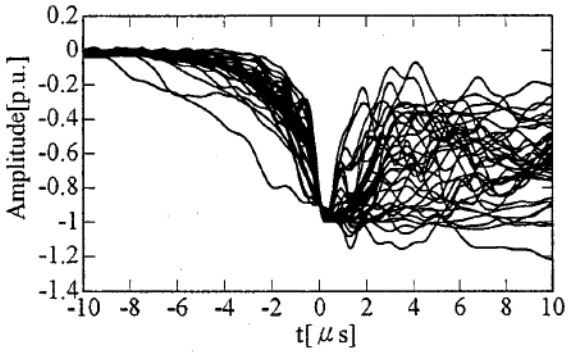

Figure 6.2-13 First stroke current waveshapes (Narita et al. 2000, pp. 429–435).

generally concave, and the steepest portions are near the current peak. The combination of crest current and maximum rate of rise determines the maximum tower top voltages that create insulator flashover. This means that a linear ramp to peak (front $S_{30\text{-}90,}$ or preferably S_M giving t_{eq} in Figure 6.2-12) is more appropriate than the double-exponential waveshape approximation of the stroke current conditions in flashover calculations near the crest of wave. CIGRE (CIGRE 1991) also recommend the following pair of equations for describing a typical first-stroke current if 31 kA with a steepness of 26 kA/μs, an equivalent front duration t_f of 3 μs and a time to half value t_h of 75 μs:

$$t < t_n: I = At + Bt^n$$
$$t > t_n: I = I_1 e^{-(t-t_n)/t_1} - I_2 e^{-(t-t_n)/t_2} \qquad 6.2\text{-}6$$

Where:
t_n = 4.67 us
n = 8.29
A = *3.24 kA/μs*
B = *3.65 x 10^{-5} kA/μs*
t_1 = *105μs*
t_2 = *0.12 μs*
I_1 = 31 kA
I_2 = 3.1 kA

6.2.9 First Negative Return Stroke Parameter Distributions

The Log-Normal Distribution

Figure 6.2-13 illustrates that the first stroke waveshapes vary greatly from flash to flash. This means that many observations must be analyzed to develop statistical descriptions, providing the mean, the dispersion, and the shape of the distribution. Most analysis leads to the use of a "log normal" distribution, with the logarithm of the parameter being normally distributed around a mean with a specified standard deviation.

$$p(x) = \frac{1}{\sqrt{2\pi}x\sigma_{\ln x}} \exp\left[-0.5\left(\frac{\ln x - \ln x_m}{\sigma_{\ln x}}\right)^2\right] \qquad 6.2\text{-}7$$

Where:
σ_{lnx} = the standard deviation of *ln x.*
x_m = the median value of *x.*

In many cases, classification of the statistical distribution using the (Pearson and Hartley 1972) criteria based on functions of skew and kurtosis do support the use of log-normal distributions.

First Negative Stroke: Peak Current Amplitude

A cumulative probability curve of peak amplitudes of first strokes is displayed in Figure 6.2-14. This distribution (Anderson and Eriksson 1980) can be approximated by a two-segment log-normal curve or a simple approximation, shown in the prominent dashed line, as suggested in previous editions of this Reference Book (EPRI 1982).

While Anderson and Eriksson note that each constituent distribution in Figure 6.2-14 had measurements greater than 3 kA, the deviation from a log-normal distribution in the low-current regime may be a result of experimental bias towards large flashes. Generally, oscilloscopes used for these measurements would have used a trigger level of between 3 and 10% of full scale, indicated by I_{trig} in their definition of impulse parameters. Since most experiments were set up to collect 200-kA peak currents, many flashes less than 10 kA may have been missed. With the improved dynamic range of digital instrumentation, more recent tower measurements would tend to have less of this bias.

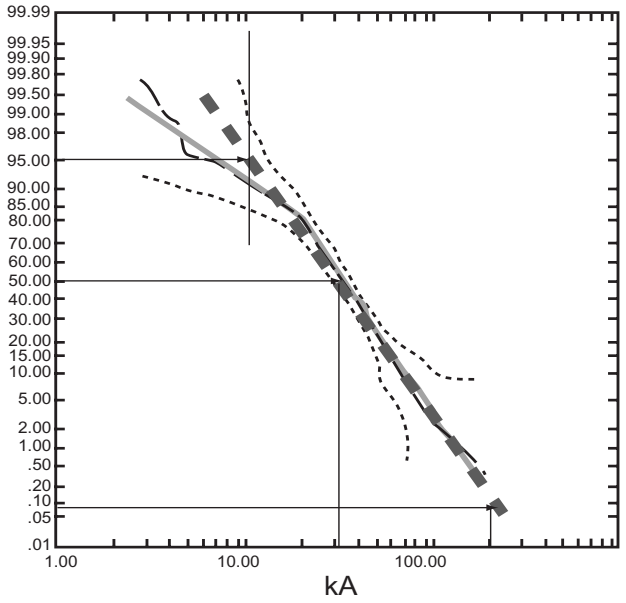

Figure 6.2-14 Cumulative distribution of first negative downward lightning flashes to objects < 60 m (Anderson and Eriksson 1980).

The dashed line in Figure 6.2-14 also shows the probability of a negative first stroke peak amplitude in excess of I_P, computed from Equation 6.2-8.

$$P = \frac{1}{1 + \left(\frac{I_P}{31}\right)^{2.6}} \qquad 6.2\text{-}8$$

This approximation differs from the log-normal distributions only at the extremes, where few data are available. In this regard, the reader should be aware that tall masts collect lightning in a significantly different way than horizontal transmission-line conductors or a flat earth, as will be discussed in Section 6.6. There may also be changes in stroke current characteristics with earth resistivity and latitudes. Rigor in mathematically-defining these statistical distributions may be academically satisfying, but our present knowledge is so limited that rigorous analytical methods contribute little to accuracy of final estimates of line lightning performance.

Lightning location systems provide measurements of peak-radiated field that are converted to stroke currents in kA using one of the transmission-line models. These measurements are precise, often reporting three significant figures, but are not accurate. Examples of anomalies that have been noted include:

- Correlation between sensor spacing and observed median amplitude (e.g., Orville and Huffines 2001), variables that should be independent
- A tendency to report a mixed distribution, with approximately 80-90% of first return strokes being correctly classified and 10-20% being incorrect reports of the first subsequent stroke amplitude. This can give a two-slope distribution that bends the opposite way to the kink in Figure 6.2-14 at 10 kA. This can also be deconvolved using the misclassification fraction if the two distributions have significantly different median currents.
- A wide range of attenuation rate with distance, depending on the local soil resistivity. The lowest attenuation is observed offshore, moderate attenuation is found in the USA NLDN (Cummins et al. 1998) and Florida (Idone 1993), and more than 50% attenuation over 400-km paths in Canada (Herodotou et al. 1990) and the Appalachian mountains (Orville and Huffines 2001).
- An ocean/land impedance discontinuity that gives 25 kA values over the ocean and 20 kA on the shore nearby, where electrogeometric models suggest the reverse should happen.
- No lake/land discontinuity in measured amplitudes over large bodies of water, such as the Great Lakes, with 80-130 Ω-m resistivity, similar to the surrounding land mass.
- Good agreement between lightning location system measurements and observations on 100-m instrumented towers (Diendorfer et al. 2002). Remote readings should be too high on tall towers, because the speed-of-light propagation velocity within the structure increases the radiated field efficiency compared to the return stroke to a shorter object.

Some impediments to the use of remote radiated field data for estimating peak stroke currents have already been addressed. For example, most of the "engineering models" of the return stroke discussed in Section 6.2.7—such as TL, MTLL, and MTLE— predict similar remote electromagnetic fields in practical networks. Studies of channel tortuosity (Levine and Meneghini 1978) show a strong effect later in the wave but little change to the peak-radiated field. Lightning has traditionally been used for geophysical prospecting, taking advantage of the strong current source to excite vertical and horizontal electric fields that give a "tilt angle" and an indication of the underlying strata. For calculations of induced overvoltage using (Agrawal et al. 1981), researchers now understand that this peak electromagnetic field itself, rather than the stroke current and return stroke velocity parameters, is the desired input parameter that illuminates distribution lines. The Sommerfeld-Norton model for sine-wave attenuation over lossy ground is described in Appendix 6.2. This model can be used to invert the observed variations in lightning peak amplitudes to characterize the soil resistivity with better detail than now available through Extra-Low Frequency (ELF) and AM broadcast attenuation maps, as shown in Section 6.10.

Present research suggests that, in spite of the anomalies listed above, there may be regional variations in stroke current amplitude of up to 50%, and that the median current may be somewhat lower than 31 kA. A focus on estimating the density of "damaging" lightning, such as the high density of positive-flash events over 85 kA in north-central U.S. and central Canada (Boccippio et al. 2001), as shown below in Figure 6.2-22, will continue to quantify the extent and significance of the observed variations in parameters.

First Negative Stroke: Rate of Current Rise

The probability of maximum *dI/dt* of a negative first stroke exceeding S_m in Figure 6.2-12, is given by:

$$P = \frac{1}{1 + \left(\frac{S_m}{24}\right)^{4}} \qquad 6.2\text{-}9$$

Where:

S_m is expressed in kA/μs.

First Negative Stroke: Charge

The probability of negative first stroke charge exceeding Q is given by:

$$P = \frac{1}{1+\left(\frac{Q}{5}\right)^2} \qquad 6.2\text{-}10$$

Where:

Q is expressed in coulomb (1 C = 1 A x 1 s).

Correlations Among First Negative Stroke Parameters

The joint probability density function between two parameters, both with log-normal distributions, is given by:

$$p(x,y) = \frac{\exp\left[\frac{-0.5}{1-\rho_c^2}\left(A_1 + A_2 - A_3\right)\right]}{2\pi \cdot x \cdot y \cdot \sigma_{\ln x}\sigma_{\ln y}\sqrt{1-\rho_c^2}} \qquad 6.2\text{-}11$$

Where:

ρ_c = the coefficient of correlation, and:

$$A_1 = \left(\frac{\ln x - \ln \bar{x}}{\sigma_{\ln x}}\right)^2$$

$$A_2 = \left(\frac{\ln y - \ln \bar{y}}{\sigma_{\ln y}}\right)^2 \qquad 6.2\text{-}12$$

$$A_3 = 2\rho_c\left(\frac{\ln x - \ln \bar{x}}{\sigma_{\ln x}}\right)\left(\frac{\ln y - \ln \bar{y}}{\sigma_{\ln y}}\right)$$

The conditional probability density function of the variable y, given $x = x_0$, is:

$$p(y \mid x = x_0) = \frac{p(x,y)}{p(x)} = \frac{\exp\left[-\frac{(\ln y - b)^2}{2\sigma^2}\right]}{\sqrt{2\pi}\, y\sigma} \qquad 6.2\text{-}13$$

$$b = \ln \bar{y} + \rho_c \frac{\sigma_{\ln y}}{\sigma_{\ln x}}\left(\ln x_0 - \ln \bar{x}\right)$$

$$\sigma = \sigma_{\ln y}\sqrt{1-\rho_c^2}$$

Narita et al. (Narita et al. 2000) give observations of 36 peak stroke currents on transmission towers, along with their maximum rate of rise, in Figure 6.2-15. A higher correlation coefficient of $\rho_c = 0.85$ for Equations 6.2-11 and 6.2-12 found between the two variables than for the CIGRE data. The Japanese UHV design point of 200 kA/μs in Figure 6.2-15 is seen to be roughly twice their highest observed values of 100 kA/μs.

In their correlation studies between electric field change and peak stroke current estimate (from lightning location systems), Mazur and Ruhnke (Mazur and Ruhnke 2001) develop a weaker experimental relationship between stroke current and leader charge, shown in Figure 6.2-16.

6.2.10 Positive Return Stroke Parameter Distributions

Since they are relatively infrequent, the parameters of first positive strokes have not been characterized as reliably as negative first strokes. The following approximations of positive return stroke parameter cumulative probabilities were derived from an accumulation of data from several sources (Anderson and Eriksson 1981; Rakov and Uman 2003). All currents are in kA, all charges are in coulomb (C).

Probability of positive peak stroke magnitude:

$$P = \frac{1}{1+\left(\frac{I}{34}\right)^{1.5}} \qquad 6.2\text{-}14$$

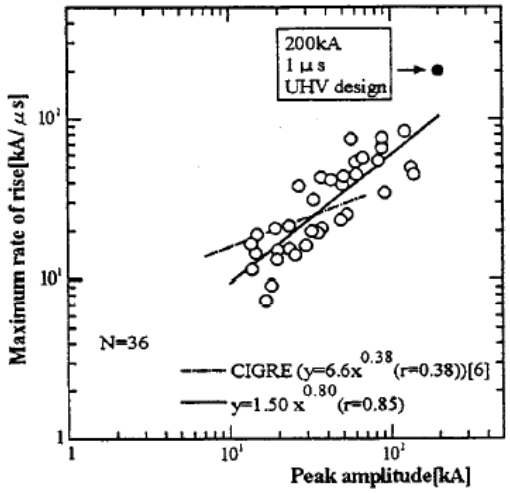

Figure 6.2-15 Observed relationship between peak amplitude and maximum rate of rise (Narita et al. 2000).

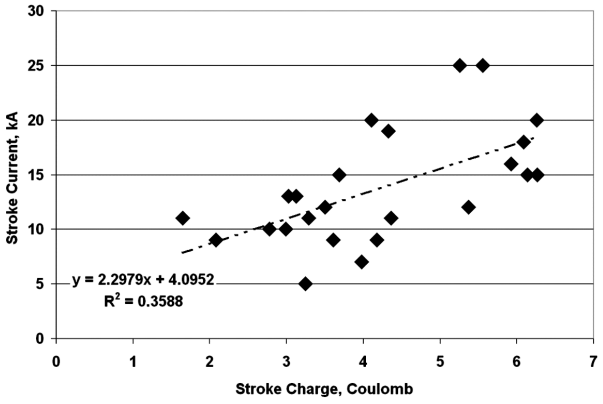

Figure 6.2-16 Return stroke current as a function of leader charge.

Probability of charge delivered by a positive first stroke:

$$P = \frac{1}{1 + \left(\frac{Q}{19}\right)^{1.34}} \quad 6.2\text{-}15$$

Where:
Q is expressed in coulomb.

Probability of total charge delivered by a positive flash:

$$P = \frac{1}{1 + \left(\frac{Q}{85}\right)^{2}} \quad 6.2\text{-}16$$

Where:
Q is expressed in coulomb.

6.2.11 Subsequent Stroke Parameters

After the passage of a return stroke, the lightning channel can re-illuminate quickly with a dart leader, resulting in a subsequent return stroke at or near the initial termination. In some measurements, 10% of the flashes have ten or more strokes per flash. The subsequent strokes tend to have lower values of charge and current, faster return stroke velocity, and less overall impact on transmission-line lightning performance. Special issues related to subsequent strokes include:

- Coordination of steep rates of voltage change (> 2500 kV/μs) with insulator puncture strength and endurance.
- Coordination of the steep rates of current rise (> 40 kA/μs) with nearby electronic equipment.
- Coordination of subsequent-stroke shielding failure flashover in cases of shielding failure where the first stroke is weak.
- Coordination of breaker reclosing times to prevent double trips and lockouts.
- Coordination of lightning surge arrester and accessory energy capability under multi-pulse excitation.

Many researchers have used artificial structures, either tall towers or rocket-triggered thin wires, to increase the probability of lightning flashes to their experimental setups. Research does support the hypothesis that, once the artificially-ionized channel from the upward leader has warmed to its task, the dart leaders and subsequent strokes along the same channel are similar to those found in nature. The median stroke current distributions, distant electromagnetic fields, and other features of natural subsequent strokes are similar to all records taken from artificially triggered lightning (Uman and Rakov 2002; Janischewskyj 1997a). However, differences in time to half value and rates of current rise have been found in some comparisons (Cooray 2003b).

As mentioned above, some of subsequent strokes are misclassified as small first strokes in lightning location systems, and some of the lower-amplitude events fall below the local detection threshold of the networks. However, multiple ground terminations are also counted as a first and a subsequent stroke, rather than two different first strokes. Both of these factors are being addressed in a process of continuous improvement for lightning location technologies.

Subsequent Stroke: Average Number

Uman (Uman 1987) suggests a mean of three subsequent strokes per flash, based on studies of Schonland in South Africa and Master in Florida. Anderson and Eriksson (Anderson and Eriksson 1981) recommend a global average ground-flash multiplicity of three, one first stroke and two subsequent strokes, for negative downward lightning. Observations from lightning location systems in the United States (Orville and Huffines 2001) show a mean negative multiplicity of 2.6 in Florida and most of the central U.S., falling to less than 2.0 in the west. Practically all positive flashes have a single stroke.

Subsequent Stroke: Interstroke Interval

The interstroke interval between subsequent strokes has been studied widely using video cameras (Anderson and Eriksson 1980) and, more recently, time-tagged observations of lightning location system data. The following expression is recommended for $t_{I\text{-}S}$, the interstroke time interval:

$$P = \frac{1}{1 + \left(\frac{t_{I-S}}{35\,ms}\right)^{1.7}} \quad 6.2\text{-}17$$

If regional variations in multiplicity occur, there could also be some regional variation of interstroke interval. Values for South Africa (Schonland 1956) and Thompson et al. (1984), areas of relatively high multiplicity, are 51 and 68 ms, respectively.

Subsequent Stroke: Overall Flash Duration

Figure 6.2-17 shows typical distributions of the duration of multiple-stroke flashes for three regions, along with a recommended relation as a solid line. The extreme values of this distribution are used for establishing protective settings for relays, especially for single-pole reclosing on unshielded lines, to ensure that the lightning event is over before the line is re-energized.

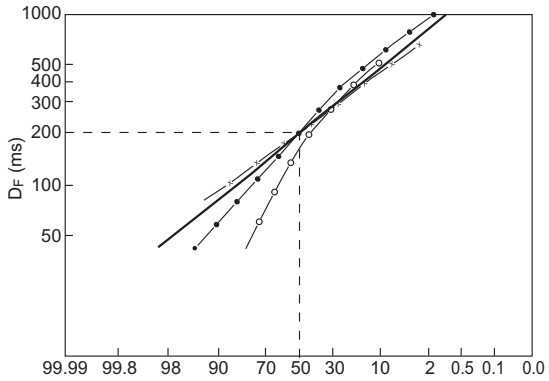

Figure 6.2-17 Percent of multiple-stroke flashes having duration exceeding vertical-axis value (Anderson and Eriksson 1980).

Subsequent Stroke: Peak Current Magnitude

Probability of negative subsequent stroke peak current > 0:

$$P = \frac{1}{1 + \left(\frac{I_P}{12}\right)^{2.7}} \qquad 6.2\text{-}18$$

Subsequent Stroke: Time to Crest

The definition of time to crest for subsequent strokes is compromised by the fact that many observations with wideband sensors show a 100-ns step from 50 to 90% of the wave.

Subsequent Stroke: Maximum dI/dt

The maximum rate of current rise of lightning determines the peak values of electromagnetically-induced voltage in closed or open loops in the vicinity of the tower (Hasse 2000). Also, the fast-rising voltages impressed across transmission-line insulators will eventually puncture cap-and-pin porcelain insulators electrically.

The maximum steepness of lightning occurs near the peak of wave. Anderson and Eriksson (Anderson and Eriksson 1980) used the maximum slope S_m to the current waveform to describe this feature. As shown in Figure 6.2-12 and 6.2-18, this portion of the wave has much greater steepness than the tangent at 10% and steepness associated with 10-90% and 30-90% points on the wave.

The dashed line in Figure 6.2-18 shows an approximate fit to the probability of maximum steepness S_{max} using:

$$P(S_{\max}) = \frac{1}{1 + \left(\frac{S_{\max}}{40\ kA/\mu s}\right)^{2.1}} \qquad 6.2\text{-}19$$

Measurements of radiated fields and return stroke currents from rocket-triggered lightning tend to have steeper distributions of maximum steepness. A mean value of 180 kA/μs for 100 measurements was reported by (Weidman and Krider 1980) based on a constant return stroke velocity assumption of $c/3$. Similar results have also been reported from rocket-triggered lightning experiments at Camp Blanding in Florida (Rakov and Uman 2003).

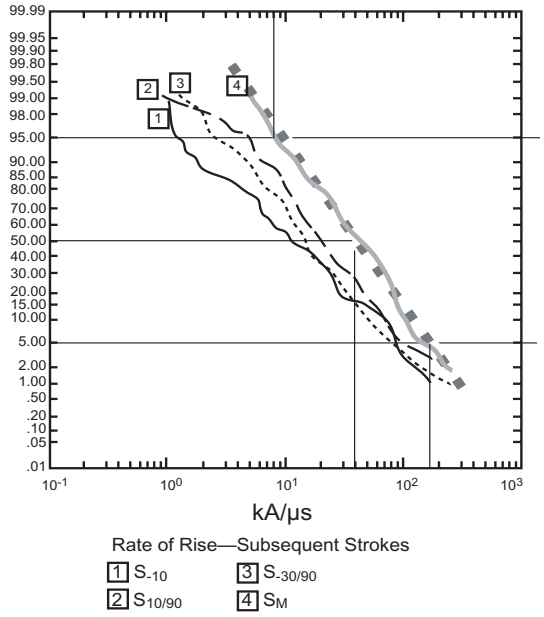

Figure 6.2-18 Probability of rate of rise of subsequent strokes.

Subsequent Stroke: Charge

The charge delivered by subsequent strokes has been shown to contribute to thermal stress on distribution surge arresters and disconnectors. The approximate model of a first stroke (median 5 C) and two subsequent strokes (each median 1 C), giving a total of 7 C, is reasonable. The probability of charge delivered by a negative subsequent stroke is estimated from:

$$P = \frac{1}{1 + \left(\frac{Q}{1}\right)^{2.2}} \qquad 6.2\text{-}20$$

Where:

Q is expressed in coulomb.

The overall probability of total charge delivered by a negative flash (including first and subsequent strokes) is given by:

$$P = \frac{1}{1 + \left(\frac{Q}{7}\right)^{1.7}} \qquad 6.2\text{-}21$$

Where:

Q is expressed in coulomb.

These values are also used for specifying adequate energy absorption capability when gapped or gapless Transmission Line Surge Arresters (TSLAs) are used on unshielded transmission lines.

6.2.12 Electromagnetic Fields from Return Strokes

LeJay (LeJay 1926) reported a relationship between the charge moment (product of charge and separation distance) of a vertical source *M* and the horizontal component of magnetic field B_h:

$$B_\phi = \frac{\mu_o}{4\pi c D^2}\left[c\frac{dM}{dt} + D\frac{d^2M}{dt^2}\right] \qquad 6.2\text{-}22$$

Where:

μ_o = the permittivity of free space, $4\pi\ 10^{-7}$ H/m.
D = the distance in m.
c = the speed of light, 3.10^8 m/s.
t = time in s.

Uman et al. (Uman et al. 1975) noted that, in effect, a current *i(t)* moving vertically upward with uniform velocity *v* produces a second derivative of charge moment that matches the current as follows:

$$\frac{d^2M}{dt^2} = 2\,vc\;i(t) \qquad 6.2\text{-}23$$

At distances greater than about 5 km from a lightning source, the induction term *dM/dt* can be ignored, meaning that the distant radiated field waveshape becomes a faithful copy of the return stroke current:

$$B_\phi\left(t+\frac{D}{c}\right) = \mu_o H_\phi\left(t+\frac{D}{c}\right) \approx \frac{\mu_o v}{2\pi c D} i(t) \qquad 6.2\text{-}24$$

For a peak stroke current of 30 kA, moving upwards at a velocity of $v = c/3$, the peak magnetic field at a distance D = 100 km is B = 20 nT. Since this is a radiated field, the impedance of free space relates the horizontal magnetic field to the vertical electric field as follows:

$$Z_o = \sqrt{\frac{\mu_o}{\varepsilon_0}} = 377\ \Omega \qquad 6.2\text{-}25$$

$$\begin{aligned} E_z\left(t+\frac{D}{c}\right) &= Z_o H_\phi \\ &= \frac{1}{c} B_\phi\left(t+\frac{D}{c}\right) \\ &= \frac{4\pi\cdot 10^{-7} v}{2\pi D} i(t) \\ &= 60\frac{v}{c}\frac{i(t)}{D} \end{aligned} \qquad 6.2\text{-}26$$

Here, E_z is expressed in V/m. For the 30-kA stroke at 100 km, E_z = 6 V/m.

This model ignores observations that neither the return stroke speed nor the source current (or its surrogate, the optical radiation strength) is constant as the wave travels up the transmission line. A wide range of modified models is discussed critically in Cooray (2003b). Many details in the use of the transmission-line model with distant radiated electric and magnetic fields to estimate lightning return stroke parameters, including location and peak current, remain to be resolved through cross-calibration and experimental validations, and this work is ongoing.

6.2.13 Upward Flashes from Tall Structures

Rizk (Rizk 1994) worked forward from the success of a switching-surge flashover model in describing the final jump to a downward leader. He described a second condition necessary for stable propagation of an upward leader. After analysis and interpretation, this model gives an estimate of the ground-level electric field E_Z that will cause an upward flash from a structure of height *h*:

$$E_Z = \frac{1600kV}{h} \qquad 6.2\text{-}27$$

Equation 6.2-26 suggests that upward leaders develop from a 100-m structure at a ground-level vertical electric field of about 16 kV/m. This electric field would be calculated from the charge structure in the cloud, prior to development of downward leaders. The upward leaders from tall structures have low currents during their development, but often bring dart leaders and subsequent return strokes to tall structures. Berger and other researchers have been careful to identify upward flashes and to segregate their parameters from downward flash results (Berger et al. 1975). Eriksson (Eriksson 1987) had previously related the observed incidence of upward flashes to structure height in the range of 80 to 550 m using

$$\%\ \text{Upward} = 52.8\ \ln(H_{\text{meters}}) - 230 \qquad 6.2\text{-}28$$

Measurements carried out on tall 553-m telecommunication towers (Rachidi et al. 2001) have established relatively low subsequent-stroke amplitudes, relative to shorter towers. Some of this bias is attributed to the ability to record an "initial uncontaminated" wave as it travels down the tower and, 3 μs later, to measure the imperfect reflection from ground. Figure 6.2-19 shows a typical fast-front record.

In the stroke current waveform, top right of Figure 6.2-19, the initial wave is an 8-kA step, and a reflection from ground of approximately 3 kA arrives at the measurement point 3μs later. The imperfect reflection coefficient, corresponding to a transient impedance of 55 Ω, is a result of the electromagnetic response of the ground plane, as described in Section 6.4. The electric and magnetic fields measured so close to the tower are influenced by several factors, such as reflections up and down the tower, as discussed in (Rachidi et al. 2001).

6.2.14 Experience on 60–140 m Towers

Narita (Narita et al. 2000) carried out 36 measurements of lightning stroke currents on transmission towers in the height range of 60 to 140 m. Table 6.2-1 (Narita et al. 2000) shows the peak current characteristics from this study, along with values from (Berger et al. 1975; CIGRE 1991) and (Eriksson 1987; Visacro et al. 2004) for first negative downward flashes.

Anderson and Eriksson (Anderson and Eriksson 1980) advanced a hypothesis that, for structures up to 60 m height, the stroke current distribution is independent of height. Figure 6.2-20 from (Narita et al. 2000) shows only a weak trend to higher currents with structure height of 60-140 m, supporting Anderson and Eriksson's idea.

6.2.15 Winter Lightning

Winter lightning, although infrequent, can be more severe, with a higher fraction of positive flashes having large peak currents, long wave fronts, and high delivered charge. Winter lightning appears to be more attracted to tall structures than summer lightning, and has been observed to strike two or more structures with the same flash (Miyake et al. 1990; Yokoyama et al. 1990). It often starts from tall structures, and the leader progresses upwards. Udo (Udo 2004) has

Table 6.2-1 Comparison of Peak Current Statistics

Reference	95% Value	50% Value	5% Value	σ of ln I	Sample Size
Berger 1975	14 kA	30 kA	80 kA		101
CIGRE 1991	6 kA	31 kA	90 kA	0.32	408
Narita 2002	11 kA	39 kA	135 kA	0.33	36
Eriksson 1987		36 kA		0.31	22
Visacro 2004	22 kA	40 kA	75 kA		79

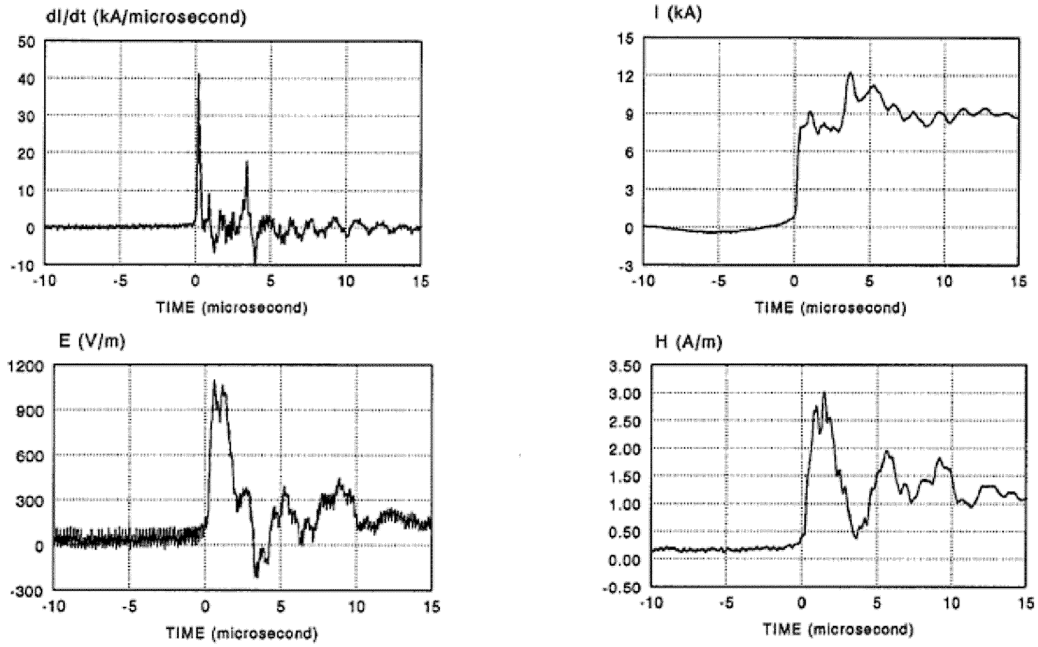

Figure 6.2-19 Typical current record at 553-m CN Tower (Rachidi et al. 2001) along with electric and magnetic fields at 2 km.

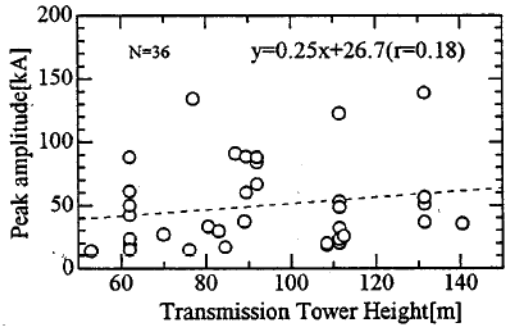

Figure 6.2-20 Observed relation between peak amplitude and tower height (Narita et al. 2000).

reported that the probability of a double-circuit flashover from a winter lightning flash is substantially higher than for summer lightning.

Evidence from a number of studies in Japan suggests that local conditions in the Sea of Japan lead to a strong local incidence of winter lightning. Physically, the dividing line of -15°C in the cloud, separating positive and negative charge centers, is closer to the ground. This factor, combined with stronger upper-level winds that tend to push the cloud top in front of the base, means that more positive lightning could develop to ground. Lightning location system data in continental U.S. also supports a summer/winter classification based on the ratio of positive-to-negative flashes, as shown in Figure 6.2-21.

6.2.16 Arc Damage from Flash Charge

As stated in Section 6.2.2, a low continuing current often flows between one or more of the high current peaks. This current can deliver substantially more charge than all the high current peaks combined, and is largely responsible for conductor ablation, burning, and general heat damage,

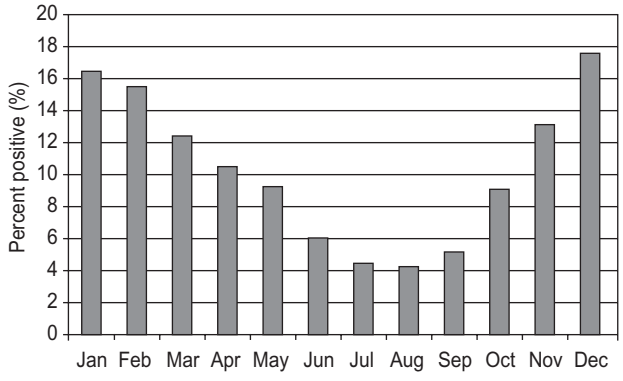

Figure 6.2-21 Mean percentage of positive cloud-to-ground lightning observed with U.S. National Lightning Detection Network (Orville and Huffines 2001).

exceeded only by arc damage from power frequency arcing in many cases. Probability approximation equations for the delivered total coulombs from a flash are given by Equations 6.2.15 and 6.2.20. Using these equations, there is a 10% probability that delivered negative charge from a flash would equal or exceed 25 C, and delivered charge from a positive flash would equal or exceed 255 C. This is equivalent to a dc arc welder applying a current of either 25 A or 255 A to a stricken object for a second.

Lightning plasma temperature is well above the melting point of metals used in transmission-line construction. In cases where continuous transfer of charge between return strokes occurs (mainly for negative flashes), or the charge of the first return stroke is large (mainly for positive flashes), there will be sufficient thermal energy to damage overhead groundwires. Lightning plasma will contribute thermal energy in three ways: radiation, arc root voltage, and chemical energy liberated by oxidation of the material. The radiation is strong, but has low energy density and can be ignored when studying damage to areas of 1 cm^2. The arc root voltage tends to be constant over a wide range of currents (Cobine 1958), so the energy contribution is simply related to the charge (the product of current and time for a rectangular pulse of current). Charge ablates (burns up) metal components in ways that are similar to industrial plasma cutting torches. The chemical energy from oxidation of the melted metal is typically as large or larger than the energy of the arc root, with aluminum providing higher energy compared to iron or zinc and being more susceptible to lightning arc damage. It should be recognized that the action integral i^2dt gives a poor estimate of heat damage in this case, because the arc terminates on either a cathode or anode spot, depending on polarity, instead of on a constant resistance.

Coulomb Probabilities

Arc root damage is an important concern in the successful application of optical fibers within overhead groundwires. IEEE Standard 1138 defines test methods and levels, depending on local flash density, the observed proportion of positive flashes, and the best data available for the parameters of impulse and flash charge. With a ground flash density N_g, and using the model of Eriksson (Eriksson 1987), each of two optical-fiber groundwires of height H would receive:

$$N_{flashes/100\,km/\,yr} = \frac{N_g}{10}\left(14\,H^{0.6}\right) \qquad 6.2\text{-}29$$

Where:

N_g = the ground flash density in flashes per km^2 per year.

H = the tower height in m.

10 provides unit conversion (attractive width in meters times 100 km length) to km^2.

For a two-year return period between damaging events on a 37-m-tall 100-km line with a ground flash density of 4 per km^2 per year, the design threat level would be 98 flashes. In an area with a 10% positive flash rate, this would give 10 positive (N^+) and 88 negative (N^-).

Design threat levels for negative flashes (N^- = 88) are computed as follows:

Negative first-stroke peak current is obtained by inverting Equation 6.2-8:

$$N^- \approx \left(\frac{I^-}{31kA}\right)^{2.6} \qquad 6.2\text{-}30$$

$$I^- \approx 31kA \cdot (N^-)^{1/2.6} = 31kA \cdot (N^-)^{0.38}$$

I^- =173 kA

Similarly, negative impulse charge is obtained by inverting Equation 6.2-9:

$$N^- \approx \left(\frac{Q^-}{7C}\right)^{1.7} \qquad 6.2\text{-}31$$

$$Q^- \approx 7C \cdot (N^-)^{1/1.7} = 7C \cdot (N^-)^{0.59}$$

Q^- = -97 C

The design threat levels for positive flashes (N^+=10) follow the same process, for example inverting Equation 6.2-15 to give a positive flash charge of:

$$N^+ \approx \left(\frac{Q^+}{85C}\right)^{2} \qquad 6.2\text{-}32$$

$$Q^+ \approx 85C \cdot (N^+)^{1/2} = 85C \cdot (N^+)^{0.5}$$

Q^+ = +266 C

It is worth noting that negative charge is about three times more damaging than positive charge per coulomb, a fact that is commonly used in electric arc welding and cutting. Typically, wire strand size of about 3 mm is needed to avoid breaking with this charge injection. Also, Boccippio et al. (Boccippio et al. 2001) present strong evidence of a regional variation in the occurrence of large positive flashes, as shown in Figure 6.2-22, and areas with many large positive flashes should use more robust Optical Fiber (OPGW) and overhead groundwires.

Test Methods

Optical-fiber overhead groundwires are tested by applying a dc current for a duration of 0.5 s. The magnitude of the current is adjusted to match the Q^- level: with the example above, a current of 194 A (negative polarity on rod, positive return on conductor) would give a charge of (194 A x 0.5 s) = 97 C. For OPGW, the performance of the optical fiber during the test and the possibility of moisture penetration are the most important pass/fail criteria. For conventional overhead groundwires, the loss of zinc galvanizing or aluminum cladding, and number of broken strands, remain as the conventional criteria.

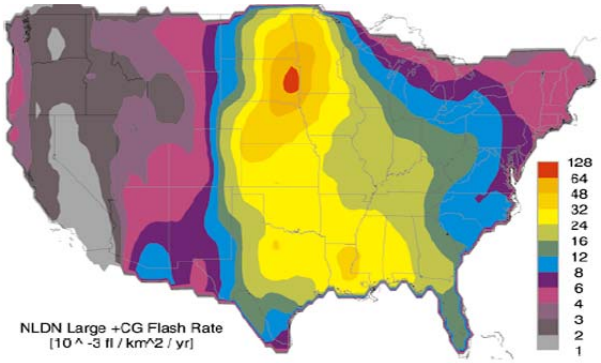

Figure 6.2-22 Occurrence of positive cloud-to-ground flashes with estimated peak currents exceeding 75 kA (Boccippio et al. 2001).

6.3 REGIONAL LIGHTNING FLASH STATISTICS AND DATA

The calculation of lightning flashover rate divides into two main areas, stimulus and response. The stimulus is described by the incidence of lightning, preferably grouped into specific ranges of stroke current amplitude. There are two important regimes of response:

1. The case where a low-amplitude flash excites an energized conductor and causes a flashover to ground. This is a *shielding failure*.
2. The case where a high-amplitude flash excites a grounded support, which responds imperfectly, causing a *backflashover* to one or more energized conductors.

Ishii (Ishii et al. 2002) used lightning location system (LLP) data to categorize lightning flashes that caused 187-kV transmission line outages. Their observations and calculations in Figure 6.3-1 suggest a roughly equal divi-

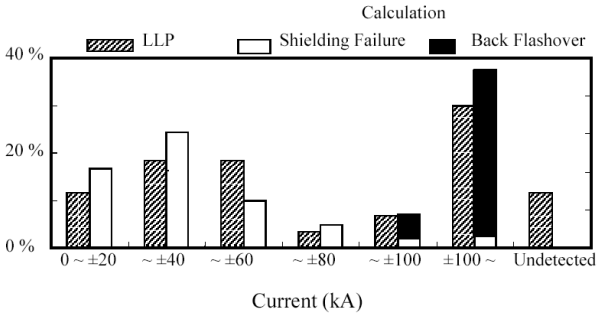

Figure 6.3-1 Lightning currents that caused 187-kV shielded transmission-line outages (Ishii et al 2002, corrected). Solid: Calculated. Hashed: Observed from Lightning Location System.

sion between shielding failures (0-60 kA) and backflashovers (>80 kA) as the root cause of tripouts.

The calculated occurrence of shielding failures at current levels greater than 40 kA is generally associated with nonvertical angles of stroke incidence. Ishii at al. also confirms in Figure 6.3-2 a hypothesis of the linear relationship between observed transmission line outage rates and observed ground flash density. The slope of this relation will be different for each voltage class of line, because higher-voltage lines have greater insulation strength.

6.3.1 Isokeraunic Maps, OTD Measurements, and Lightning Flash Counters

In the second edition of the EPRI Red Book, there was a heavy reliance on the use of the meteorological observations of "Thunderstorm Day" (*TD)* as defined by World Meteorological Association standards (see Figure 6.3-3).

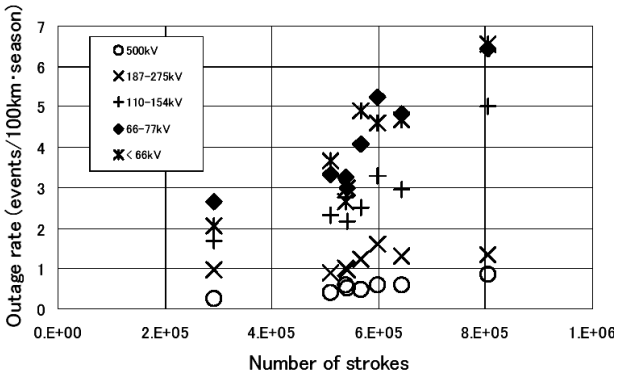

Figure 6.3-2 Transmission outage rate versus total number of lightning ground strokes in Japan (Ishii et al. 2002).

Various expressions were given to relate TD observations to the area density of ground flashes, *GFD,* usually expressed in flashes per square kilometer per year. Generally, ten years of observations are needed in areas of moderate thunderstorm activity (TD = 40 days/year) to obtain the 400 counts needed for a 5% relative standard deviation. Values obtained from areas with TD = 5 need 80 years of data to have the same certainty. This rule-of-400-counts applies to all GFD measurement methods.

Independent measurements of ground flash density have become increasingly sophisticated. In the 1970s, several long-term studies were initiated with the use of CIGRE 10-kHz lightning flash counters. In their 4-m vertical antenna configuration, these instruments advance a mechanical counter whenever a rapid, 26 V/m electrostatic field change occurs. Cross-calibration experiments and calculations support an average detection radius of 20 km, although the counters can respond to some strong flashes as far as 50 km away. An extensive program of measurements was carried out in South Africa, covering a broad range of flash density values over an 11-year period with the results in Figure 6.3-4.

The following expression was recommended for relating thunderstorm day levels in South Africa to ground flash density (CIGRE 1991):

$$GFD = 0.04TD^{1.25} \qquad 6.3\text{-}1$$

Figure 6.3-4 also introduces data from the Optical Transient Detector (OTD) experiment (Christian et al. 2003), which was established in 1995 to measure lightning flash characteristics using a satellite. The strong trend for higher ground flash density in the east of South Africa forms one

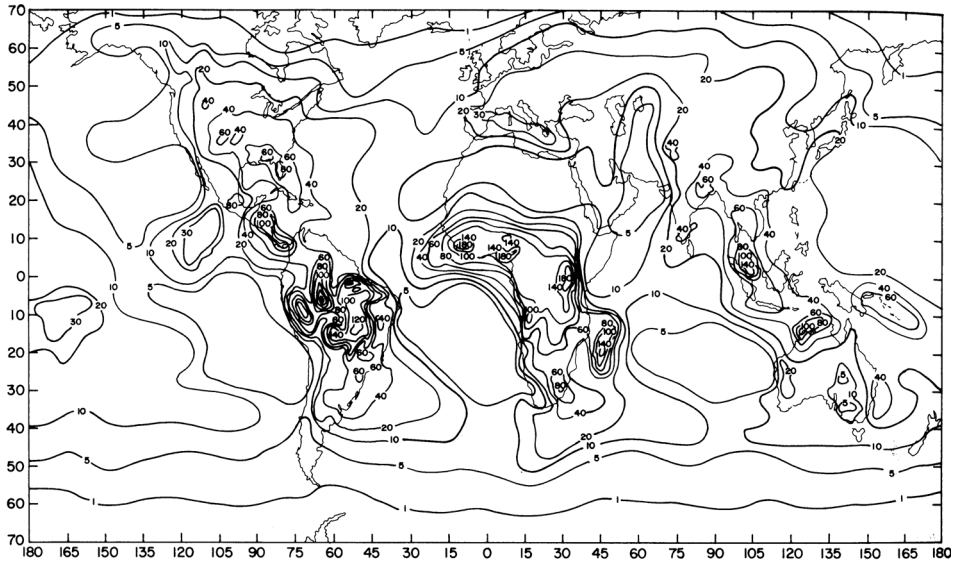

Figure 6.3-3 Global map of Thunderstorm Days per year (WMO 1953, www.wmo.int).

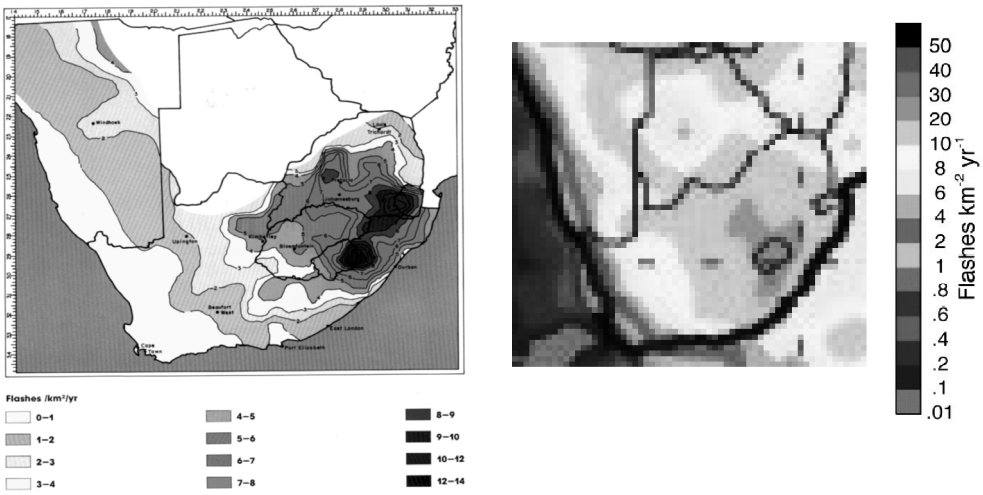

Figure 6.3-4 *Left:* Records of ground flash density from CIGRE 10-kHz lightning flash counters, 1975-1986; *Right:* Records of (CC+CG) flash density from optical transient detector (Christian et al. 2003).

of the best areas for intercomparison and calibration of the OTD data, which are less reliable because there are far fewer samples in each grid square. The OTD data are discussed below.

When applied to the continental U.S. map of *isokeraunic* lines of equal lightning density in Figure 6.3-5, the South African expression suggests peak ground flash density values of $0.04\ (130)^{1.25} = 17.5$ flashes per km^2 per year in central Florida, with values reaching 11 flashes per km^2 per year in areas of nine states that have TD levels greater than 90 days per year. The high local density of thunderstorm days in the central U.S. does not translate directly into an elevated level of ground flash density obtained from lightning location systems (MacGorman et al. 1984), leading to a hypothesis that thunderstorm-hour data would have a more linear relationship. Figure 6.3-6 shows the ground flash density estimates based on the recommended expression, $GFD = 0.054\ (TD)^{1.1}$, for the continental U.S.

Later studies by Chisholm, Janischewskyj, and Beattie (Chisholm and Janischewskyj 1992; Janischewskyj, Chisholm et al. 1997) showed, however, that the relationship between TH and ground flash density also has a regional dependence, comparing continental U.S. and Canada. There are more thunderstorm hours per year than thunderstorm days, so fewer years are needed to obtain the desired 400 observations, and this is perhaps the strongest advantage of TH measurements.

A more direct resource has become available to estimate lightning ground flash density in the absence of lightning location network or lightning flash counter data. Optical transient detectors, operated in low-earth orbit since 1995,

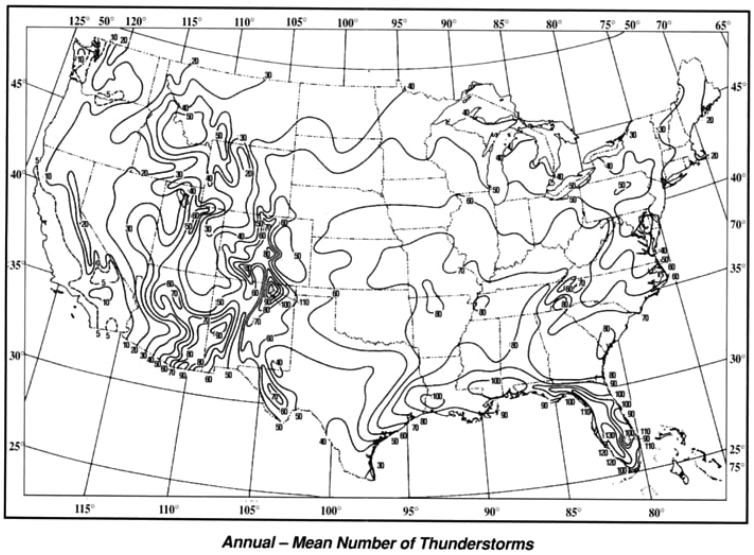

Figure 6.3-5 Isokeraunic map of the contiguous United States (MacGorman et al. 1984).

Figure 6.3-6 Estimate of ground flash density from Thunderstorm Hour (TH) values (MacGorman et al. 1984).

contribute another 10^6 flash observations per year, sampling most of the world's surface. These instruments provide an estimate of ground flash density in areas where lightning location systems have not been operated. Figure 6.3-7 shows the mission summary, which has been corrected for uneven sampling in each area and converted to a (Cloud-to-Cloud + Cloud-to-Ground) flash density.

Intercomparison of the OTD data and values from a second satellite, with a Lightning Imaging Sensor (LIS) with lightning location system data in the continental U.S. has validated an average value of (IC:CG) ratio $Z = 2.94$, with a standard deviation of 1.28 (Boccippio et al. 2001). However, by comparing Figure 6.3-7 with other measurements of ground flash density in Australia, Brazil, Canada, China, Colombia, Italy, Japan, and South Africa, the best estimates of ground flash density are obtained by dividing the (intracloud + ground flash) density values in Figure 6.3-7 by $(Z + 1) = 3.0$ rather than 3.94.

For ease of use, Applet G-2 provides the observed OTD count and the estimated ground flash density (using a factor of 3.0 OTD per ground flash) for any value of longitude and for latitudes from -60° to 60°. Figures 6.3-8 to 6.3-10 show the raw OTD data used in this applet, using expanded scales and the native 0.5x 0.5° resolution of the data. The strongest advantage of the OTD data over other observations is a lack of location bias, but the number of counts in each grid square is less than 50 in areas of low density. Additional studies, integrating more recent LIS data, may

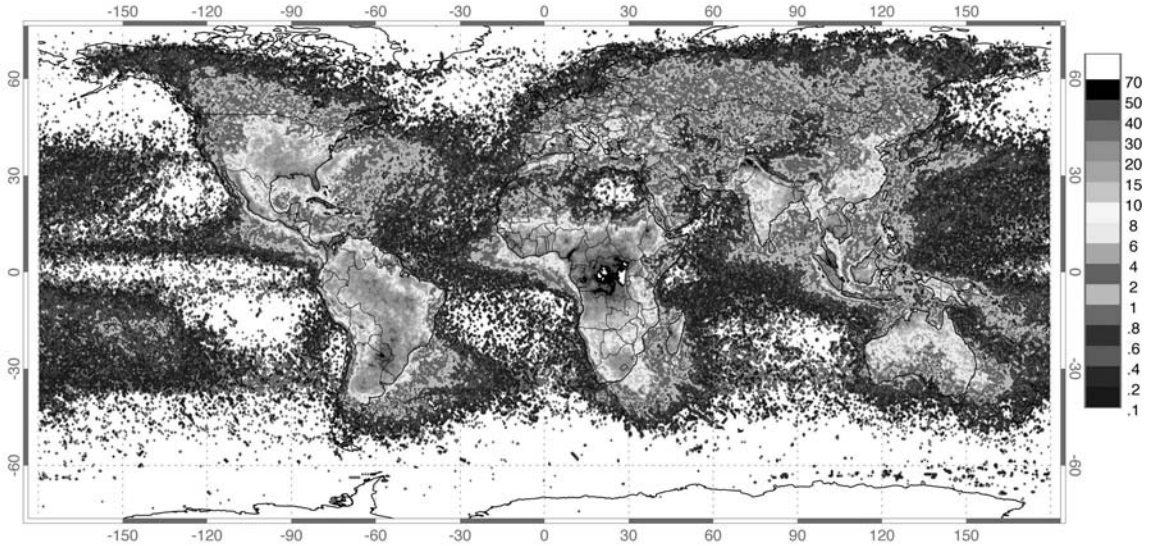

Figure 6.3-7 Global frequency and distribution of combined Inter-Cloud (IC) and Cloud-to-Ground (CG) lightning, as observed from space by the Optical Transient Detector and Lightning Imaging Sensor satellites (Christian 2002).

eventually improve the statistics and refine the value of Z in equatorial regions where existing observations can be unreliable and where the lightning flash density has its largest regional variations.

Wide-area lightning location systems, such as those using a combined time-of-arrival and direction finding approach (Cummins et al. 1998), offer important improvements in observations of ground flash density compared to any of the methods described above. The basic instrumentation, using magnetic loop antennas and regulated power supply, retains its calibration better than lightning flash counters, and its measurement range is 10 to 20 times larger. There has been a steady improvement in the detection efficiency and location accuracy of networks (Cummins et al. 1998) and better understanding of the need for sensors outside the area of interest. For example:

- Lightning observations up to 200 km south of the U.S.–Canada border improved when the North American Lighting Detection Network (NALDN) integrated a number of sensors in Canada (Orville 2002).
- Lightning observations in Brazil improved when a cooperative network of lightning location sensors was integrated from five independent systems (Cherchiglia et al. 2002).
- Observations along the U.S.–Mexico border retain a variety of measurement errors related to lack of sensors in Mexico.

6.3.2 General Observations

Latitude Effects

Several researchers have studied the possibility that there are differences between lightning in tropical areas and lightning in temperate climates. Most studies have traditionally been carried out in Australia, Europe, Japan, North America, and South Africa, where there have been more resources to apply and protect. This has led to problems, for example, in the basic estimate of ground flash density from thunderstorm-day level in areas where there are more than 150 TD per year, each tending to be of short duration. However, high levels of lightning, combined with difficult grounding conditions and increasing rate of development,

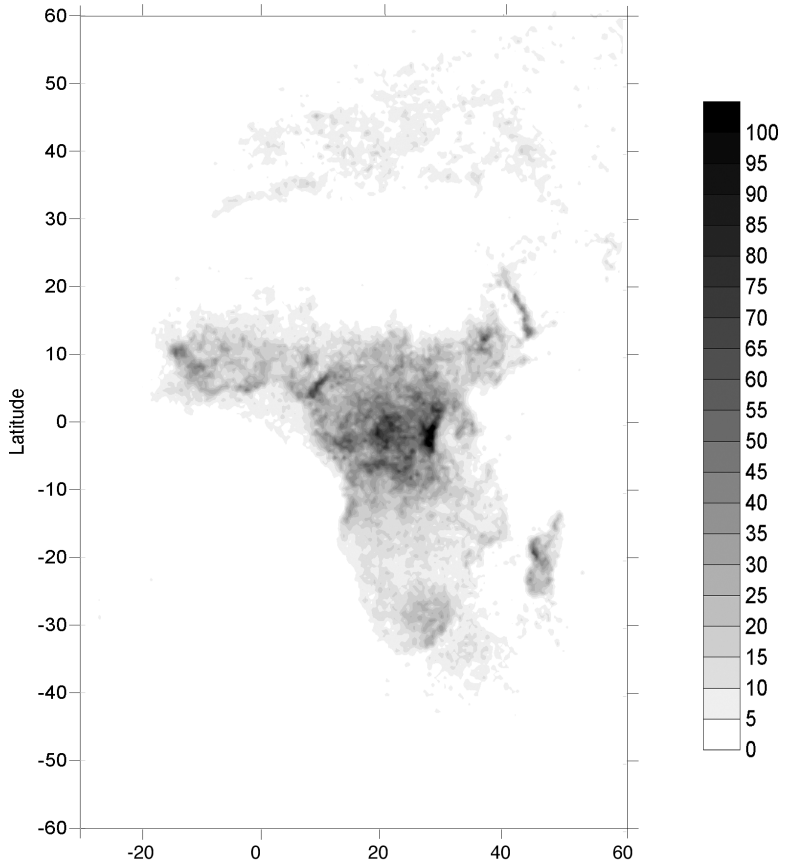

Figure 6.3-8 Combined LIS/OTD data for Africa and Europe. Units: (Cloud + Ground) flashes per km^2 per year.

have resulted in important contributions from Brazil, China, Colombia, and other regions.

Prentice and Mackerras (Prentice and Mackerras 1977) have studied the relationship of the IC:CG ratio Z as a function of latitude. This parameter changes significantly from storm to storm, but the researchers noted a tendency for Z to increase to $Z = 6$ at the equator, compared to $Z = 3$ in temperate regions from 30 to 60°. Their later work (Mackerras and Darveniza 1994) found Z largely independent of latitude. Boccippio (Boccippio et al. 2001) did not find any trend of Z variation with latitude either, but did note a strong increase in Z in the central U.S., possibly as a function of the fraction of positive-to-total flashes.

Measurements of peak stroke current distribution across the U.S. and Canada presently show a strong cross-border influence, with median lightning in Canada being less than 18 kA, a level observed only in limited areas of the U.S., where the earth resistivity is also high. At the fringe of the lightning location network used to gather the data in Figure 6.3-11, small-amplitude flashes are not detected, and the median value increases.

The median current level of 18 to 20 kA in much of continental U.S. is well below the 31-kA median reported by (Berger et al. 1975) and adapted into lightning calculations, including those presented here. It should be noted that the median from the lightning location system includes several competing biases, such as:

- A small fraction of misclassified subsequent strokes (12 kA median versus 31 kA); for example, a distribution with 20% subsequent strokes and 80% first strokes would have a median of about 27 kA.
- Correct identification of multiple ground terminations, each of which may have a reduced leader charge and peak amplitude compared to single-termination events collected at tall, instrumented towers.
- A single model for attenuation of normalized signal strength (Cummins et al. 1998) for the entire region,

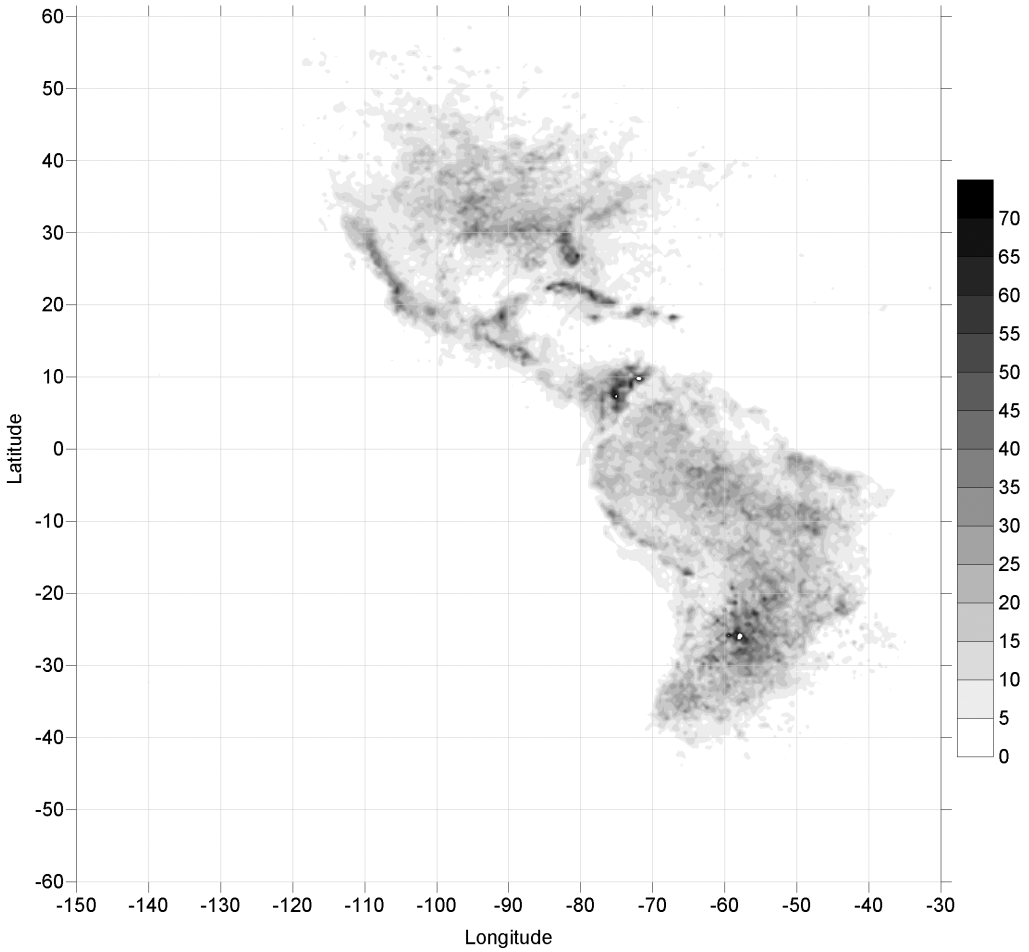

Figure 6.3-9 Combined LIS/OTD data for the Americas. Units: (Cloud + Ground) flashes per km^2 per year.

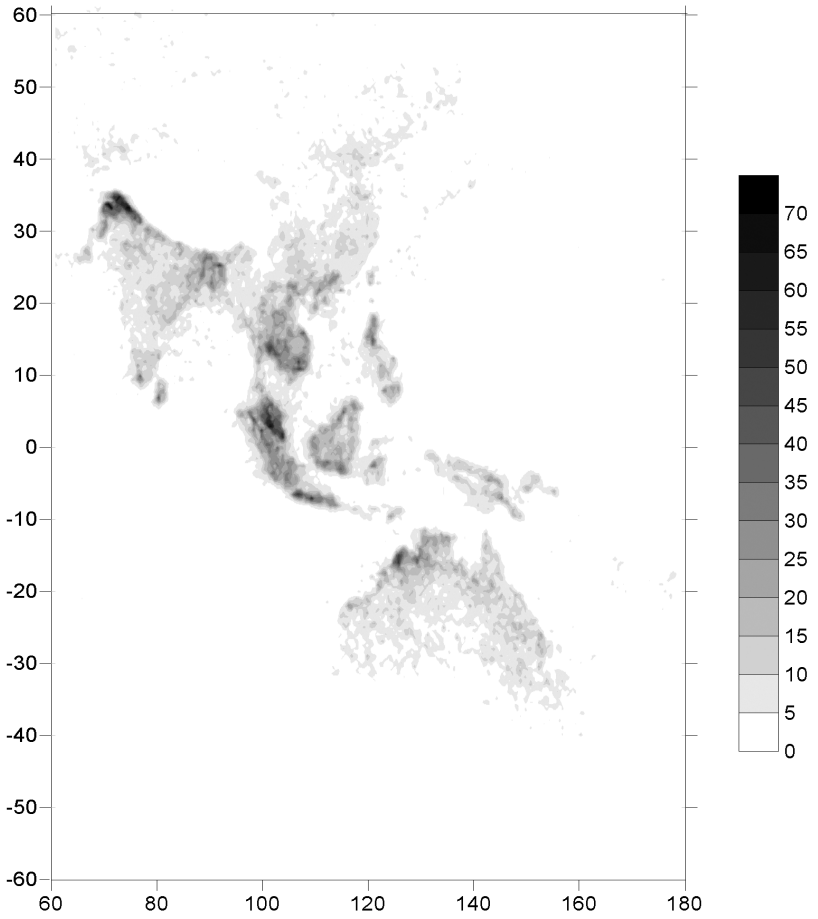

Figure 6.3-10 Combined LIS/OTD data for Asia. Units: (Cloud + Ground) flashes per km^2 per year.

which has a wide range of resistivity values given in Section 6.10 and Applet G-2.

- A wide range of baseline distances between sensors, as shown in Figure 6.3-14.

The saltwater-to-land transition has more of an effect than any variation with latitude in Figure 6.3-11. There is no such effect over large bodies of fresh water, which has a resistivity 400 times higher than saltwater. There are at least three hypotheses that can explain why observed lightning amplitudes are about 20% higher over the ocean:

- An abrupt reflection coefficient for ground-wave impedance occurs at the ocean-to-land interface, increasing the apparent source strength of electromagnetic waves arriving from the ocean side.
- The propagation of the electromagnetic wave from the return stroke is minimally attenuated over saltwater compared to its theoretical inverse-distance relation, but the peak signal strength attenuates by 10-30% over a typical 10-100 km land path.

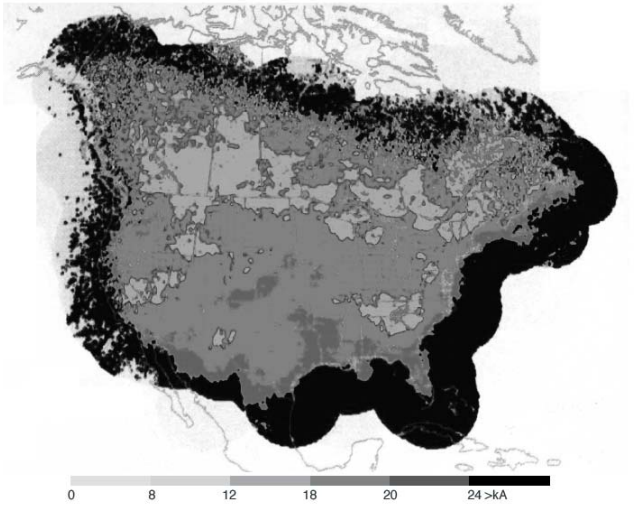

Figure 6.3-11 Observed median negative peak stroke current for North American Lightning Detection Network, 1998-2000 (Orville at al. 2002).

- The internal source impedance of the lightning flash, described as about 3000 Ω in Figure 6.2-7, encounters the minimum (35 Ω) surge impedance of a hemisphere electrode in the low 0.25 Ω-m resistivity of the ocean and a higher 600-Ω average impedance in a typical lightning termination on 100-1000 Ω-m soil.

The second and third hypotheses both argue for the use of the stroke current distribution observed over the ocean for well-grounded transmission-line structures. However, in view of these uncertainties, the important questions about the correct stroke current amplitude distribution, and its regional dependence, remain to be resolved by additional research and discussion. One possible treatment in the meantime would be to tabulate the incidence of stroke currents above a given backflashover critical current. Also, advanced studies of the leader charge and its relation to stroke current may refine the shielding failure model as well.

Time-of-Year, Time-of-Day Variation

Lighting shows a significant time-of-day variation, with low levels of activity from midnight to 10 a.m. local time, and high levels of activity peaking from 2 to 5 p.m., as shown in Figure 6.3-12. This is well understood by most electrical utility transmission line maintenance staff, and is reflected in a biased workday that starts early (6 to 7 a.m.) to minimize risk of interruption from lightning. In the northern hemisphere, Figure 6.3-13 shows a strong seasonal lightning variation with a peak in July and August.

6.3.3 The North American Lightning Detection Network

History of Commissioning

At the time of preparation of the second edition of the Red Book, the basis of modern lightning location technology had been described by Krider et al. (Krider et al. 1976) and tested for finding forest fires. EPRI and its members have promoted the technology for the NALDN through the 1980s, leading to successful commercialization in 1989. As a direct result of this work, there has been an increase in the number of observations of lightning:

- **1978:** approximately 10^6 observations per year in 1978, mainly registrations of lightning flash counters.
- **1989:** 12 x 10^6 measurements of gated wideband peak magnetic field and analog bearing per year in the continental U.S. alone (Orville and Huffines 2001).
- **1998:** 25 x 10^6 measurements of peak-radiated field and global positioning system (GPS) synchronized time per year in the continental U.S. (Orville and Huffines 2001).

Present Detection Technology—Magnetic Direction-Finding and Time-of-Arrival

In the mid-1990s, experience demonstrated that the combined use of magnetic direction finding (DF) and time-of-arrival (TOA) offers more robust estimates of lightning locations. The time-of-arrival technique proved to be less dependent on local site errors than direction finding, which is affected by reradiation from local conducting loops of various dimensions. The combined technology was optimized (Cummins et al. 1998), using GPS receivers to give accurate local time references.

Detection Efficiency and Location Accuracy

Since the peak-radiated field from lightning return strokes falls off more than inversely with distance, the sensitivity of a sensor network is established to some extent by the distance from the lightning to the nearest sensors. In the original (DF only) network, two time-synchronized sensors were needed to obtain a unique location. The addition of time-of-arrival capability increased the average number of sensors responding (ANSR) requirement to three or more if the DF data were not used in the computation. At least one IMPACT magnetic-field sensor reading is still needed in the NALDN to compute stroke amplitude. Figure 6.3-14 shows that baseline distance between magnetic-field amplitude

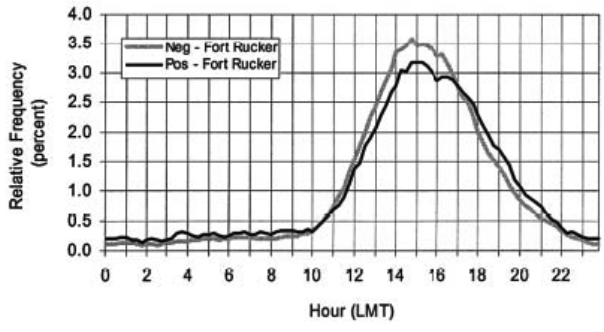

Figure 6.3-12 Observed summertime diurnal variation in lightning occurrence at Fort Rucker, Florida (Zajac and Rutledge 2001).

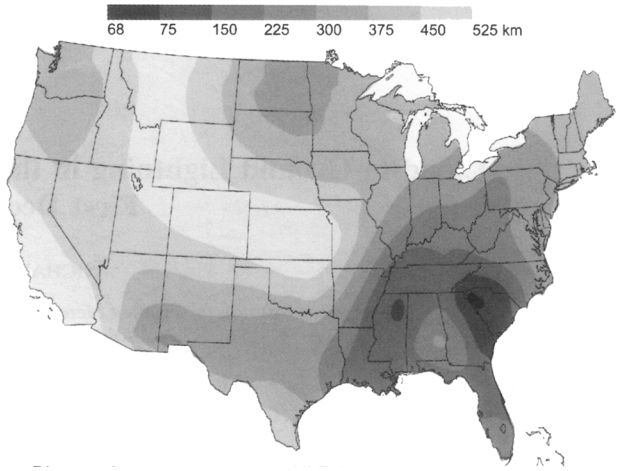

Figure 6.3-14 Distance between nearest pairs of IMPACT DF sensors in NALDN (Orville et al. 2002).

sensors in the U.S. NLDN network vary from 100 km in the Southeast and more than 400 km in the West.

Cummins (Cummins et al. 1998) has computed that the variation of baseline distance in Figure 6.3-14 does not affect the probability of detection and has focused network development on improving fringe coverage along the U.S.-Canada border by combined operation as a single NALDN. Experience with co-operative networks of lightning location sensors in Japan, Europe, Canada (Alberta/BC), and Brazil has demonstrated that accurate and uniform probability of detection within a region requires that sensors be placed on the border of, and preferably a distance of 200 km outside, the region. As an example, the increased ground flash density in U.S. states on the 49° latitude in Figure 6.3-16, compared to Figure 6.3-15, is most likely a function of the improved probability of detection when the two networks were integrated in 1998**.** Values within the center of an extensive network are relatively stable, while values at the edges of the network change considerably with improvements to network configuration.

Ground Flash Density Maps

Procedures to Perform an Adequate Study

When data are being binned, sampling error is defined as the square root of the number of counts. If the bin size is too small, it becomes impossible to say whether any particular count (say, a square km with 10 flashes per year) is significantly different from an adjacent area (say, with only 8 flashes per km^2 per year). For counting lightning events, it is recommended that a minimum of 400 counts should be aggregated. With typical ground flash density of less than 1 flash per km^2 per year in the western United States, year-by-year comparisons of 20 x 20 km grids would be valid, and the minimum grid size of 6 x 6 km would be acceptable in an 11-year study.

Insights from FALLS (Fault Analysis and Lightning Location System) Studies

It has always been an interesting challenge to establish the parameters of lightning flashes that actually cause transmission-line outages. In 1962, the Edison Electric Institute (EEI) initiated a ten-year study, called the "Pathfinder Project," to establish root causes. This research was carried out at a time when the U.S. utilities were spending several

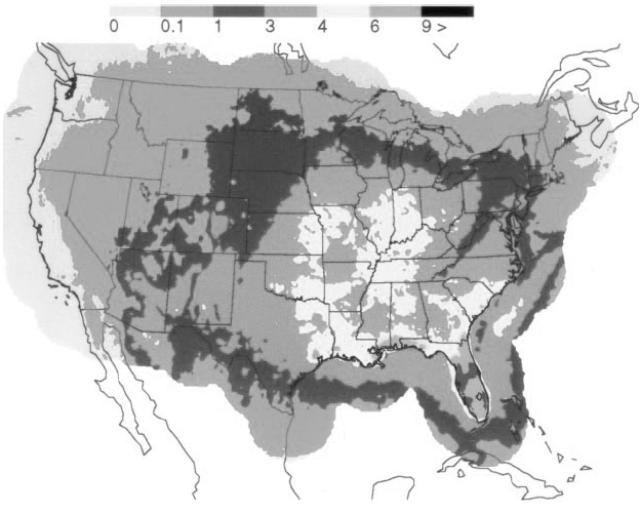

Figure 6.3-15 Mean annual negative lightning ground flash density, contouring 216 x 10^6 flashes from 1989 to 1998, without correction for detection efficiency (Orville et al. 2002).

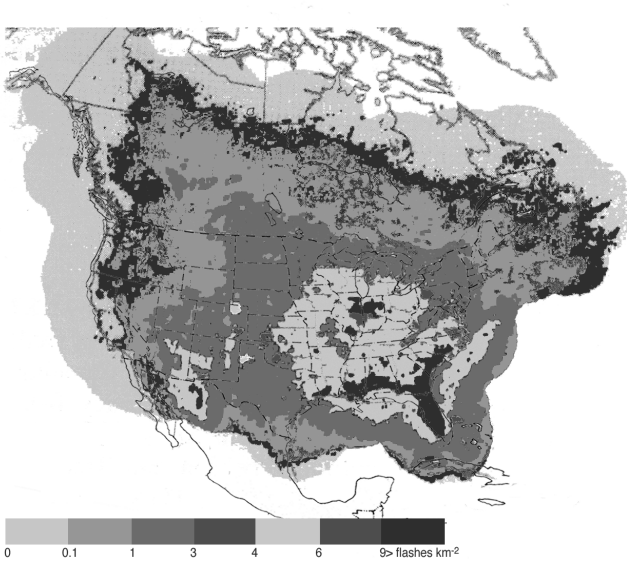

Figure 6.3-16 Mean annual lightning ground flash density, 1998-2002, after extension of network into Canada.

billion dollars per year on EHV infrastructure. Approximately 4600 instruments were installed on 400 miles (644 km) of transmission line, giving 138 operations on 89 separate strokes. Of these, 48 were identified as shielding failures, and 39 were backflashovers. Figure 6.3-17 provides a summary of operations for the project.

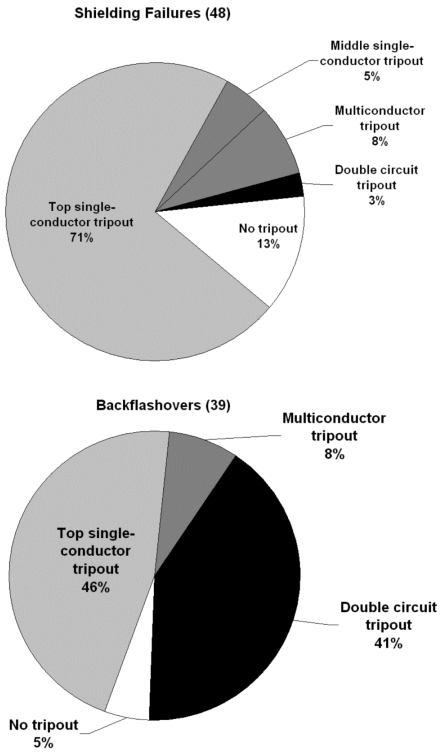

Figure 6.3-17 Summary of "Pathfinder" instrument operations for root cause analysis of lightning tripouts.

Whitehead (Whitehead 1971) found a 93% proportion of negative flashes in this study and developed a more conservative model of transmission-line shielding, taking advantage of the concurrent work on switching-impulse flashover by Paris and Cortina (Paris and Cortina 1968). Most utilities now overlay LLS data onto geographic information systems to establish specific outage causes on existing lines.

6.3.4 Inter-comparison of Lightning Detection Methods

Cross Calibrations

Chisholm and Janischewskyj (Chisholm and Janischewskyj 1992) carried out an inter-comparison of a DF80-02 lightning location network with 70-km baselines and registrations of CIGRE 10-kHz lightning flash counters (LFC). They found that, while the nominal detection radius of the LFC was 20 km, some flashes were detected as far as 45 km from the LFC. Tests with an all-sky camera located 50 km from the nearest DF 80-02 receiver showed an overall detection efficiency of 70% using this older technology.

Boccippio et al. (Boccippio et al. 2002) compared registrations of the lightning location network in the United States with observations of optical transients viewed from above. While low sampling density at any one location remains a problem, these researchers were able to establish a ratio of cloud flashes to ground flashes (Z) of 2.94.

Calibration using Features that Attract Lightning

While it would seem logical to look for a concentration of lightning flashes around tall structures, this has not always led to success. Measurements on a 100-m tower in Austria have been quite successful, leading to an estimate of 400-m location accuracy (Diendorfer et al. 2002). Correction of the signal strength for the additional radiation caused by the presence of the tower leads to a moderate discrepancy of 20% in the recorded amplitudes.

In contrast, the lightning location systems tend to reject electromagnetic signals from taller towers. As illustrated in Figure 6.2-19, there is a pronounced second peak, in the current measured on the 553-m CN Tower. The second peak is delayed by the two-way propagation time of current down and up the tower, and is significantly higher than the first peak. Signals like this fail a lightning location system waveform test meant to reject signals that have been distorted by excessive propagation distance (>600 km) through ionospheric reflection.

Local orographic features, such as oceans and mountain ridges, exert show a strong influence on ground flash density. The land-water contrast also leads to differences in estimated peak current over seawater and land, as shown previously in Figure 6.3-11. This difference does not, however, show up over the Great Lakes, which have a resistivity of 80 to 125 Ω-m, similar to the surrounding land, and thus may be an electromagnetic effect (such as a partial reflection of the incoming waves).

6.4 SURGE IMPEDANCE AND CORONA EFFECTS

Surge impedance concepts are used to provide a sufficiently accurate and detailed transfer function between the majority of input currents described in Section 6.3 and the dominant descriptions of insulation strength, based on voltage waveforms, in Section 6.5. For some aspects, such as slow input currents or late times to flashover, surge impedance effects are not important, but tower surge response and travel time have significant sensitivity in the predicted lightning performance of tall transmission lines.

Analysis of the response of transmission lines to lightning currents has been carried out with a variety of approaches. There is a broad range of excitation described in Section 6.2. Table 6.4-1 classifies these features in terms of time, frequency, and distance.

Table 6.4-1 Time-Domain and Frequency-Domain Features of Lightning Components

Parameter	Feature	Time-domain Description	Equivalent Bandwidth and λ/10 Wavelength
Subsequent Stroke	50-90% rise time	100 ns	1.7 MHz, 18 m
Subsequent Stroke	Peak	12.kA with 40 kA/μs	520 kHz, 58 m
First Stroke	30-90% rise time	2.3 μs	91 kHz, 330 m
First Stroke	Peak	31 kA with 24 kA/μs	124 kHz, 242 m
Continuing Current	Duration	100 ms	5 Hz, 6 x 10^6 m

The equivalent bandwidth is computed using one of two expressions:

$$f = \frac{0.35}{t_{10\%-90\%}} \qquad 6.4\text{-}1$$

$$f = \frac{dI/dt}{2\pi\hat{I}} \qquad 6.4\text{-}2$$

The λ/10 wavelength corresponds roughly to the size of structure for which traveling-wave or antenna-mode representation starts to become important.

The concave shape of the lightning stroke current ensures that the maximum steepness occurs at the same time as the peak of the current wave. This means that any insulator voltage rise from inductive effects ($L\ dI/dt$) will be added to the voltage rise from resistive components ($R\ I$) at the crest of wave. Fourier analysis of double-exponential and concave-front waves with the same peak magnitude does not highlight this important difference.

6.4.1 Surge Impedance of Single Wires and Bundles

Under Linear Conditions

A lightning stroke to a conductor produces a traveling wave of current I and voltage V, related by a surge impedance $Z = V/I$. This surge travels along the conductor at the speed of light unless there is a dielectric or a convoluted path. The surge impedance is purely resistive, so V and I have the same waveshape. Surge impedances of transmission lines and cables are functions of their distributed self-inductance L_{11} and self-capacitance C_{11} per unit length:

$$Z = \sqrt{\frac{L_{11}}{C_{11}}} \qquad 6.4\text{-}3$$

$$v = \frac{1}{\sqrt{L_{11}C_{11}}} \qquad 6.4\text{-}4$$

In cases where there is no dielectric between the conductor and ground, the speed of propagation v will equal the speed of light c, 3 x 10^8 m/s. In this case, it is easy to estimate the inductance L or capacitance C using the travel time τ of the line segment L_{seg} and its surge impedance Z. Equation 6.4-5 shows that this process, for speed-of-light propagation, simplifies to the well-known $\tau = ZC$ and $\tau = L/Z$ expressions for time constants in electric circuits.

$$\tau = \frac{L_{seg}}{c} \quad L = Z\tau \quad C = \frac{\tau}{Z} \qquad 6.4\text{-}5$$

From installing 75-Ω cable for television (CATV), many people are now familiar with the surge impedance of coaxial cables, defined for two concentric cylinders of inner radius r_1, outer radius r_2, and insulation dielectric constant ε_r as:

$$Z = \frac{60}{\sqrt{\varepsilon_r}} \ln\frac{r_2}{r_1} \qquad 6.4\text{-}6$$

The speed of propagation is reduced by the presence of dielectric material to:

$$v = \frac{c}{\sqrt{\varepsilon_r}} \qquad 6.4\text{-}7$$

Under lightning surge conditions, some of the air around the conductor ionizes and makes a temporary corona dielectric that functions in the same way as the plastic core of a coaxial cable, to reduce the surge impedance and slow down the velocity of propagation.

The surge impedance of a round wire of radius r at a height H over perfectly conducting ground plane can be calculated from expressions for the per-meter inductance and capacitance of the wire and its image at $2H$. The surge impedance is defined as the square root of the ratio of the self-inductance to the self-capacitance:

$$Z = \sqrt{\frac{L_{11}}{C_{11}}} = \sqrt{\frac{\frac{\mu_o}{2\pi}\ln\left(\frac{2H}{r}\right)}{\frac{2\pi\varepsilon_0}{\ln\left(\frac{2H}{r}\right)}}} = 60\ln\left(\frac{2H}{r}\right) \qquad 6.4\text{-}8$$

In the case of bundles of multiple conductors, an equivalent radius is obtained using the geometric mean of the wire self radius r_{11} and the distances r_{12}, r_{13} … r_{1n} to the other wires in the bundle:

$$R_{eq} = \sqrt[n]{r_{11} \cdot r_{12} \cdot r_{13} \cdots r_{1n}} \quad 6.4\text{-}9$$

In the case of a conductor in corona, the wire or bundle radius will increase as a function of voltage to model the additional capacitance, as described below in Equations 6.4-22 and 6.4-23.

The surge impedance relates the conductor potential that will be reached after injection of a unit step current. While it is defined for an infinite wire, the surge impedance values of relatively short wire segments are still useful for describing the electromagnetic response using electrical circuits. This will be discussed in further detail in Section 6.4.2.

If there is a step change in geometry that leads to a change in surge impedance, then the voltages and currents will change on both sides of the interface. It is useful to define a reflection coefficient for the interface from a surge incident from Z_1 to Z_2 as follows:

$$\rho_{12} = \frac{Z_2 - Z_1}{Z_2 + Z_1} \quad 6.4\text{-}10$$

The reflection coefficient from a surge moving from Z_2 towards the interface is ρ_{21}, which does not equal ρ_{12}. The voltage at both sides of the interface is constant after the surge arrives, and the sum of the currents moving towards and away from the interface must also be zero. This gives the following relationships:

	$t<t_o$	$t>t_o$
V_1	$I_o Z_1$	$(1+\rho_{12})\, I_o Z_1$
I_1	I_o	$\rho_{12}\, I_o$
V_2	0	$(1+\rho_{12})\, I_o Z_1$
I_2	0	$(1-\rho_{12})\, I_o$

6.4-11

The relationship that $V_2 = Z_2 I_2$ can be used to obtain an expression for Z_2 as a function of a known source impedance Z_1 and an observed reflection coefficient ρ_{12}:

$$Z_2 = \frac{1+\rho_{12}}{1-\rho_{12}} Z_1 \quad 6.4\text{-}12$$

This relationship is used for single or multiple reflections in a measurement technique called Time Domain Reflectometry, or *TDR*. TDR methods have been used to study the lightning surge response of transmission-line towers since the 1950s in full-scale and miniature model experiments.

As an example, a wire of 10-mm radius at a height of 30 m above ground is connected to a bundle of four wires, each with 10 mm radius but spaced in a square of 450 mm. The equivalent radius of the bundle is 0.189 m. The surge impedance of the single wire is Z_1 = 522 Ω. The surge impedance of the bundle is Z_2 = 346 Ω. The reflection coefficient at the interface is ρ_{12} = –0.203. A surge current of I_1 = 1 kA surge injected into the single wire over ground produces a surge voltage of 522 kV with the same waveshape. This surge propagates at the speed of light until it arrives at the interface. Then a surge current of I_2 = 1203 A continues in the bundle conductor away from the source, and a reflection of $-\rho_{12} I_1$ = 203 A starts to travel back towards the source, satisfying Kirchoff's law at the junction. The voltage wave propagating into the bundle conductor is 416 kV, computed either from $I_2 Z_2$ or from $(1 + \rho_{12}) V_1$. A negative voltage wave component with magnitude $\rho_{12} V_1$ = -106 kV reflects back towards the source (see Figure 6.4-1).

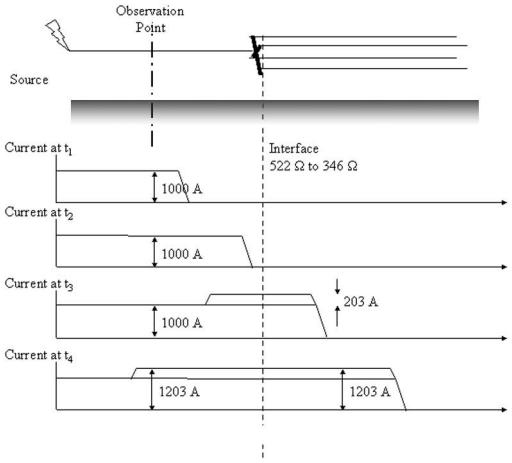

Figure 6.4-1a Time and space evolution of traveling current waves at interface.

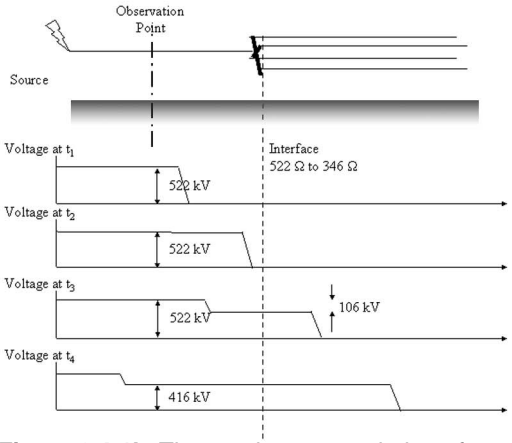

Figure 6.4-1b Time and space evolution of traveling voltage waves at interface.

The concept of getting more current into the bundle conductor than was originally injected into the single wire is sometimes difficult. However, when the single-wire section is considered as a voltage source with series impedance Z_1, it is more readily grasped that the open-circuit voltage is double the voltage into a matched load $Z_2 = Z_1$ (and the open-circuit current is zero). The short-circuit current is double the current into a matched load, and the short-circuit voltage is zero. The open-circuit, matched-load, and short-circuit cases correspond to $\rho_{12} = 1$, $\rho_{12} = 0$ and $\rho_{12} = -1$.

Conventional TEM Coupling Coefficients

When an undriven conductor is placed in parallel to a conductor that is excited by a surge source, the mutual capacitances and inductances combine to make a mutual surge impedance. This mutual surge impedance causes a faithful copy of the original wave, reduced in magnitude, to appear on the undriven conductor. The calculations of this Transverse ElectroMagtnetic (TEM) response are valid for all frequencies. At higher frequencies, corresponding to conductor height h of more than a tenth of a wavelength ($h > \lambda/10$, λ = 300 m or about 1 MHz for 30-m conductors) other modes of electromagnetic response also contribute, but the TEM mode remains a dominant term. For very fast rise times, there is a time delay in establishing coupling, which will be discussed in the next section.

Figure 6.4-2 shows the dimensions to be used in calculating the TEM coupling coefficients, based on the direct distance from driven to undriven conductor (D_{12}) and the distance from the undriven conductor to the image in a perfectly conducting earth of the driven conductor (D'_{12}).

$$Z_{11} = 60 \ln \frac{2H_1}{r_1} \quad Z_{22} = 60 \ln \frac{2H_2}{r_2} \qquad 6.4\text{-}13$$

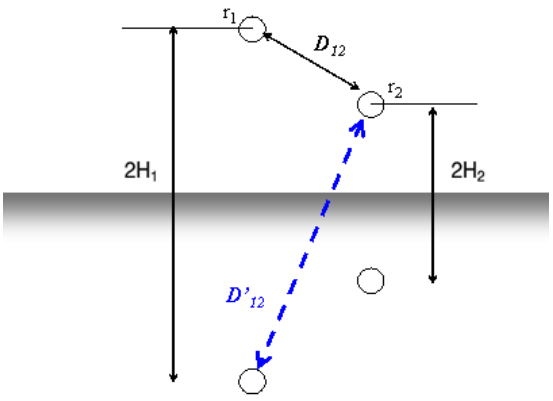

Figure 6.4-2 Dimensions for calculation of TEM coupling coefficient.

$$Z_{12} = Z_{21} = 60 \ln \frac{D'_{12}}{D_{12}} \qquad 6.4\text{-}14$$

$$v_1 = i_1 Z_{11} + i_2 Z_{12} \qquad 6.4\text{-}15$$

$$v_2 = i_1 Z_{21} + i_2 Z_{22} \qquad 6.4\text{-}16$$

With no current source on an undriven conductor, $i_2 = 0$ and the induced voltage v_2 simplifies to:

$$v_2 = \frac{Z_{21}}{Z_{11}} v_1 = c_n v_1 \qquad 6.4\text{-}17$$

The coupling coefficent c_n provides important mitigation of lightning. The line insulation is stressed by the difference in potential, $(v_1 - v_2)$. Any increase in the coupling factor reduces this potential difference (see Figure 6.4-3). On typical transmission lines, TEM coupling reduces insulator stress by 30 to 50% under backflashover conditions, and this can reduce transmission outage rates by a factor of three. Coupling can be deliberately enhanced by using more overhead groundwires, placed closer to (or under) the phases. This tends to increase losses from induced currents, and can cause other problems with clearances, electromagnetic compatibility (EMC), or mechanical loads.

Time Delay in Establishing Coupling

The TEM propagation assumes a uniform plane wave, and also assumes that the current in the undriven conductor is zero. Two exercises in nanosecond-model simulation of the TEM coupling can contribute insight into the value and limitations of this model. Nanosecond models use signal sources such as current step or impulse generators with >1ns rise time, along with wideband sampling oscilloscopes to allow efficient simulation of the complex electromagnetic waves using miniature wires and towers over conducting ground planes (Fisher et al. 1960).

If a wideband current transformer is placed around the driven conductor, a fast-rising step of current is measured as the wavefront passes. If a second CT is placed around the undriven conductor, an impulse, corresponding to the derivative of the first current, is measured. This impulse is also delayed in time, depending on how far along the measurement is taken from the excitation source. The source

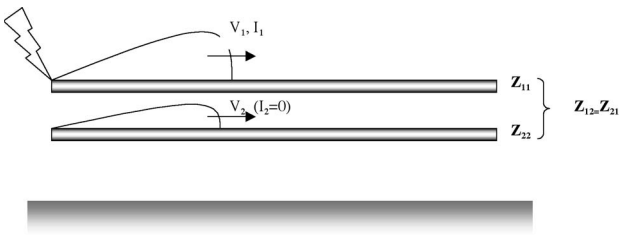

Figure 6.4-3 TEM coupling factor for two overhead lines.

excites a spherical wave that, in the limit of great distance, eventually flattens out into a plane. However, the lightning calculation is carried out near the source, and this time delay adds to insulator stress.

It is also useful to try out a technique for measuring voltage, using a probe technique originated by (Newi 1968) for fast high-voltage measurements. A high–impedance probe tip is connected to the driven or undriven conductor, and the probe sheath is maintained at a constant height over ground. Since the geometry is constant and the surge impedance can be relatively low compared to the probe, the relative error would be expected to be small. With a 5-kΩ probe impedance working into the usual 50-Ω coaxial cable of good high-frequency equipment, a 500-Ω surge impedance would introduce a 10% error at late time. However, a comparison of the current and voltage records quickly establishes that the voltage probe rise time is slowed to several times the wire height divided by the speed of light. This again is the time to establish the TEM coupling, and the degraded rise time is not real: the voltage and current should have the same waveshape. In general, the most useful voltage measurements in nanosecond model studies (or full-scale studies) are those taken across small distances (for example, from an undriven conductor to a nearby tower or across insulator strings) and measured locally or brought out to the oscilloscope on an optical fiber link. Measurements of currents are preferred because the results are unambiguous and less sensitive to probe routing.

Nanosecond modeling is an important complement to calculation of electromagnetic fields using advanced computer methods. One set of numerical results from (Baba and Ishii 2000) illustrates the concept of time variation of coupling coefficient using the NEC-2 computer software. Figure 6.4-4 shows this variation for a step function case without towers, and for more realistic cases where a 120-m tower and 2μs wavefront are introduced.

The delay in establishing TEM coupling is an important issue in the calculation of lightning outage rates for tall overhead lines, which remains to be integrated into future evaluation methods.

Impulse Corona Onset Voltage

At voltages below corona onset, the current resulting from a lightning impulse is purely capacitive. Above corona onset, however, the movement of corona-generated space charge near the conductor produces an additional current component. Impulse corona characteristics of transmission-line conductors are generally obtained as charge-voltage diagrams or *q-v* curves, with the simultaneous recording of the voltage *v(t)* and charge *q(t)* displayed along the x and y axes of the curve. The *q-v* curves on conductors may be obtained in laboratory (Davis and Cook 1960) or outdoor (Maruvada et al. 1977) cages and sometimes on a transmission line (Gary et al. 1989). A typical *q-v* curve is shown in Figure 6.4-5.

As the voltage increases from zero up to the corona onset voltage v_0, the current is purely capacitive (i.e., dielectric displacement current), and is given as

$$i(t) = C_0 \frac{dv}{dt} \qquad 6.4\text{-}18$$

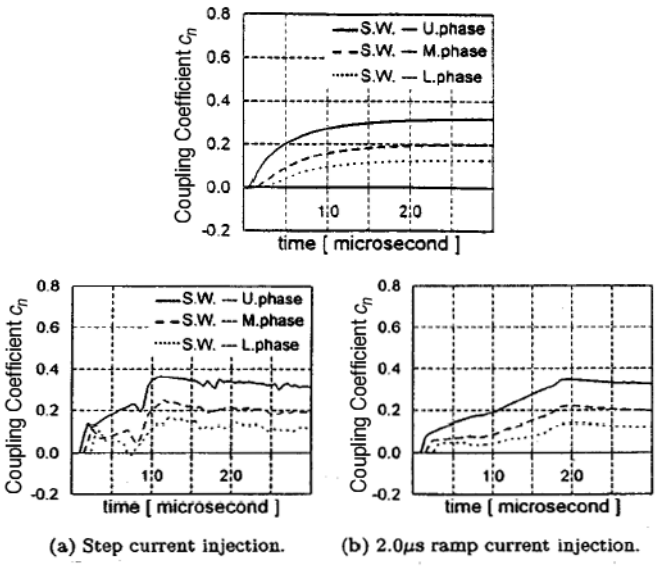

Figure 6.4-4 Time variation of shield-wire to phase-conductor coupling coefficient for step and 2-μs ramp injection (Baba and Ishii 2000).

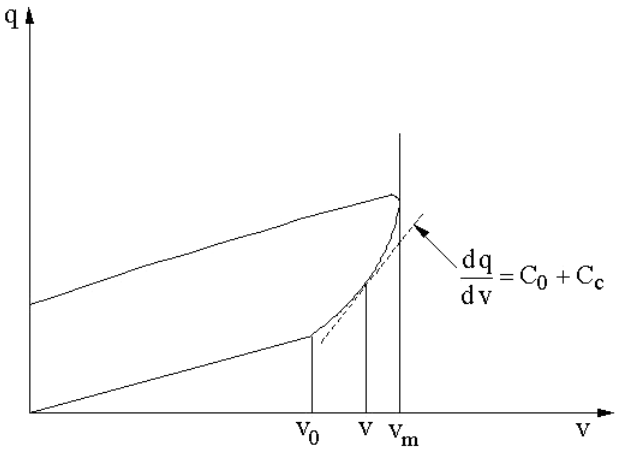

Figure 6.4-5 Charge-voltage curve for lightning impulse.

and the charge is given as

$$q(t) = \int i(t)\,dt = C_0\,v(t) \qquad 6.4\text{-}19$$

Where:

C_0 is the geometric capacitance of the conductor configuration.

Above the corona onset voltage v_0, however, the current consists, in addition to the capacitive component, a component due to the creation and movement of corona-generated space charge. The total current is then given as

$$i(t) = C_0 \frac{d\,v}{d\,t} + \frac{d\,q_c}{d\,t} \qquad 6.4\text{-}20$$

Where:

q_c is the charge produced by corona.

The second term in this equation may be expressed as

$$\frac{d\,q_c}{d\,t} = \frac{d\,q_c}{d\,v}\cdot\frac{d\,v}{d\,t} = C_c\cdot\frac{d\,v}{d\,t} \qquad 6.4\text{-}21$$

The term $\frac{dq_c}{dv}$ may be interpreted as an equivalent corona capacitance C_c, which is dynamic, nonlinear, and time-varying. Referring to the *q-v* curve between v_0 and the peak voltage v_m, the slope at any point corresponds to the total capacitance $C_t = C_0 + C_c$. After reaching the peak value v_m, the voltage decreases gradually to zero and the upper, more or less straight line, part of the *q-v* curve is obtained.

The shape of the *q-v* curve affects the attenuation characteristics of lightning impulses propagating on a transmission line. The principal parameters defining the *q-v* curve are: corona onset voltage v_0, corona capacitance C_c, and the energy absorbed due to corona, which is given by the area included in the *q-v* curve.

Experimental studies have shown (Davis and Cook 1960; Maruvada et al. 1977; Gary et al. 1983) that the corona onset gradient of a conductor, and hence the onset voltage, is higher for impulse voltages than that given by Peek's formula for power-frequency voltages. In fact, the onset gradient increases with the steepness of the impulse wavefront. For lightning impulses, the onset gradient may be 10-15% higher (Maruvada et al. 1977) than that given by Peek's formula in Equation 11.4-2. Although the corona capacitance varies nonlinearly with voltage above onset, a simplified linear representation is often used for the total capacitance C_t between v_0 and v_m, as shown in Figure 6.4-6. In the simplified representation, the return part of the *q-v* curve is represented by the geometric capacitance C_0. The ratio C_t/C_0 is found to vary between 1.5 and 5, depending on conductor configuration and the steepness of the impulse wavefront. The ratio is also found to increase with conductor size, but decrease with the number of conductors in the bundle (Maruvada et al. 1977). The energy absorbed by corona also depends on the impulse wavefront. For the same peak voltage, the energy absorbed is higher for steep-front lightning impulses than for slower-front impulses.

Modeling corona for studies on the attenuation of lightning impulses are carried out (Davis and Cook 1960) by taking into account the reduced speed of propagation due to the increased corona capacitance. More recently, Suliciu proposed (Suliciu and Suliciu 1981) a method of propagation analysis, which takes into account the overall *q-v* curve.

Reduction in Impedance Under Corona

The production of corona under lightning impulse conditions can be modeled as a dielectric loading near the driven conductor, leading to reduced surge impedance and a slower propagation time. In the second edition of the Red Book (EPRI 1982), the negative corona was modeled using an envelope approach, with a critical gradient E_o = 1500 kV/m in Equation 6.4-22. This expression converges quickly to the corona radius R_c for a conductor voltage V by starting with an initial value of R_c = 0.01 m.

$$R_C = \frac{V}{E_o \ln\left(\frac{2h}{R_C}\right)} \qquad 6.4\text{-}22$$

The corona envelope modifies the capacitance but not the inductance, so the self surge impedance of the conductor is given by:

$$Z_{Corona} = 60\sqrt{\ln\left(\frac{2h}{R_C}\right)\ln\left(\frac{2h}{r}\right)} \qquad 6.4\text{-}23$$

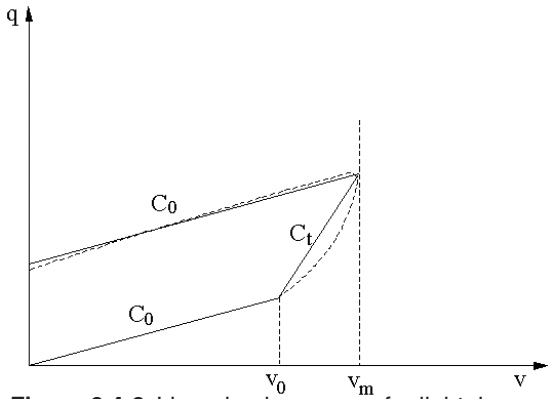

Figure 6.4-6 Linearized *q-v* curve for lightning impulse.

In Equation 6.4-23, r is the self radius r_{11} for single conductors and R_{eq} from Equation 6.9-4 for bundles.

Figure 6.4-7 shows the predictions of this model for a driven wire of 30 m height and 10 mm diameter, an undriven wire of 25 m height and 20 mm diameter, and a horizontal separation of 2 m, along with a calculation of surge impedance using (Gary 1989).

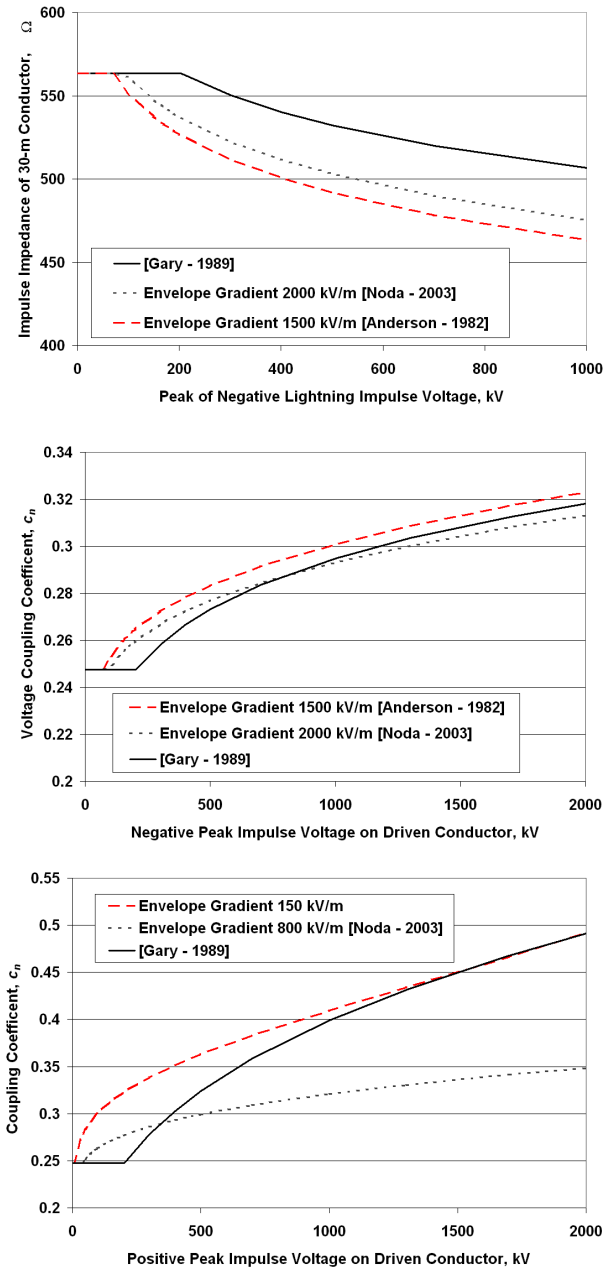

Figure 6.4-7 Changes in impedance (*top*), coupling under negative impulse corona (*middle*), and coupling under positive impulse corona (*bottom*).

The 1500-kV/m gradient model is found to be satisfactory, although a value of 2000 kV/m fits the Gary model slightly better. The 2000 kV/m surface state coefficient for negative corona was also recommended by Noda (Noda et al. 2003). For positive corona, the envelope gradient must be reduced to about 150 kV/m for good predictions of coupling coefficient above a conductor voltage of 1000 kV. This is much higher than the value of positive corona surface state gradient of 800 kV/m recommended by Noda, and will overstate the size of the zone in calculations of the corona radius, as discussed in the section on midspan flashovers. The strong increase in coupling coefficient for positive lightning is an important mitigation factor in calculations of positive-stroke backflashover rate.

6.4.2 Surge Impedance of Towers

The typical EHV transmission tower has a height that is relatively large compared to the rise time of some components of the lightning strokes. There are three options open to describe the role of the tower.

1. It can be considered as a series of one or more lumped circuit elements, usually inductances.
2. It can be modeled as a short transmission-line section with constant or variable surge impedance.
3. It can also be modeled as a series of electromagnetically coupled objects—for example, using moment methods to calculate self and mutual impedances as a function of frequency, and then convolved with input currents in the frequency domain, using inverse Fourier transforms to obtain a time-domain response.

It is possible to convert back and forth between inductance and surge impedance models using the tower travel time where this is well defined. However, measurements show that surges take a variety of path lengths down and back along tower crossarms, making estimation of travel time more difficult. This section describes the basic approaches to transmission tower modeling and recommends a simple surge impedance treatment, commensurate with the sensitivity of tower impedance and travel time in the calculation of backflashover rates.

Approximate Model—Self-Capacitance for Travel Time

The capacitance C_o of a finite cylinder of radius r of length L_{seg} at a height H over a conducting ground plane is given by (Markuviz 1986):

$$C_o = \frac{2\pi\varepsilon_o L_{seg}}{\cosh^{-1}\left(\frac{H}{r}\right)} \qquad 6.4\text{-}24$$

This expression retains its accuracy close to the ground for large objects like transmission towers, unlike the approximate expression $Z = 60\ ln\ (2H/r)$ used in Equation 6.4-8. The travel time τ of the cylinder, when excited from one end, is l/c, where c is the speed of light. The travel time and capacitance can be combined to give the surge impedance of the infinite element as follows:

$$Z_o = \frac{\tau}{C_o} = \frac{L_{seg}\ \cosh^{-1}\left(\frac{H}{r}\right)}{2\pi\,\varepsilon_0 L_{seg} c} = 60\ \cosh^{-1}\left(\frac{H}{r}\right) \quad 6.4\text{-}25$$

The effect of finite conductor length can be evaluated with a calculation of self-capacitance C_{11} using the surface area A, shape factor C_f, and geometric radius g:

$$C_{11} = \varepsilon_0 C_f \sqrt{4\pi A} \quad 6.4\text{-}26$$

$$g = \sqrt{2r^2 + (\frac{L_{seg}}{2})^2} \quad 6.4\text{-}27$$

$$A = 2\pi r L_{seg} + 2\pi r^2 \quad 6.4\text{-}28$$

$$C_f = \frac{3.54g}{\sqrt{A}\ln\left(\frac{23.7g^2}{A}\right)} \quad 6.4\text{-}29$$

$$C_{12} = 8\pi\varepsilon_0 H \quad 6.4\text{-}30$$

$$C_o = \frac{1}{2\left(\frac{1}{C_{11}} - \frac{1}{C_{12}}\right)} \quad 6.4\text{-}31$$

The shape factor C_f is a slowly-varying or "variational" parameter (Chow and Yovanovic 1982) that does not change much from unity for a fairly wide range of objects. The mutual capacitance term C_{12} between the tower element and its image can usually be neglected. This approach leads to estimates of stub impedance, as shown in Figure 6.4-8.

The circuit model, treating the finite wire as a capacitance, leads to a reasonable approximation of the sinusoidal input impedance in the frequency range from 10 kHz to 200 kHz for stub lengths of 10 to 100 m compared to the reference expression, $Z = Z_o \cot(\beta L_{seg})$ where $\beta = 2\pi f/c$. At higher frequencies, such as the curve shown for 1 MHz, traveling-wave effects start to affect the results. The deviation in behavior at 1 MHz starts to occur at $\lambda/10 = 30$ m.

The transmission tower can be treated in the same way to establish a surge response. The overall surface area of the tower is the sum of the face area of the tower (in the plane at right angles to the line direction) and the tower perimeter, multiplied by the thickness of the tower along the line direction. For any smooth body, such as a cone or cylinder, the estimate of tower surge impedance obtained using the known travel time (at speed of light propagation) and the calculated capacitance is in close agreement with theoretical estimates using expressions for conical or cylindrical towers, given next.

Tower as Single Inclined Overhead Line

The simplest approach to transmission tower surge impedance modeling may be developed from the following sequence of waveforms. In Figure 6.4-9, a step voltage with unit amplitude is launched into an overhead wire, having a constant surge impedance of $Z_o = 60\ ln\ (2H/r_o)$. At the junction, there is a step increase in radius, leading to a change in surge impedance $Z_1 = 60\ ln\ (2H/r_1)$. The figure shows a larger radius, so the impedance is lower. A voltage wave of 82% of the initial surge continues on in the section with larger radius, and a negative reflection of 18% arrives back at the source after a delay calculated from the conductor length and the speed of light.

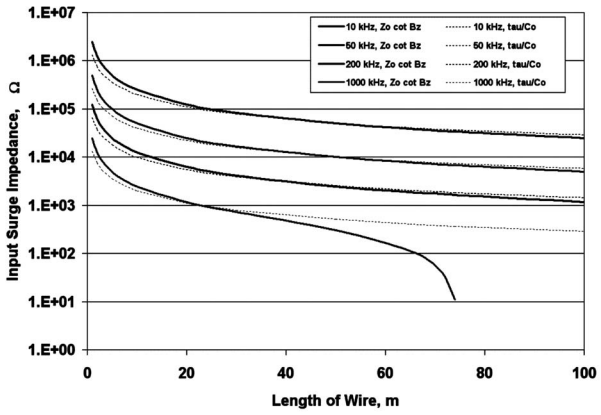

Figure 6.4-8 Input surge impedance of finite wire over ground using exact expression and capacitance approximation.

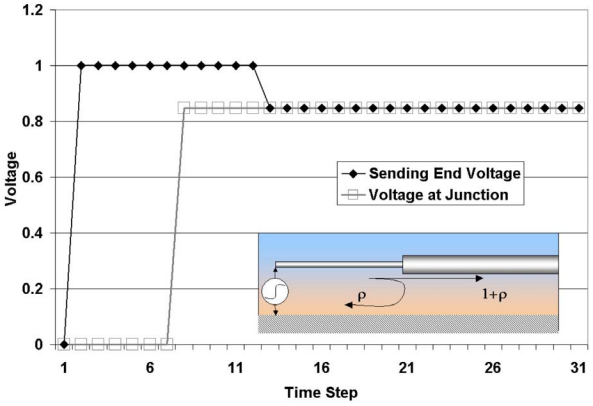

Figure 6.4-9 Sending-end and junction voltages for overhead wire with step change in radius.

If there are multiple changes in radius, these changes set up multiple reflections that can be computed with the use of a Bewley lattice diagram using a spreadsheet. Figure 6.4-10 shows the results from a geometry with constant wire height above ground but increasing radius.

The traveling wave response is no longer "crisp" and starts to approximate an exponential decay. The situation where the wire radius is held constant, but the height is reduced at each step until it reaches the ground, is shown in Figure 6.4-11. The transmission line here is terminated in a low impedance of 20 Ω. The voltage at the junction in Figure 6.4-11 shows a gradual reduction, eventually reaching a constant value given by the division of the open-circuit source voltage between the source impedance and the grounding resistance.

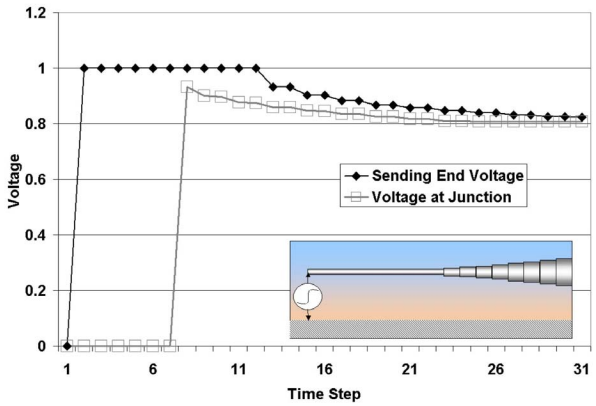

Figure 6.4-10 Sending-end and junction voltages for overhead wire with gradual change in radius.

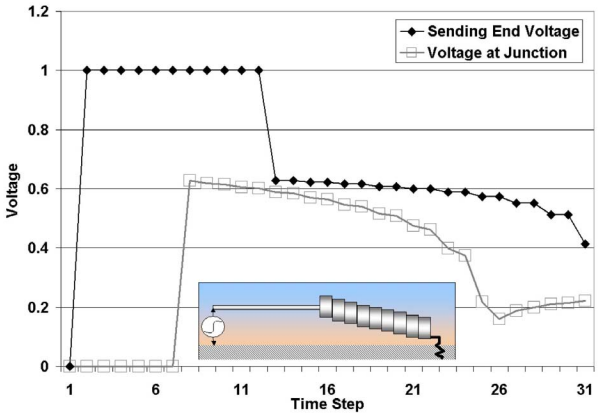

Figure 6.4-11 Sending-end and junction voltages for overhead wire with gradual change in height, terminated in 20 Ω.

The gradual modification of the horizontal line to a vertical tower is now apparent. With the knowledge that, electromagnetically, the orientation of each of the discs does not have a strong influence on its impedance, the voltage at the junction in Figure 6.4-11 is nearly the same as the voltage that appears on the top of a cylindrical tower of stacked elements with the same radius.

There remains one interesting surprise in this analysis. If the tower has a large radius at the top and a small radius at the base, then its impedance tends to be constant. Figure 6.4-12 shows that this establishes a constant junction (tower-top) voltage until a sharp reflection occurs from the 20-Ω termination at tower base. This behavior differs from the case where a vertical current is injected into a vertical cone: there, injection at the cone vertex gives a constant impedance (Markuviz 1986).

The response of a vertical tower to a surge in a horizontal wire is relevant for strokes to overhead groundwires near the tower. Since it is relatively simple to understand where the impedance values come from with this model, it is also the case covered in Applet L5 for showing why the tower travel time is so long compared to the tower height divided by the speed of light.

Tower as Solid Cone or Cylinder

The spherically symmetric TEM electromagnetic field formed between a pair of cones is well understood (Markuvitz 1968; Jordan and Balmain 1968; Kraus 1988) and useful in many antenna designs, such as the familiar bow-tie antenna for UHV television reception.

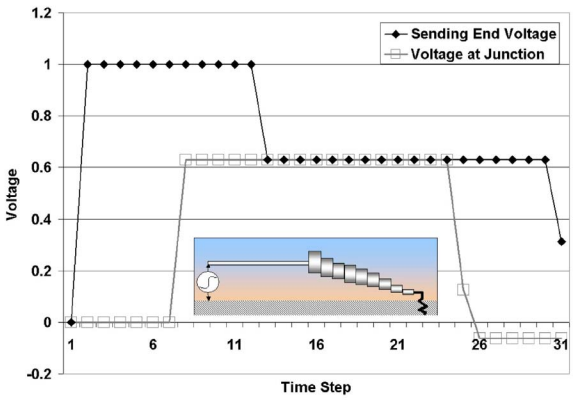

Figure 6.4-12 Sending-end and junction voltages for overhead wire with gradual reduction in both height and radius (inverted cone), terminated in 20 Ω.

The surge impedance is defined in general between two cones, each with half-angle θ_1 and θ_2, and the inner cone $\theta_1 < \theta_2$, as in Equation 6.4-32 and Figure 6.4-13.

$$Z = 60 \ln \frac{\cot\left(\frac{\theta_1}{2}\right)}{\cot\left(\frac{\theta_2}{2}\right)} \quad 6.4\text{-}32$$

The cone does not need to be perfect to have constant surge impedance. Triangular plates and wire-frame "bow-tie" approximations to a bicone can also be designed to present constant impedance over a wide range of frequencies. In the special case of the inner cone (tower) over a ground plane, θ_2 becomes 90°, the cotangent of 45° is unity and the tower impedance becomes as shown in Equation 6.4-33 and Figure 6.4-14.

$$Z = 60 \ln \cot\left(\frac{\theta_1}{2}\right) \quad 6.4\text{-}33$$

Equations 6.4-32 and 6.4-33 describe the impedance seen at a current injection point at the cone apex and remain valid for finite-length cones until two "tower travel times," given by the height of the cone divided by the speed of light.

In the case where the apex of the tower is excited by a vertical filament of current, Sargent and Darveniza (Sargent and Darveniza 1969) derived a constant surge impedance, shown in Equation 6.4-34 and Figure 6.4-15.

$$Z = 60 \ln \frac{\sqrt{2}}{\sin\theta} \quad 6.4\text{-}34$$

For slender towers with cone angles of less than 10°, the impedance to vertical injection at the apex is calculated to be 21 Ω higher than the impedance of the conical tower excited over a ground plane. This estimate has been verified by calculations of Baba (Baba and Ishii 1999), who found that the tower impedance for a vertical lead was 10% higher than for a horizontal lead.

When cylindrical towers are treated in the same way as the cones of Figure 6.4-13, a "bi-cylindrical" transmission line is nonuniform, with a capacitance per unit length and surge impedance that vary along the line. Jordan and Balmain (Jordan and Balmain 1968) note that, for thin antennas, each cylinder slice of thickness *dh* can be considered as an element of a biconical line with cone angle $\theta_1 = r/h$, with *r* being the cylinder radius and *h* being the distance from the excitation point to the element *dh*. The impedance of a bicylindrical transmission line is:

$$Z_o(h) = 120 \ln\left(\frac{2}{\theta_1}\right) = 120 \ln\left(\frac{2h}{r}\right) \quad 6.4\text{-}35$$

The impedance increases as the wave moves away from the injection point. An average impedance of the bicylinder antenna is given by integrating over the antenna height *H*:

$$Z_o(H) = \frac{1}{H}\int_0^H 120 \ln\left(\frac{2h}{r}\right) dr = 120\left[\ln\left(\frac{2H}{r}\right) - 1\right] \quad 6.4\text{-}36$$

Wagner and Hileman (Wagner and Hileman 1960) rederived the original approach of Jordan (Jordan 1934) to obtain the transient response of a vertical cylinder to an

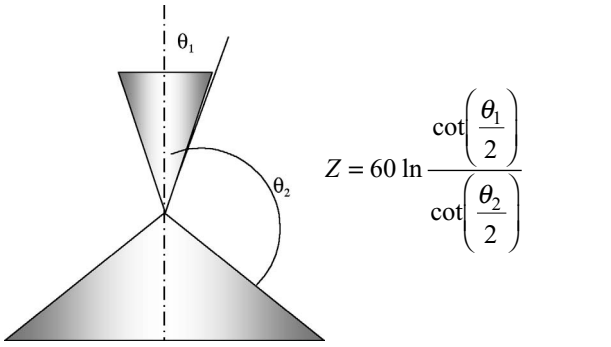

Figure 6.4-13 Surge impedance of two-cone antenna.

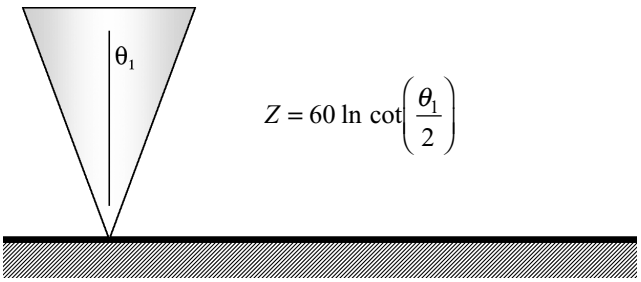

Figure 6.4-14 Surge impedance of vertical cone over ground plane.

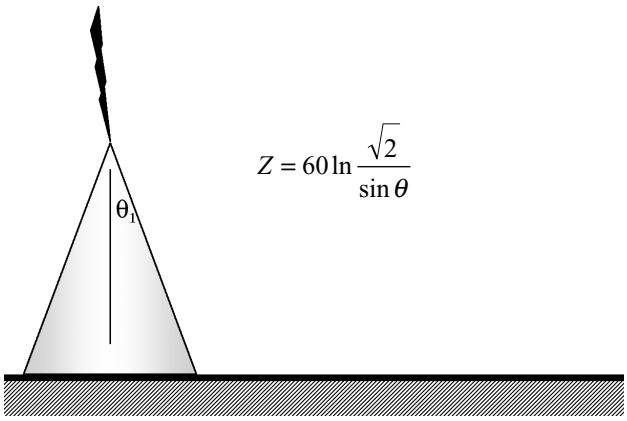

Figure 6.4-15 Surge impedance of cone with vertical current source at apex.

impressed lightning current using electromagnetic field theory. They express a transient tower surge impedance of a cylinder of radius *r* as shown in Equation 6.4-37 and Figure 6.4-16.

$$Z = 60 \ln \sqrt{2}\,\frac{ct}{r} \qquad 6.4\text{-}37$$

The highest value of tower-top potential is achieved at a time $t = 2h/c$. The transient impedance of the cylinder at this time differs from the impedance of a wire of the same radius over ground ($Z = 60 \ln (2h/r)$) by 21 Ω. Sargent and Darveniza (Sargent and Darveniza 1969) noted that the average surge impedance of the cylinder was 60 Ω less than the maximum value.

Chisholm (Chisholm et al. 1983) established that the response of transmission towers depends on the direction of current injection. In tests with time-domain reflectometry, inverted to obtain impedance as a function of distance down the tower, experiments showed that:

- The impedance of a cone over a ground plane is constant and is accurately estimated by Equation 6.4-33.
- The impedance of a cylinder over a ground plane starts out at a low value and increases, and is about 21 Ω lower than estimated by Equation 6.4-37.
- The impedance of a tower, excited by an incoming wave on a horizontal conductor, differs from the impedance when excited by a vertical current.
- For horizontal excitation, the cone with the apex at the ground has constant surge impedance while the cone with the apex at the wire has a highly variable surge impedance, as shown in Figure 6.4-17.

It is possible to estimate the surge impedance of individual sections of towers using the same expression for the surge impedance of that section over ground, for both horizontal and vertical portions of complex towers. The TEM impedance of *Z = 60ln (2H/r)* for thin wires was used in the previous section. For towers with a wide cross section at the base, the impedance based on the cone angle θ in Equation 6.4-32 is more physical. For horizontal excitation of a vertical cylinder of radius *r*, the transient impedance is calculated to be (Chisholm et al. 1985):

$$Z = 60 \ln \cot\frac{1}{2}\tan^{-1}\left(\frac{r}{H - ct}\right) \qquad 6.4\text{-}38$$

As in Wagner and Hileman, *t* is the time after a current step reaches tower top. The expression for the cone of base radius *r* with apex pointing up is:

$$Z = 60 \ln \cot\frac{1}{2}\tan^{-1}\left(\frac{rct}{H(H - ct)}\right) \qquad 6.4\text{-}39$$

Numerical integration of these transient impedances over the tower height gives average values that are 54 to 57 Ω less than the maximum values given at $t = 2h/c$, similar to the results of Sargent and Darveniza for vertical injection to a cylinder. For a wide range of tower shapes and with 5% accuracy, (Chisholm et al. 1985) recommended the following expression for the average impedance of a transmission tower, as shown in Figure 6.4-18.

$$Z_{avg} = 60 \ln \cot\frac{1}{2}\tan^{-1}\frac{r_1H_2 + r_2(H_1 + H_2) + r_3H_1}{\left(H_1 + H_2\right)^2} \qquad 6.4\text{-}40$$

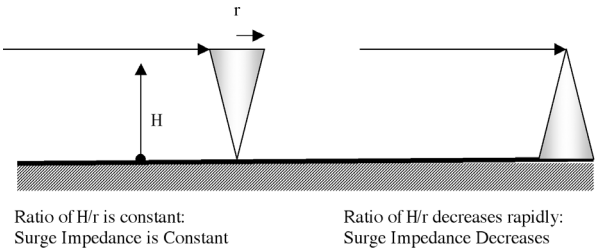

Figure 6.4-17 Surge impedance of cones for horizontal current injection.

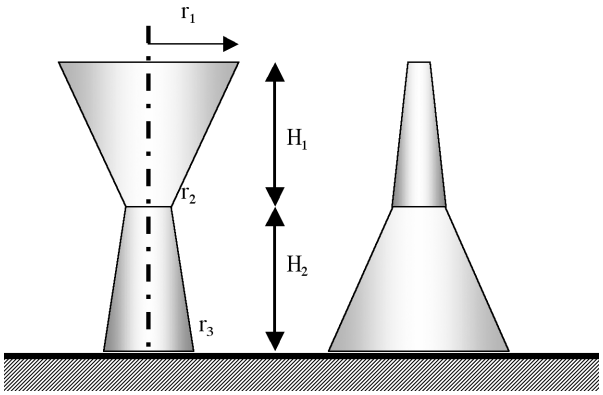

Figure 6.4-18 Surge impedance of two-section towers using conical model.

Towers with Crossarms

Many experimental results, obtained by measuring the time needed to observe a reflection (voltage reduction) from the tower base, suggest that the wave does not travel at the speed of light. Estimates of propagation speed by (Kawai 1964) ranged from 0.71 to 0.89 c, and measurements on scale models of typical towers also show effective propagation speed of 0.61 to 0.73 c. The extra travel time is a consequence of the convoluted and extended path length for the traveling waves.

Lattice mesh techniques are finite-difference (FD) methods for analyzing transients on traveling-wave systems. The "Telegrapher" equations of propagation on a lossless transmission line are solved in the time domain (TD) with a suitable FD scheme. Nonuniform transmission lines, such as slanted wires over ground or vertical cylinders, are treated with the use of reflection and refraction coefficients at each physical interface between sections. The use of an impulse for the source function allows direct calculation of transfer functions and efficient convolution at any point in the system.

Bewley (Bewley 1963) presented a lattice diagram method for analyzing traveling-wave systems in 1931. A typical lattice diagram is shown in Figure 6.4-19.

In Figure 6.4-19, time increases as the waves progress down the page. The total potential at any point in time and space can be calculated by superposition of all the reflected and refracted wave components that reach that point. At impedance discontinuities, the normal reflection and refraction coefficients (ρ and (1 + ρ) for voltage) are applied to the wave components.

Simple transmission-line systems can be analyzed efficiently with lattice diagrams because there are only a few interfaces. However, when the impedance of a system varies continuously or there are several interfaces, the multiple reflections in the diagram proliferate. At a certain point (typically more than three discontinuities), it is more efficient to formulate the problem in terms of general left-going and right-going waves above and below each interface. This is fully equivalent to a Lax-Wendroff central-difference operator for numerical solutions of the wave equations (Mitchell and Griffiths 1980):

$$U_x^{t+1} = 2\,(1-a)\,U_x^t + a\,U_{x-1}^t + a\,U_{x+1}^t - U_x^{t-1} \qquad 6.4\text{-}41$$

The subscript x refers to the discrete distance elements (the horizontal axis in Figure 6.4-18), and the superscript t refers to time steps, incrementing vertically from the top of the lattice diagram. The value a is used to speed up the calcula-

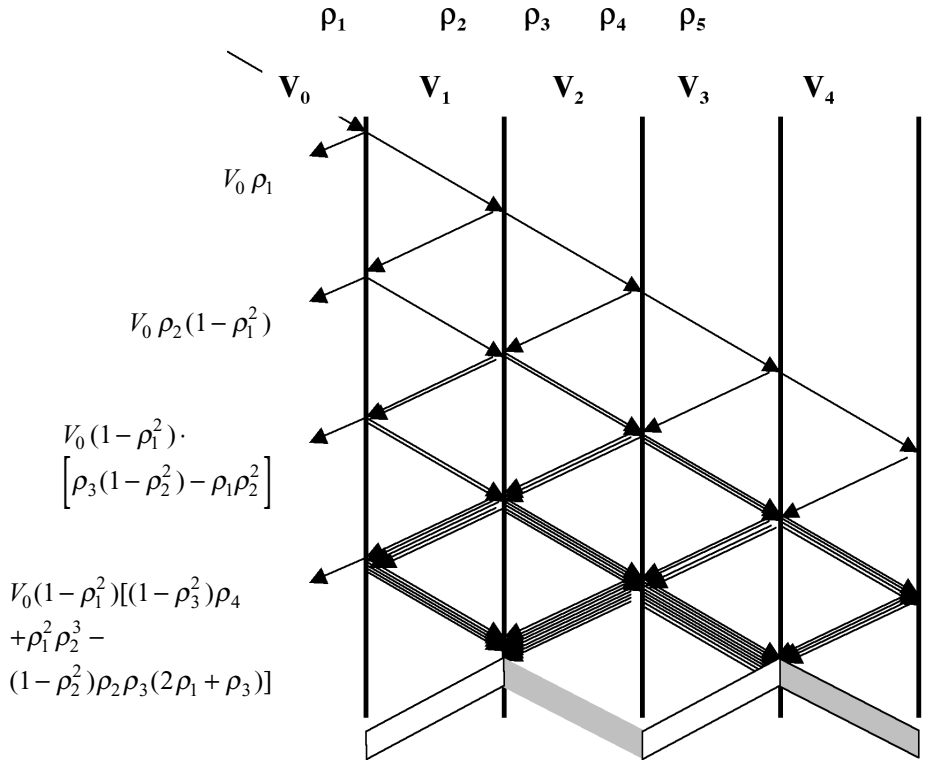

Figure 6.4-19 Lattice diagram for traveling waves with multiple reflections.

tions while maintaining the numerical stability of the calculation. The formulation in Equation 6.4-41 can be simplified by choosing a = 1, which simplifies programming and stability while increasing computation time. The boundary conditions for left-going and right-going waves are:

$$\begin{aligned} (right-going) \quad & U_x^{t+1} = \rho U_x^{t-1} + (1+\rho) U_{x-1}^t \\ (left-going) \quad & U_x^{t+1} = \rho U_x^{t-1} + (1+\rho) U_{x+1}^t \end{aligned} \qquad 6.4\text{-}42$$

Source terms in the form of derivatives of electric and magnetic field components from nearby lightning (or other electromagnetic illumination) can be included in the finite-difference scheme of Equation 6.4-42. Examples of formulations include (Taylor et al. 1965) for mixed fields, (Agrawal et al. 1980) for vertical and horizontal electric fields, and (Rachidi 1993) for vertical and horizontal magnetic fields.

When the transmission line is not uniform, every spatial location has nonzero reflection coefficients relative to its neighbors. Extension of the Lax-Wendroff equations for this case leads to an eight-point FD scheme. This is normally addressed by using different reflection coefficients for left-going (ρ_{12}) and right-going (ρ_{21}) waves with $\rho_{12} \neq \rho_{21}$, in fact $\rho_{12} = -\rho_{21}$. To show the equivalence of Bewley lattice calculations and the finite-difference methods for partial differential equations, it is more convenient to break the problem into left-going (*VL*) and right-going (*VR*) components, with the total voltage at any time and position given by the sum of these two components:

$$\rho_n = \frac{Z_{n+1} - Z_n}{Z_{n+1} + Z_n}$$

$$\begin{aligned} VR_n^{t+1} &= (1+\rho_n) VR_{n-1}^t - \rho_n VL_{n+1}^t \\ VL_n^{t+1} &= (1-\rho_n)\, VL_{n+1}^t + \rho_n VR_{n-1}^t \end{aligned} \qquad 6.4\text{-}43$$

$$U_n^{t+1} = VR_n^{t+1} + VL_n^{t+1}$$

As a double-check and to help visualize the various components, for the uniform-line case, the value of ρ will be 0, leading to:

$$\begin{aligned} U_n^{t+1} &= VR_{n-1}^t + VL_{n+1}^t \\ &= (U_{n-1}^t - VL_{n-1}^t) + (U_{n+1}^t - VR_{n+1}^t) \\ &= U_{n-1}^t + U_{n+1}^t - VL_n^{t-1} - VR_n^{t-1} \\ &= U_{n-1}^t + U_{n+1}^t - U_n^{t-1} \end{aligned} \qquad 6.4\text{-}44$$

This is the desired central-difference scheme of Equation 6.4-41, with *a = 0*.

The method can be extended to handle the case of a stub transmission line or parallel path. This is important for modeling the effects of tower crossarms and overhead groundwires. The reflection coefficients at a three-way interface with main path Z_1 to Z_2 and side path Z_3 will be ρ_1 from the incident wave in Z_1 to the parallel combination of $Z_2||Z_3$, ρ_2 from Z_2 to $Z_1||Z_3$ and ρ_3 from Z_2 to $Z_1||Z_3$.

$$\rho_1 = \frac{Z_2 Z_3 - Z_1(Z_2 + Z_3)}{Z_2 Z_3 + Z_1(Z_2 + Z_3)}$$

$$\rho_2 = \frac{Z_1 Z_3 - Z_2(Z_1 + Z_3)}{Z_1 Z_3 + Z_2(Z_1 + Z_3)} \qquad 6.4\text{-}45$$

$$\rho_3 = \frac{Z_1 Z_2 - Z_3(Z_1 + Z_2)}{Z_1 Z_2 + Z_3(Z_1 + Z_2)}$$

$$\begin{aligned} VR_{stub}^{t+1} &= \rho_3\, VL_{stub}^t + (1+\rho_1) VR_{n-1}^t + (1+\rho_2) VL_{n+1}^t \\ VR_n^{t+1} &= \rho_2\, VL_{n+1}^t + (1+\rho_1) VR_{n-1}^t + (1+\rho_3) VL_{stub}^t \\ VL_n^{t+1} &= \rho_1\, VR_{n-1}^t + (1+\rho_2) VL_{n+1}^t + (1+\rho_3) VL_{stub}^t \end{aligned} \qquad 6.4\text{-}46$$

Applet L-5, Tower Surge Impedance, implements the above method for lattice diagrams to illustrate some important points in tower surge response. The individual impedances of each section are estimated very simply with the expression $Z_n = 60\ ln(2h_n/r_n)$, where h_n is the average height of segment *n* above ground, and r_n is the radius of the circle that gives the same surface area as the segment. This expression is valid with some error (about 21 Ω) for both vertical and horizontal directions of propagation. For square segments of side length *C*, the perimeter is 4C, and the equivalent radius is $r_n = 2C/\pi$.

In Figure 6.4-20, a screen capture from Applet L-5, the surge current is injected into the apex of one of the overhead groundwire supports. At this point, the current splits into two components, one into the parallel impedance of the nearest overhead groundwire, and another into the support arm. At the center of the tower, the surge current splits again. A component travels back up the support arm to the opposite overhead groundwire, a portion is reflected back to the source, and the remainder travels vertically down the tower body. At each of the three crossarms, additional reflections and refractions occur. Voltages at the injection point and at the ends of each insulator crossarm are presented as a function of time. In addition, the time integral of the transfer impedance (in units of inductance) is also

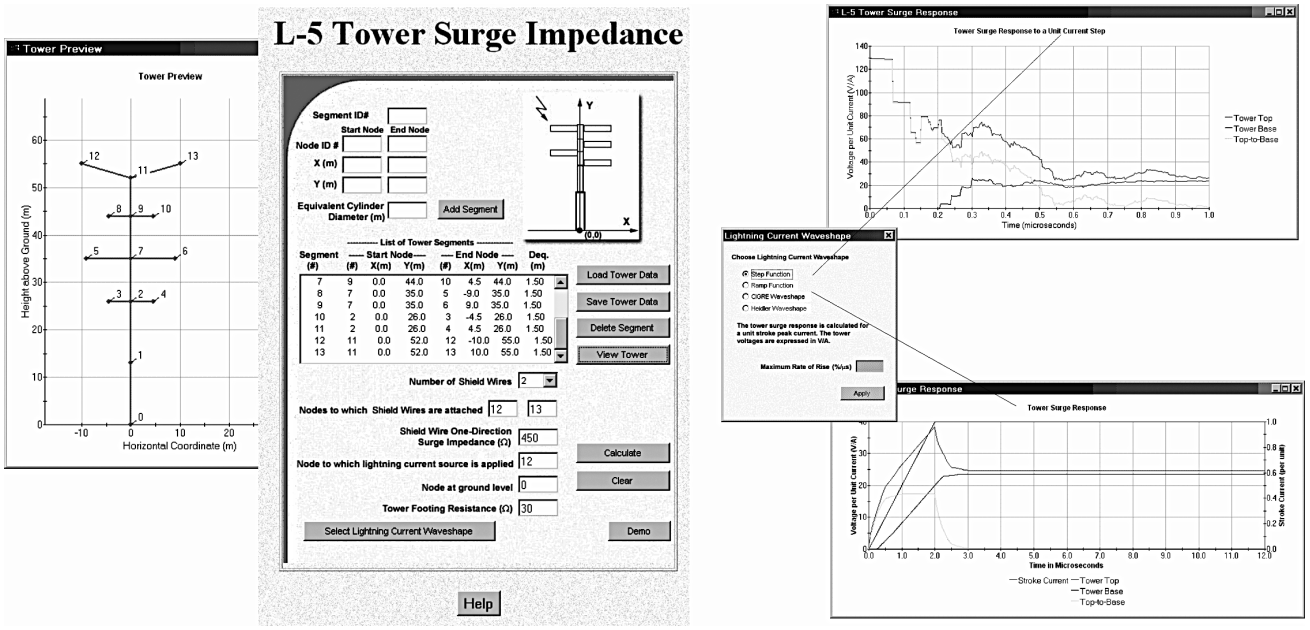

Figure 6.4-20 Traveling-wave model of transmission tower features.

calculated for comparison with estimates using simpler models. With the impulse injection source, it is possible to observe voltage doubling at the open-circuited ends of tower crossarms. This can be verified experimentally as well and contributes slightly to insulator stress. The dominant contribution, however, is the extended travel time associated with the additional propagation (at the speed of light) out and back along each stub element.

Towers with Multiple Parallel Paths to Ground

Some important tower types, including those with guy wires and H-frames, can be modeled as several inclined paths in parallel. While it is possible to compute and use the mutual coupling between these paths, this is not done in Applet L5, because this does not give better accuracy than a simple parallel combination of the individual impedance values. For a guyed-V tower of 60 m with 1-m diameter sections, a 206-Ω surge impedance is reduced to 170 Ω with two guy wires of radius 0.01 m. The L5 applet can be used to study this effect by adding guywire segments from the tower bridge (horizontal element above ground) down to near the ground plane, then adding another horizontal segment to terminate them to the central ground point at the apex of the tower.

Since guy wires carry considerable transient impulse current for short durations, they should not be electrically insulated or mounted in insulating anchors. Instead, the guy anchors should be used as launching points for radial crowfoot electrodes in areas of high soil resistivity, as described in Section 6.10.

Surge Impedance of Perfect Ground Plane

At the tower base, the surge impedance response of the tower continues. This surge response adds to the resistive rise from the tower footing resistance, as described in Section 6.8. Even with a perfectly conducting sheet of metal at the tower base, there is no "magic cancellation" that gives an immediate and perfect short circuit with reflection coefficient of $\rho = -1$. Instead, there is a distributed reduction in impedance that can be approximated in at least three ways.

The first model for ground plane surge response uses the expression for the surge impedance of a cone, excited at its apex. For a cone angle θ, this is given above in Equation 6.4-33 as:

$$Z_{cone} = 60 \ln\left(\cot\frac{\theta}{2}\right) \qquad 6.4\text{-}47$$

While the wave is propagating down the cone, the ratio of radius to distance from the apex remains constant, so the surge impedance is also constant. At the base, the radius of the perfectly conducting ground plane starts to increase, but the vertical distance remains constant, so that θ increases and Z starts to decrease.

- At two tower travel times ($\tau = H/c$), the wave will be a distance H away from the base, giving an angle θ of about 45° with a corresponding impedance of $Z = 53\Omega$.
- At 3τ, $\theta = \tan^{-1}(2H/H) = 63°$ and $Z = 29\ \Omega$.
- At 4τ, $\theta = \tan^{-1}(3H/H) = 72°$ and $Z = 20\ \Omega$.

Eventually, the cone angle will reach θ = 90°, and the "perfect" short circuit at low frequency will be established.

Experimentally, the reflection coefficients measured at the base of conical towers in a pair of parallel planes are imperfect, but not as high as suggested by the first ground-plane surge response model. A second model, based on the excitation impedance of a cylindrical waveguide, gives a simple expression for ground-plane surge response at the base of a tower of height H_{tower}:

$$Z_{ground} = \frac{60 H_{tower}}{ct} \qquad 6.4\text{-}48$$

This expression becomes valid for $ct > h$ and means that the initial (high-frequency, short-time) reflection coefficient at the base of a thin 300-Ω tower is approximately:

$$\rho_g = \frac{60\ \Omega - Z_{tower}}{60\ \Omega + Z_{tower}} \approx -0.7 \qquad 6.4\text{-}49$$

The imperfect ground reflection at the base of tall, thin, conical towers has been observed (Gorin et al. 1977; Janischewskyj 1997 and Willet et al. 1989) and verified experimentally (Bermudez et al. 2003) on full-scale measurements of lightning on tall towers. The effect can be analyzed comprehensively using advanced electromagnetic models such as NEC2 (Baba and Ishii 2001). Bermudez (Bermudez 2003) used measurements of lightning stroke currents at two heights on a tall tower to derive the reflection coefficient as a function of frequency, as shown in Figure 6.4-21.

With the experimental results in Figure 6.4-21, it is possible to propose a third, very simple model for the ground reflection at high frequency: the use of a constant value of $\rho = -0.7$ to terminate the transmission line model at the tower base. This model is appropriate for studying the effects of tower features, but is not relevant to calculation of outage rates because the low-frequency resistance is a function of the soil resistivity and the shape and size of the tower footing.

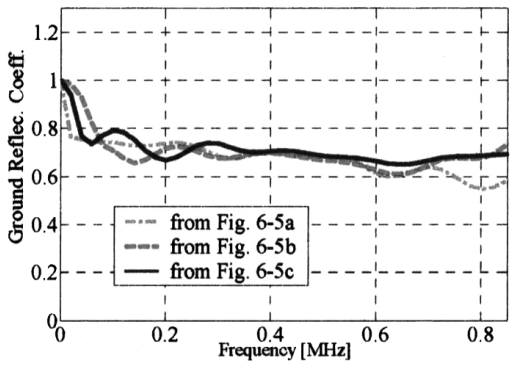

Figure 6.4-21 Observed ground reflection coefficient versus frequency for three pairs of tall-tower current measurements (*top and bottom*).

6.4.3 Calculation of Insulator Voltage and Lightning Performance

Figure 6.4-20 shows the schematic of Applet L-5, which is used to illustrate how the transmission tower affects the waveshape and magnitude of insulator voltage.

For simple cases, such as cylindrical or conical cross sections, Applet L-5 predicts transmission-line surge response that matches the corresponding equations from antenna literature. These cases should be explored first, using short crossarms to evaluate the influence of tower position on the insulator stress.

Crossarms provide a mixed effect in Applet L-5. They tend to lower the tower surge impedance and increase the tower travel time. Waveshapes on the bottom phases of the tower tend to have slower fronts, while the top phases can show significant oscillations that are predicted to increase the probability of flashover by accelerating the development of leaders across the insulation.

For short towers of less than 20 m, the tower surge response should not have much influence on the overall line performance, and the dominant result is that the insulator voltage is simply the input current, divided by the parallel impedance of the overhead groundwire network and the local footing resistance. This simple relationship exists until reflections return from adjacent towers, as shown in the Applet L-4. However, for taller towers of 50 m or more, the additional stresses associated with convoluted propagation paths and ground-plane surge impedance play an increasing role in the lightning performance.

6.5 INSULATION STRENGTH FOR LIGHTNING IMPULSES

Lightning performance is calculated by comparing the insulator stress with strength. The insulator stress is a function of:

- Input current parameter distributions, as described in Section 6.2.
- Lightning incidence statistics, as described in Section 6.3.
- The transfer function between the input current to the tower/overhead groundwire structure and the insulator voltage, as described in Sections 6.4 and 6.10, occasionally leading to backflashover, as computed in Section 6.7
- The transfer function between input current to the phase conductor and the insulator voltage, as described in Section 6.6, usually leading to shielding failure flashover

Section 6.2 has shown that there is no "one" lightning waveshape, and that a statistical approach is needed to define the stress correctly. The response of transmission-line insulation to lightning surge voltages was shown in Section 6.4 to be complex and dynamic. Steep-rising overvoltages with duration that is limited by the distance to adjacent structures can be far less prone to flashover than test results obtained with a standard 1.2 x 50 μs voltage wave. As a rough guide, the 50% increase in strength for short-time impulse strength (2 μs), compared to standard impulse flashover, can decrease transmission outage rates by a factor of three. Reliable calculation methods for transmission outage rates in Sections 6.6 and 6.7 all have models for the increase in impulse strength with decreasing time, however crude or empirical.

6.5.1 Volt-Time Curve Penetration Algorithm, Evaluated at Span Reflection Time

The second edition of the Red Book used a simple empirical description (Darveniza et al. 1975) of the flashover process. The dielectric strength of an insulator string as a function of time to flashover for a standard lightning impulse voltage wave is approximated as:

$$V_{50\%} = \left[400 + \frac{710}{t^{0.75}}\right][L] \qquad 6.5\text{-}1$$

Where:
$V_{50\%}$ = the median flashover voltage in kV.
t = the time to flashover in μs.
L = the length of the insulator string in meters.

This expression is valid for the case of a negative lightning to the overhead groundwires, making the conductor positive relative to the tower. For wet tower insulation in center or outside phases, Hileman (Hileman 1999) recommends a positive-polarity gradient for Critical Flashover (+ CFO) of 560 kV/m for positive polarity (corresponding to evaluation of Equation 6.5-1 at 7 μs) and 605 kV/m for negative polarity (- CFO). Hileman recommends the same gradients for both line and substation clearances and gives an alternate expression to Equation 6.5-1 for volt-time characteristic, illustrated in Figure 6.5-1. The difference between median and critical flashover levels is set by international standards and typically uses a relative standard deviation of 3% for lightning impulses. For this reason, the use of V_{50} is common in lightning calculations, including those in the applets.

The use of volt-time curves like those in Figure 6.5-1 is correct only while the applied waveform matches the standard 1.2/50 μs wave. If the applied voltage deviates from the standard wave, in particular by the arrival of canceling reflections from adjacent towers that reduce the voltage, then the model becomes less useful. The most appropriate applications of the volt-time curve are to model the flashover strength exactly at the span reflection time, as done in the IEEE FLASH program (IEEE 1997b), and to validate parameters of more sophisticated models, as shown in the next two sections.

6.5.2 The Disruptive Effect (DE) Algorithm, Typically for Faster-Front Flashover/Puncture

Below a critical flashover level V_o, shown in Figure 6.5-2, the applied voltage can be withstood for a relatively long time. This leads to models where all voltage above an ionization threshold contributes to the development of the flashover path. A general form used for many models of

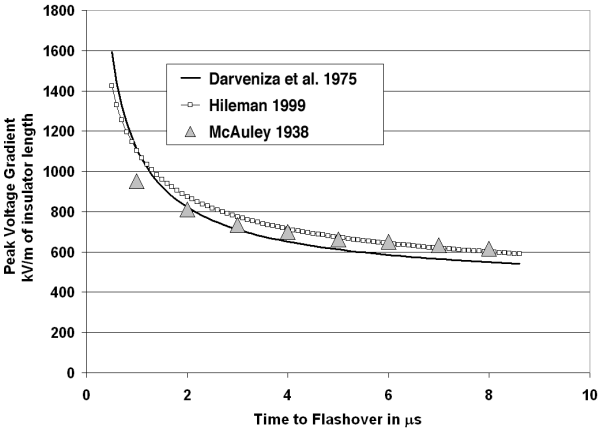

Figure 6.5-1 Volt-time characteristic of porcelain insulators under standard positive lightning impulse voltage (tower negative relative to conductor).

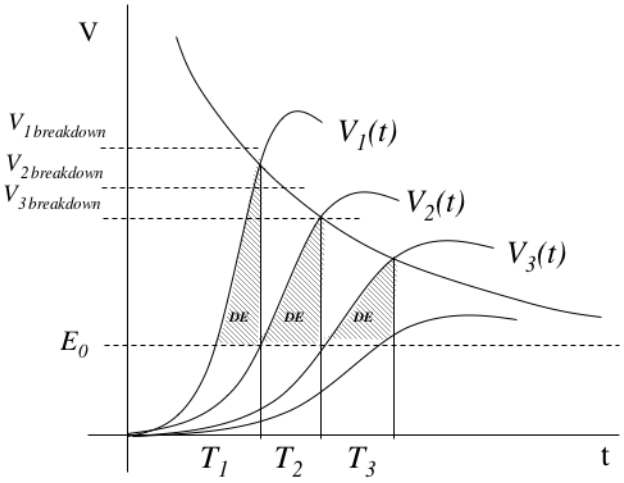

Figure 6.5-2 Disruptive effect for three nonstandard voltage waves.

insulation is the Disruptive Effect, given in Equation 6.5-2 and discussed in more detail in Appendix 6.1.

$$DE = \int_{t_o}^{T_d} (V(t) - E_0)^{\,n} dt \qquad 6.5\text{-}2$$

(Caldwell and Darveniza 1973) found that the DE method with $n = 1$ gave good results, with better than 10% agreement between measured and calculated values. An IEEE Task Force (IEEE 1996b) noted that the use of $n = 2.5$, DE of 10^{10}, and E_0 of 300 kV gave the best match to the volt-time characteristics of porcelain insulators in Equation 6.5-1, with a relative standard deviation of 6% for both front-of-wave and tail-of-wave flashover. Figure 6.5-3 shows, however, that good results (constant value of DE for a wide range of times to flashover) can be obtained with a wide range of exponents after the wave crest at 1.2 μs.

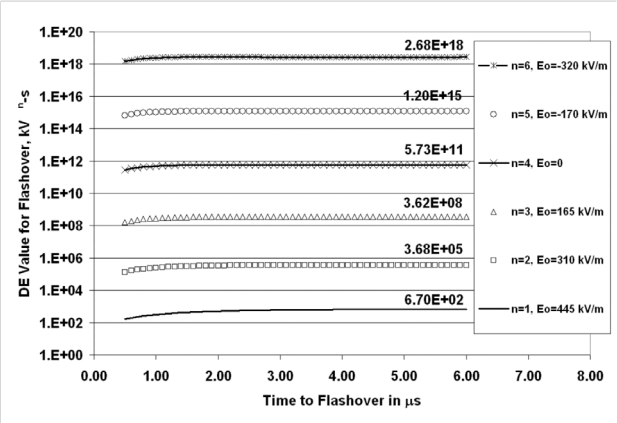

Figure 6.5-3 Disruptive effect at flashover of 1.2/50 μs standard lightning impulse wave for various exponents n and optimal value of E_o for fitting Equation 6.5-1.

6.5.3 The Leader Progression Model, Typically Evaluated for Several Span Reflection Times

The insulator voltage $v(t)$ is a source term for a differential equation that describes the growth of a leader across the gap. The growth rate and coupling terms are established from experimental results. By solving the differential equation, the leader progression models can lead to more realistic breakdown characteristics for nonstandard impressed waveforms, especially across air gaps. There are two times of interest in the high-voltage flashover process: t_s, the time to develop streamers across the gap from both electrodes, and t_l, the time for a leader to propagate across the gap.

The streamer propagation time is a function of the average voltage overstress in the gap, compared to its 50% flashover voltage V_{50}. (Pigini et al. 1989) gives the following estimate of streamer time for impulse voltages of either polarity:

$$t_s = \frac{1}{1.25\left(\dfrac{V}{V_{50}}\right) - 0.95} \quad \text{for } t_s \text{ in } \mu\text{s} \qquad 6.5\text{-}3$$

The streamer time t_s in Equation 6.5-3 is relatively constant at 0.5 to 2 μs. The difference between streamer time and total time to flashover in Equation 6.5.1 provides an estimate of the leader propagation velocity as a function of applied voltage as follows. The leader propagation time, using Equations 6.5-1 and 6.5-3, becomes, for a CFO of 560 kV/m:

$$t_l = \left(\frac{710}{E - 400}\right)^{1.333} - \left(\frac{448}{E - 426}\right) \qquad 6.5\text{-}3\text{A}$$

E is the peak breakdown voltage per meter of insulation, expressed in kV/m, and the leader time is given in μs. The leader propagation velocity dg/dt is simply the gap length divided by the leader propagation time. Figure 6.5-4 shows how this velocity is predicted to increase as a function of voltage stress for two insulator string lengths.

The results suggest that leaders need a minimum of 500 kV to develop, and also suggest that the average leader velocity is faster for longer gaps.

The expression proposed by (CIGRE 1991) for the leader progression process is:

$$\frac{dg}{dt} = kV(t)\left[\frac{V(t)}{l - g} - E_0\right] \qquad 6.5\text{-}4$$

Where:

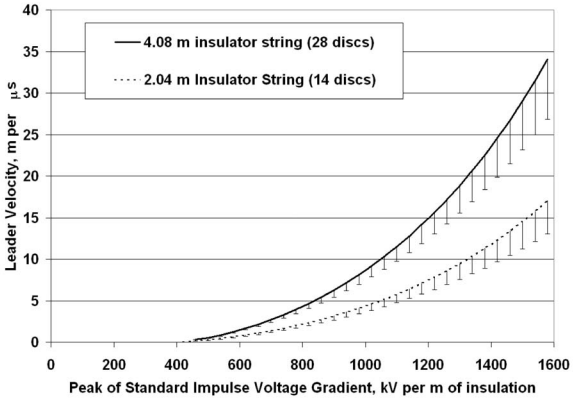

Figure 6.5-4 Estimate of leader velocity across porcelain insulator string, based on (flashover time) minus (streamer time) for E_o = 520 - 560 kV/m.

dg/dt = the leader velocity in m/s.
k = a constant given in Table 6.5-1.
$V(t)$ = the voltage across the gap in kV.
g = leader length in m.
l = the air gap length in m.
E_0 = the breakdown gradient as given in Table 6.5-1.

CIGRE recommends the matrix of values for E_0 and k shown in Table 6.5-1.

Table 6.5-1 Recommended Values for Leader Progression Model of Lightning Impulse Flashover

Configuration	Polarity	k $m^2/(kV^2\text{-}\mu s)$	E_0 KV/m
Air gaps, post insulators, long-rod polymer insulators	Positive	0.8×10^{-6}	600
	Negative	1×10^{-6}	670
Cap-and-pin porcelain and glass insulator strings	Positive	1.2×10^{-6}	520
	Negative	1.3×10^{-6}	600

A common simplification for implementation in the Electromagnetic Transient Program (EMTP) or other modelling programs is to assume a constant leader velocity, but Figure 6.5-4 suggests this may not be appropriate.

Figure 6.5-5 shows the CIGRE recommendations for leader propagation modelling along with the reference volt-time characteristic for standard lightning impulse voltage on a 1-m insulator string, described empirically by Equation 6.5-1. At the important times to flashover between 1.5 and 4 μs, the leader propagation estimate of strength for cap-and-pin insulators is 30% too high, and this would understate lightning outage rates by a factor of two. The Motoyama model (Motoyama 1996) is more satisfactory in the time of greatest interest, but drifts away from the reference for longer times to flashover, where the CIGRE model for cap-and-pin flashover begins to converge to observations.

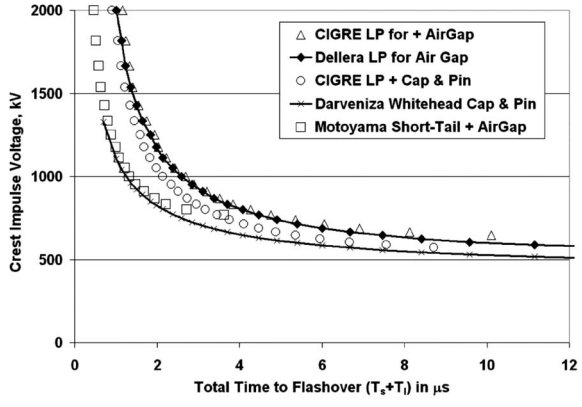

Figure 6.5-5 Comparison of predicted crest flashover voltage for leader progression (LP) models and observed volt-time characteristic of Equation 6.5-1.

6.5.4 Insulator Puncture Strength

Every lightning flash generates high transient stresses across the insulators. A typical subsequent stroke with rate of current rise 40 kA/μs, working into the minimum transient impedance of 60 Ω at tower base, generates a voltage wave with steepness of 2400 kV/μs. Shielding failures are particularly severe because the surge impedance of the stricken phase conductor would be three times greater. Some national insulator standards (CSA C411.1, ANSI C29.1) for cap-and-pin porcelain insulators call for twenty steep-front tests at the 2500 kV/μs level to establish adequate long-term performance. Morita (Morita et al. 1997) endorses this recommendation and provides experimental data on the puncture and flashover strength of individual insulators.

Insulator B in the left graph of Figure 6.5-6 has a longer leakage distance. Morita noted that, for time-to-flashover of less than 0.2μs, there was a stronger relationship between flashover voltage and insulator leakage distance, compared the usual relationship between standard lightning impulse strength and dry-arc distance for 1-10 μs times to flashover. In this case, the puncture strength of Insulator A is greater than the external flashover strength, so a single steep-front application is not likely to cause puncture. However, Figure 6.5-7 shows that repeated impulses with high steepness eventually cause wear-out failures. Impulses with higher peak magnitude, shown as $V_{0\text{-}4}$ in Figure 6.5-7, lead to a 2% failure rate for 20 impulses at 415 kV peak, but a 95% failure rate if the voltage is increased to 560 kV. This range of voltage stress per insulator disc is common on single-conductor high voltage lines when subsequent strokes follow the same path as a shielding failure. The puncture wear-out process occurs at lower stress levels on insulators with lower grades of porcelain, leading to insulator string end-of-life, when the number of sound insulators in a string falls below safe levels for live maintenance. The insulator puncture process can be summarized by noting that puncture will occur when voltage rise times become so extreme that the volt-time strength of the air along the surface of the insulator becomes higher than the volt-time strength of the insulator material. The latter has little volt-time turn-up at short times.

6.6 SHIELDING FAILURE CALCULATIONS

Overhead groundwires on a transmission line can be thought of as horizontal lightning air terminal. Their purpose is to intercept any lightning flash that would otherwise terminate on one of the phase conductors. Usually overhead groundwires are quite successful in intercepting

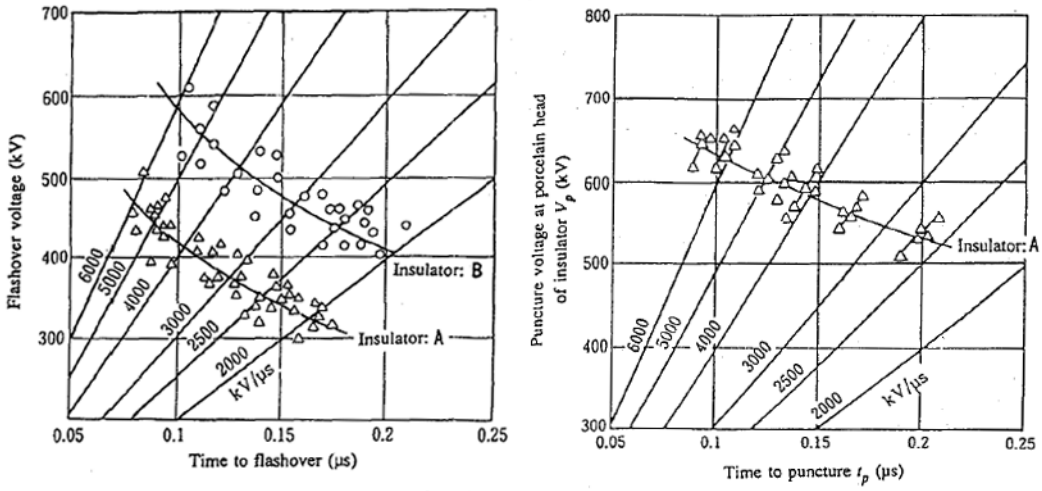

Figure 6.5-6 *Left:* Steep-impulse flashover characteristic of cap-and-pin porcelain disc insulators; *Right:* Steep-impulse puncture characteristic of cap-and-pin porcelain disc insulator (Morita 1997).

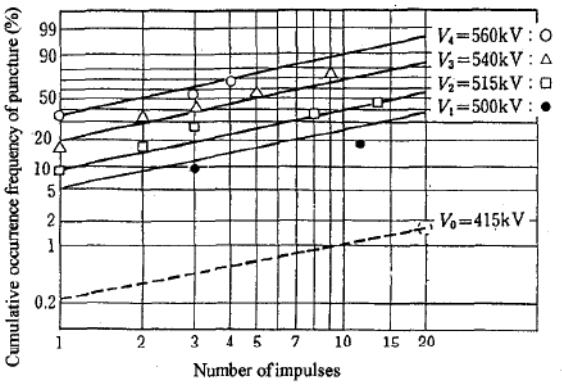

Figure 6.5-7 Number of impulses needed to cause electrical puncture on new cap-and-pin insulator at 5000 kV/μs steepness (Morita 1997).

lightning flashes, but sometimes a leader appears in such a location that it gets by the shield wire protection and strikes a phase conductor. This "shielding failure" can be a common cause of transmission-line lightning flashovers, and has been extensively studied for more than 50 years.

6.6.1 The Shielding Failure Process

The basic shielding failure process is sketched in Figure 6.6-1. A descending leader carrying a high negative charge is approaching the vicinity of a transmission line. As it moves earthward, it induces positive charges on the transmission-line conductors and on the earth below. The positive charges build up on the wires to magnitudes sufficient to trigger positive upward leaders from both the shield wires and the rightmost phase, and in some cases from the earth beneath the downward leader tip. At this moment, a race develops between the shield wire leader and the phase wire leader to resolve which will reach the tip of the downward leader first and complete the link. If the phase wire leader reaches the downward leader tip first, a shielding failure occurs, which may or may not cause a flashover, depending on the stroke current amplitude, the insulation strength, and the phase surge impedance. If the downward leader is sufficiently far away, the leaders from the wires are unable to

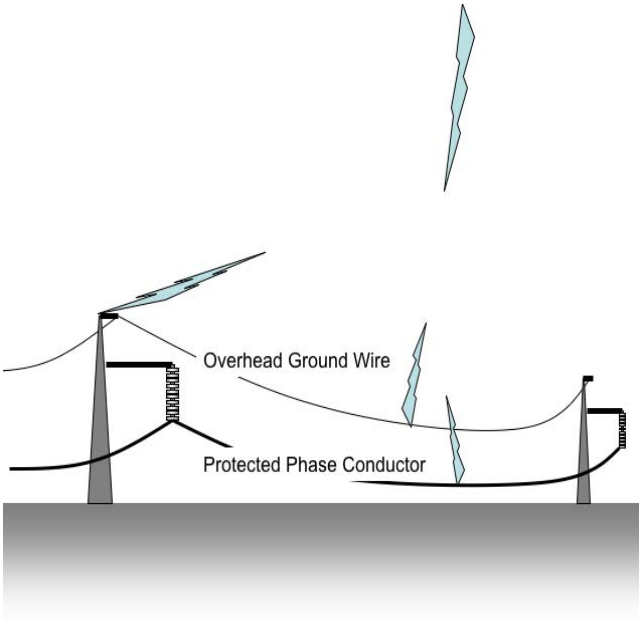

Figure 6.6-1 Upward leader competition for a line-shielding failure.

reach the downward leader and the latter terminates on the ground. Applet L-2 attached to this chapter provides a graphic simulation of this entire process, including a step-by-step downward leader progression (either for a straight leader channel, or a degree of randomization typical of what is seen in lightning photographs) and upward leaders from the conductors of either one or two transmission lines on either flat terrain or on a hillside.

In Figure 6.6-2, as a leader approaches a transmission line, each conductor emits an upward leader with striking distance R_s for the shield wire and R_p for the phase. If the downward leader tip penetrates Zone A, a strike to the shield wire occurs, or if it penetrates Zone B, a shielding failure occurs, or if Zone C, the flash is to ground. The striking distances R_s and R_p are determined by the charge on the downward leader, and hence on the first stroke current that the flash will deliver. Note in Figure 6.6-2, a distance to ground R_g is required in some algorithms to represent the striking distance to earth of the downward leader. Other algorithms simply consider a strike to ground to be a default condition if the downward leader is beyond the reach of R_s and R_p.

6.6.2 Uncovered Areas in the Shielding Failure Models

The classical "electrogeometric" analysis of shielding failure frequency considers that the flashover process originates at the tip of the downward leader, which develops downward until it achieves a point of discrimination among conductors and ground. The striking distance models from leader to conductor, and the attractive radius of later models, as shown in Figure 6.6-2, have much in common with regard to overall dimensions, increasing reach with current level and moderate sensitivity to height. The

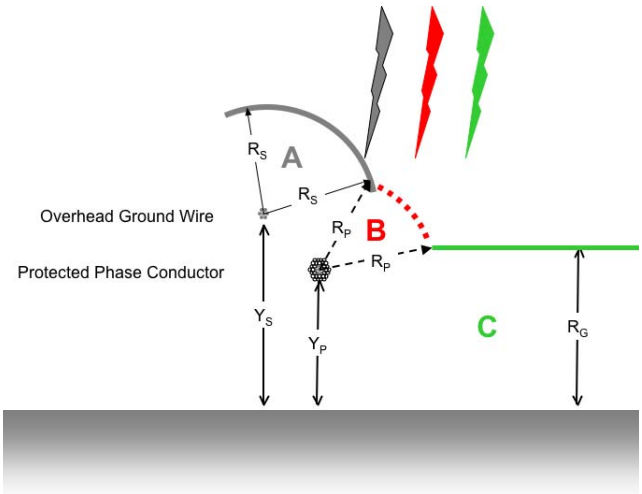

Figure 6.6-2 Shielding failure striking distances for a two-conductor line.

equations of striking distance as a function of stroke current and conductor height comprises the fundamental basis of the electrogeometric theory of shielding failures, and many variations of these equations have been proposed. It has also become common to compare striking distance and attractive radius equations directly, because they are both imperfect models of the same process, with leader development now observed to develop from both ends towards the middle.

6.6.3 Recommended Strike Distance Equations

A table of proposed strike distance equations was included in a previous edition. Recent ones include the following:

IEEE Standard 1243—1997

$$R_s = R_p = 10.0I^{0.65} \qquad 6.6\text{-}1$$

$$R_g = [3.6 + 1.7\ln(43 - y_c)]I^{0.65} \quad y_c < 40\ \text{m} \qquad 6.6\text{-}2$$

$$R_g = 5.5I^{0.65} \quad y_c >= 40\ \text{m} \qquad 6.6\text{-}3$$

Rizk—1990

$$R_s = 1.57I^{0.69}y_s^{0.45}; R_p = 1.57I^{0.69}y_p^{0.45} \qquad 6.6\text{-}4$$

Eriksson—1987

$$R_s = 0.67I^{0.74}y_T^{0.6}; R_p = 0.67I^{0.74}y_p^{0.6} \qquad 6.6\text{-}5$$

Where:

R_s = strike distance to shield wire, m.
R_p = strike distance to phase wire, m.
R_g = strike distance to ground from leader tip, m.
I = peak stroke current, kA.
y_c = average height of any conductor
y_p = average phase conductor height
y_s = average shield wire height
y_T = shield wire height at the tower

The average height of a conductor in a span is given by its height at the tower, minus two-thirds of the midspan sag.

At present, there is controversy over which of these strike distance equations correlates best with experience, but Rizk's equation (Equation 6.6-4) is recommended. In Applet L-1, all three can be used, and the highest number of shielding flashovers used as the most conservative value. Applets L-1 and L-2 permit the user to experiment with application of these equations. If the height exponent is selected to be zero in any of the above, Applet L-1 uses an approximation of Equations 6.6-2 and 6.6-3 for strikes to ground.

Usually lower current strokes under 20 kA are responsible for shielding failure flashovers, although leaders approaching a transmission line at an acute angle from the vertical

can cause high-current shielding failures. Historically, cosine or cosine-squared angle distribution has been used, but most present shielding failure theories usually assume only vertical leaders can develop. This simplifies the mathematics, but downward leaders are rarely straight and vertical.

6.6.4 Perfect Shielding

In the past, much has been made of the concept of "essentially perfect shielding," wherein the shield wires and outermost phases are so located with respect to each other that shielding failure flashovers can never occur. This is mathematically possible but of dubious reality. Figure 6.6-3 shows one conceptual perfect shielding model. For a downward leader carrying a current I, R_s represents the horizontal striking distance from the shield wire S to the downward leader, and R_p represents the striking distance from the outermost phase. Depending on which striking distance formula is used, R_s and R_p do not have to be of the same length. The heights Y_p of the phase and Y_s of the shield wire are usually set by clearance and code requirements, but the horizontal position of the shield wire with respect to the phase can be determined by tower design. In Figure 6.6-3, the phase conductor is given the relative x coordinate of zero, and it is desired to move the shield wire horizontally until perfect shielding is attained.

The current I_{crit} to use is the minimum stroke current required to initiate a flashover. It is given by:

$$I_{crit} = \frac{2 \cdot CFO}{Z_0} \qquad 6.6\text{-}6$$

Where:

I_{crit} = critical stroke current causing flashover, kA.
CFO = insulator critical flashover voltage for the stricken phase, kV.

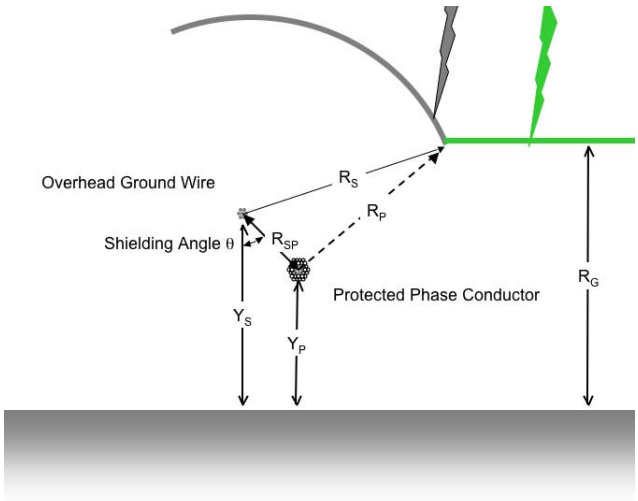

Figure 6.6-3 A conceptual zero shielding failure model.

Z_0 = phase surge impedance, ohms as modified by corona.

It is suggested that the Rizk equation (Equation 6.6-4) be used to calculate R_S and R_P using I_{crit}. Then, in Figure 6.6-3, the required horizontal distance X_{sp} between the shield wire and the outermost phase given by:

$$X_{sp} = R_s - \sqrt{R_p^2 - (Y_s - Y_p)^2} \qquad 6.6\text{-}7$$

and the required shield angle θ is:

$$\theta = \tan^{-1}\left(\frac{X_{sp}}{Y_s - Y_p}\right) \qquad 6.6\text{-}8$$

This ensures that $I < I_{crit}$, so that any remaining shielding failure is too weak to cause a flashover. Even if R_s and R_p are the same length, the shield wire is likely to absorb a preponderance of the flashes, since—being higher—the upward leader from the shield wire initiates sooner than the upward leader from the phase conductor.

One of the limiting problems in the use of "perfect" shielding angles is that, on average, two subsequent strokes tend to follow the same ionized path as the first stroke. Thus, while the first stroke may be less than I_{crit} in (Equation 6.6-6), one of the subsequent strokes may well have a current that is greater. The subsequent stroke current distribution seems to be independent of the first-stroke current, so the conditional probability that one of the subsequent peaks is greater than the first peak becomes large as the first-peak amplitude falls below 15 kA.

6.6.5 The Method of Maximum Heights

Analytical formulas for shielding failure flashover rates have been published by a number of authors and summarized in (CIGRE 1991), but when a multiplicity of wires, asymmetry of wire positions, and variations of striking distance with wire height are involved, an analytical approach becomes extremely complex, and step-by-step digital algorithms become much more tractable. One such algorithm is the "method of maximum heights," which is used in Applet L-1.

In Figure 6.6-4, a leader channel is positioned near an example set of two line conductors. This channel does not have to be vertical, but can be tilted in a Monte Carlo method to represent leaders approaching the line from a side. The striking distance from each conductor is calculated and connected to the channel, and flashover is assumed to occur to the conductor whose striking distance intercept reaches the highest position on the channel. The leader is assumed to occupy an area A_s, having a width of 1 m and a length consisting of the line length of 100 km.

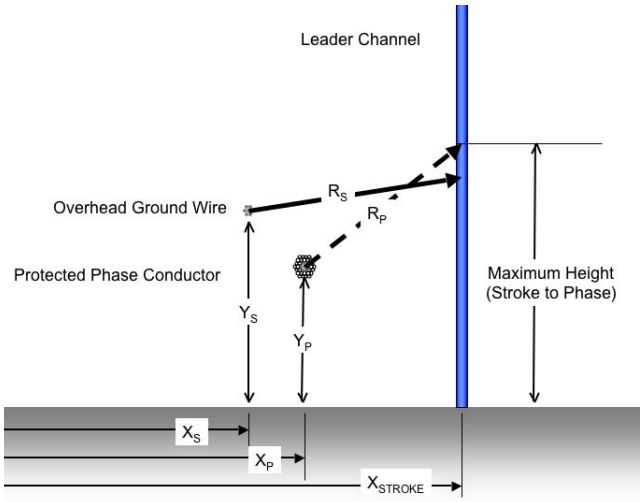

Figure 6.6-4 The method of maximum heights.

Then, if the ground flash density (GFD) is known, the total expected flashes N_t to area A_s per year can be determined. From the IEEE stroke current probability equation:

$$P = \frac{1}{1+\left(\frac{I}{31}\right)^{2.6}} \qquad 6.6\text{-}9$$

Where:

P = cumulative probability distribution of peak stroke currents.

I = peak stroke current, kA.

The question about the correct shape of the stroke current distribution in the shielding failure domain, from 3 to 20 kA, remains open. The data used to establish the two-slope distribution in (CIGRE 1991) mix measurements from systems with different trigger thresholds that were on the order of 5% of 200-300 kA full scale. All measurement systems probably captured 30-kA flashes, but fewer would have responded to 10-kA flashes, giving bias at the low end of the distribution. Data from lightning location systems are interesting strictly from the large number of observations, but also because cross-calibration with independent observations of low-amplitude events has been successful. The combination of time-synchronized tripout and non-tripout events from travelling wave fault recorders, along with lightning location records, remains a resource to be exploited to establish which stroke currents cause shielding failures (and which ones do not).

The probability of occurrence of any stroke of magnitude I ± 1 kA can be determined within the total population N_t. By scanning the complete range of stroke magnitudes from 2 kA to 160 kA in each area A_s, moving the leader area from the far right of the line to the far left in 1-m steps, and calculating the maximum heights to the leader channel of all the wire striking distances, one can count the number of flashes per 100 km per year to each wire. Several special strategies were adopted in Applet L-1 to speed the processing time.

6.6.6 Cascading Flashovers

In actual forensic examinations of lightning flashover damage in the field, insulator burns and/or structural damage usually leads one to conclude which support structure was associated with the lightning event. However, it is frequently the case that the structure with the observed damage is located one or more spans remote from the actual lightning strike location. A flashover at one tower can inject voltage on one or more phases, which travels to adjacent towers in both directions, causing them to flashover also, and the flashover closest to the generation holds in and turns off the others. These "cascading flashovers" can occur as far as three spans or more beyond the strike location.

6.6.7 Transmitted Stress to Terminals

A lightning event—either a shielding failure or a backflashover—can inject severe transient voltages on a phase that can travel for kilometers to enter a substation and—at the same time—create a severe power frequency fault that must be cleared. The power frequency fault can create severe mechanical stresses from magnetic forces, particularly in transformers. The high-voltage transient may arrive as an open breaker or disconnect switch tries to double, so even if it has been attenuated by corona and lossy ground effects, the increased voltage can still exceed the substation insulation level, leading to a failure of insulation coordination. The distance from the lightning backflashover to the open terminal at the station plays a fundamental role in the level of this transient overvoltage. It is important that, whenever possible, transmission lines within a kilometer or more of a substation or generating plant should be well shielded, grounded, and insulated to ensure that any transient voltages have to propagate over sufficient distance to minimize transferred stresses. Surge arresters, located near the open terminals or possibly on the transmission-line entrance, can play a role in limiting the overvoltage exposure economically.

6.6.8 Calculation Procedures

One of the most successful ways to estimate the lightning shielding failure flashover rate of a new transmission circuit is to perform a multiple linear regression of the observed performance for nearby lines against the most sensitive parameters. This is especially helpful when comparing lines with similar conductor geometry, tower style, and span length. Linear regression against remaining variables such as local ground flash density, shielding angle, height of adjacent vegetation, and right-of-way width can be as successful at predicting future performance as the most sophisticated treatment. In this context, equal weight

is given to describing simplified and complex models for the lightning performance of transmission lines.

6.6.9 Simplified Models

Rolling Sphere Methods

Many lightning protection standards now make use of a "rolling sphere" method (Lee 1978) adapted from transmission-line electrogeometric shielding calculations to identify protected and unprotected areas on buildings and lower structures. Lee's insight was that a sphere, with radius R_s associated with a critical current I_{crit}, rolled around a three-dimensional model of a set of ground-based shield wires, was an efficient way to evaluate shielding. This approach assumes that Whitehead's validation (Whitehead 1977) of the electrogeometric (EGM) from transmission-line data was sufficiently applicable to buildings.

According to the "Standard for the Installation of Lightning Protection Systems (NFPA 1997, Standard 780), 2000 Edition:

> "The zone of protection shall include the space not intruded by a rolling sphere having a radius of 150 ft (46 m). Where the sphere is tangent to earth and resting against a strike termination device, all space in the vertical plane between the two points of contact and under the sphere shall be considered to be in the zone of protection. A zone of protection shall also be formed where such a sphere is resting on two or more strike termination devices and shall include the space between those devices [see Figure 6.6-5]. All possible placements of the sphere shall be considered when determining the zone of protection using the rolling sphere model."
>
> "For structure heights exceeding 150 ft (46 m) above earth or above a lower strike termination device, the zone of protection shall be considered to be the space in the vertical plane between the points of contact and under the sphere where the sphere is resting against a vertical surface of the structure and the lower strike termination device or earth. The zone of protection shall be limited to the space above the horizontal plane of the lowest terminal unless it can be extended by further analysis, such as in rolling the sphere to be tangent to earth."

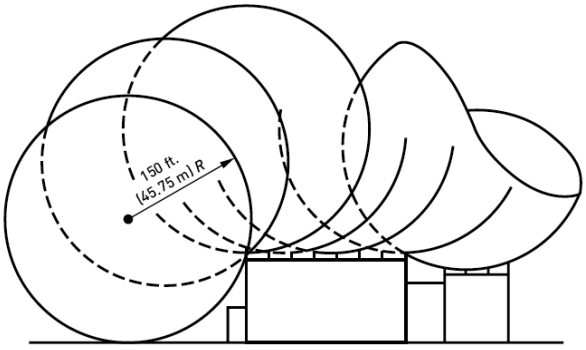

Figure 6.6-5 Rolling sphere method for analysis of shielding (NPFA 2004) (Reprinted with permission from NPFA 780-2004, *Installation of Lighting Protection Systems*, Copyright © 2004, National Fire Protection Association).

In international standards, R_s is defined directly to give an appropriate level of protection from shielding failures, with more critical installations calling for smaller radii (corresponding to less-probable weak first strokes). Typical values for the rolling sphere radius are found in Table 6.6-1.

Table 6.6-1 Recommended Values of Rolling Sphere Radius from International Standards

Standard	Rolling-Sphere Radius (m)	Equivalent Current (kA)
NFPA 780 / 2000	46 m	10.5 kA (94% protection)
NFPA 780 / 2000	30.5 m (flammable)	5.6 kA (99% protection)
BS 6651	60 m	15.7 kA (85% protection)
IEC TC81 Level I	20 m	2.9 kA (99% protection)
IEC TC81 Level II	30 m	5.4 kA (97% protection)
IEC TC 81 Level III	45 m	10.1 kA (91% protection)
IEC TC81 Level IV	60 m	15.7 kA (84% protection)
IEEE Std 998	$8\ I^{0.65}$	I = CFO/Bus Impedance

(Mousa and Srivastava 1989) recommends that a reduced striking distance expression and reduced median current of 25 kA be used for substation protection, and these have both been implemented in IEEE Standard 998 (IEEE 1996b).

The rolling sphere method can be applied in three dimensions to transmission lines near ground. This approach can be particularly helpful in areas where lines cross one another or enter a substation.

FLASH 1.8 Calculation of Shielding Failures

The IEEE Working Group on Estimating the Lightning Performance of Transmission Lines studied various methods for calculating the line flashover performance, including the methods of (Brown 1978; Darveniza 1979; EPRI 1982) and the method described in the second edition of this book. After comparing calculation results with observations on a calibration set of more than 20 transmission lines, the Working Group published a pair of papers recommending the following:

- Use of a height-dependent value for β, the factor that relates striking distances to ground and conductor, which varies with height. Originally, a value of $\beta = 22/H$ was selected to force the EGM to agree with the stroke incidence model, based on a shadow width of $(b + 4H^{1.09})$ for average overhead groundwire height H and separation b in meters. This factor was later revised in IEEE Standard 1243 (IEEE 1997b) to match the stroke incidence model of (Rizk 1990).

- Use of a striking distance of $R_s = 8\ I^{0.65}$ (IEEE 1985), intended to give a conservative shielding practice, but also leading to a gross overestimate of the shielding failure rate on 500-kV double-circuit lines with 6° shield angle. This expression was returned to its original value of SD = $10\ I^{0.65}$ in (IEEE 1993).

The Anderson method (EPRI 1982), as revised by the IEEE, was made available to the electrical industry in a variety of formats. With the difficulty of error-free completion of the schedule of calculations, even with scientific calculators, the program was converted to a series of computer languages, starting with FORTRAN, then Commodore BASIC, DOS (within a 64-k memory limit), C++, and most recently Excel. Versions of the DOS executable and BASIC versions are provided with IEEE Standard 1243. The Excel version, FLASH 1.8.1, is available on-line at www.ieee.org/pes-insulators.

The success of the FLASH program in predicting accurate transmission-line outage rates relates more to its use of accurate, but empirical models, than in its careful reproduction of the lightning interception process. For example, the effect of corona on the surge impedance of the stricken phase conductor is described using a gradient of 1500 kV/m at the edge of the envelope. This increases the capacitance (but not the inductance) of the phase and gives a realistic voltage dependence that matches experimental results by (Gary 1989). The FLASH program does not, however, consider subsequent-stroke shielding failure flashover effects, and this limitation can be addressed by assuming with little error that all shielding failures result in flashovers.

APPLET L-2

Applet L-2 attached to this chapter is designed as a tutorial for examination of the electrical and geometric parameters involved in the shielding failure process. It incorporates randomness in downward leader progression, influence of charges on the line conductors in attracting the tip of the downward leader and initiation of upward leaders from the line conductors, the contributions of line geometries and multiple circuits to the shielding failure process, effects of stroke current magnitudes, and general electrogeometric modeling. Four different mechanism options are provided to the user for simulation of the shielding failure process:

Option 1. Leader initiates from a conductor when induced charge on the conductor reaches some critical value.

Option 2. Leader initiates from a conductor when the average gradient between the tip of the conductor and the tip of the descending leader reaches some critical value.

Option 3. Upward leader length from a conductor is governed by the parameters in the general electrogeometric striking distance equation:

$$R_s = Ah^B I^C$$

Where:
R_S = striking distance, m.
A = striking distance parameter.
h = wire height, m.
B = a height exponent.
I = stroke peak current, kA.
C = a current magnitude exponent.

Option 4. Rizk attractive distance algorithm. Similar to Option 3 with specific values of the parameters;

$$D = 1.57h^{0.45} I^{0.69}$$

Where:
D = an attractive distance.

The user can modify any of the following default variables involved in the propagation process:

- Cloud-to-earth electric field at leader initiation: 15 kV/m.
- Distributed charge in lower regions of the leader channel: 15 μC/m.
- Critical gradient at wire corona wall: 30 kV/cm.
- Critical wire charge for upward leader initiation: 10 μC/m.
- Ratio of upward leader velocity to downward leader velocity: 2.0.
- Critical gradient at earth's surface for initiation of upward leader: 300 kV/m.
- Electrogeometric critical striking distance parameters.
- Critical gradient between leader tip and line conductors for final strike.

Figure 6.6-6 shows a graphic display of downward and upward leader progression created by the Applet L-2 for the base case of a shielded and unshielded transmission line running in parallel and for the choice of random leaders. A total of 100 flashes are shown, with 58 being inter-

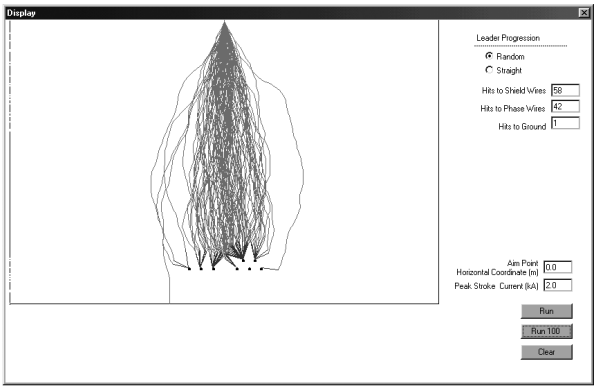

Figure 6.6-6 Graphic display of downward leaders by the Applet L-2.

cepted by the overhead groundwires, and 42 terminating on the phase conductors, mostly on the unshielded line but 3 on the shielded line.

A detailed description of the operation of the Applet L-2 is located in the Applet Help File.

6.7 INITIATION OF BACKFLASHOVERS

Backflashovers from negative first downward lightning strokes are the dominant root cause of transmission-line momentary outages.

6.7.1 The Backflashover Process

Backflashovers start with the normal interception of the lightning onto the overhead groundwires, as described in Section 6.6. For every intercepted lightning flash, the tower rises in potential relative to the phase conductors. Under these conditions, streamers can form from the tower to the phase conductors, ionize into leaders, and quickly bridge the tower-conductor gap. Phases with ac voltage in opposition to the stress tend to develop leaders most efficiently, and are most likely to initiate the backflashover from tower to phase. Once the leader has bridged the gap, the ac current can maintain this plasma channel continuously. The fault must be detected by protective relaying, so that automatic circuit breakers can remove the voltage for a sufficient time to allow the arc to cool and extinguish. The discussion here focuses on effectively grounded systems, but backflashovers may also occur on three-phase delta networks in other areas.

Contributions of Ground Resistance and Ground Plane Surge Impedance

Ground resistance is the most important variable in an insulator voltage equation. For typical transmission towers, the parallel resistance of four tower legs to remote earth is in the initial range of 60 Ω, rising or falling to a low-frequency value of 10-100 Ω within a few tower travel times. The initial surge response can be approximated as an inductance that varies with tower height, with 17 μH corresponding to a typical 30-m tower (Chisholm and Janischewskyj 1989). With a median peak current of 31 kA and a median rate of current rise of 25 kA/μs at peak from Section 6.2, the potential rise at the base of a tower is thus 700 to 3500 kV. Typical lightning impulse insulation strength for standard impulse waves is 540 kV per meter of distance, and a quick calculation shows that high-resistance grounds on 230-kV lines with 2 m of insulation are likely to have a high fraction of backflashovers in response to each lightning flash. As insulation level increases, this fraction decreases significantly, but even UHV lines at 735 kV and 765 kV are not immune to backflashovers.

Transmission towers are spotted with typical span lengths of 300 m. This means that, as the lightning surge current spreads out into the ladder network formed by footings and overhead groundwires, the impedance and resulting surge voltage drop continuously. Simplified methods of analysis achieve some success by performing an evaluation just before the first of these reflections from adjacent tower returns, making the local resistance at each tower a dominant input parameter.

Contributions of Tower Surge Impedance/Tower Inductance

The total voltage rise at the top of the transmission tower is the sum of two components:

- RI voltage rise from the footing resistance R and the peak current I.
- $L\ dI/dt$ voltage rise from the tower inductance L and the rate of current rise at the current peak.

The studies of lightning parameters show that the peak rate of rise occurs only slightly before the maximum of the current, so an arithmetic sum gives the peak voltage stress:

$$V_{tower-top} = R_{footing}\hat{I} + L_{tower}\frac{dI}{dt} \qquad 6.7\text{-}1$$

The correlation between I and dI/dt, for example as shown in Figure 6.2-14, is relatively high. This coupling of stress parameters can be exploited by using an analysis with an equivalent front time t_f, obtained by extrapolating back in time from the peak of wave to zero current at the maximum steepness.

Tower inductance can be calculated in a number of ways. As described in Section 6.4.2, some towers are relatively complex structures, with crossarms that provide multiple traveling wave path lengths. In most cases, it is efficient to calculate the capacitance C_t of the tower to free space using its surface area and shape factor, and the surge impedance of the body of the tower Z_t using a cylinder or cone expression from antenna theory. These two values are combined to give an average tower travel time ($\tau = Z_t C_t$) and the equivalent inductance ($L_{tower} = \tau Z_t = Z_t^2 C_t$). Anderson (EPRI 1986, Chapter 12) demonstrated that a realistic value of tower inductance will be higher than $L = \tau Z_t$ and is a function of tower footing resistance, but the classical value is generally used because the footing resistance itself is generally nonlinear with current.

Contributions of Shield Wire Coupling

The presence of overhead ground wires reduces the stress on insulation in two important ways. First, the parallel combination of all OHGW can give a surge impedance of about 120-140 Ω, which will appear in parallel with $R_{footing}$ to form a limiting case. For a ramp current with equivalent

front time t_f, the tower-top voltage with parallel OHGW impedance Z_{gw} becomes:

$$V_{tower-top} = \hat{I}\frac{\left(R_{footing} + \frac{L_{tower}}{t_f}\right)Z_{gw}}{R_{footing} + \frac{L_{tower}}{t_f} + Z_{gw}} \qquad 6.7\text{-}2$$

Second, and more sensitive in the calculation, is that the surge currents in the overhead groundwires produce voltages that are electromagnetically coupled to the phase conductors. This is normally modeled with an equivalent circuit of the mutual and self-impedance of the OHGW and phase conductor, leading to a coupling coefficient C_n as follows for the single OHGW case:

$$\begin{aligned} Z_{11} &= 60\ln\frac{2H_1}{r_1} \\ Z_{12} &= 60\ln\frac{D'_{12}}{d_{12}} \\ C_n &= \frac{Z_{12}}{Z_{11}} \end{aligned} \qquad 6.7\text{-}3$$

Here, D'_{12} is the distance from the phase conductor to the image of the OHGW in the earth, and d_{12} is the direct distance. For typical geometries, between 15 and 35% of the voltage appearing on tower top also appears with the same waveshape on the phase conductor, delayed in time but faithful to the original waveshape in most respects. Since the voltage on the insulator is the difference in potential between tower and phase conductor, the insulator voltage becomes, for insulators close to the top of the tower:

$$V_{insulator}(t) \approx V_{tower-top}(t) - C_n V_{tower-top}(t - \frac{2H}{c}) \qquad 6.7\text{-}4$$

The $2H/c$ term in Equation 6.7-4 is twice the travel time from the shield wire to its image in the earth, and represents the delay in creating the coupled voltage.

Contributions of Corona

High electric fields accelerate stray electrons, and these electrons can knock off other electrons from neutral air molecules, in a process called *ionization*. This process occurs at points of high stress under normal ac voltage, and is responsible for wet-weather corona loss, and electromagnetic and audible noise. Since the lightning surge voltages are so much higher than the normal ac voltage, it is correct to assume that impulse corona phenomena affect lightning backflashovers.

As an energy absorber, corona plays three roles in mitigating backflashover. These roles both enhance the contribution of overhead groundwire protection. First, the corona energy reduces the surge impedance of the overhead groundwire system. Second, there is an improvement in the efficiency of voltage coupling. Above the corona inception voltage, the value of C_n increases, and this reduces the stress across the insulation. The voltage-dependent corona model described in Section 6.4.1 is used to model these two aspects, using an envelope gradient of -2000 kV/m for negative flashes. Finally, the tower itself can be in corona during the flashover process (particularly for wood poles), tending to reduce the tower surge impedance and the apparent ground resistance.

Contributions of Power Frequency Voltages

The lightning impulse appears at a random time relative to the power frequency voltage. At any particular time, one or two of the phases have instantaneous ac potentials that add to the stress across the insulation. However, the phase voltages are also affected by tower position, mostly related to the lower values of coupling coefficient for phases that are farther from the overhead groundwires. Generally, the presence of ac voltage increases the chance of backflashover, and—importantly for high-voltage double-circuit lines—influences the order of phase conductor flashovers.

6.7.2 Dynamic Models for Electrical Insulation Strength

Section 6.5 described various models for the increase in electrical strength of air insulation as surge duration decreases. The empirical description of the insulator string flashover, using a volt-time curve, is useful when applied correctly to establish the magnitude of a voltage wave. A "correct" application is generally restricted to cases dominated by resistive response (for example, no strong tower or ground plane inductive peaks) and prior to the wave becoming "nonstandard," as canceling reflected waves arrive from adjacent towers after two span travel times.

When a detailed tower and ground plane surge response model is introduced, it shows that the insulator voltage can be significantly distorted from the traditional lightning impulse. Exercise of Applet L-4 in Section 6.5 demonstrates that the insulator voltage waveforms on the bottom phases can be quite different in nature from the top phases of the same tower. The Destructive Effect (DE) model from Section 6.5.2 is recommended to evaluate the flashover of insulators exposed to these nonstandard waves. Some mathematical aspects of the disruptive effect are discussed in Appendix 6.1.

6.7.3 Calculation Procedures

One of the most successful ways to estimate the lightning performance of a new transmission circuit is to perform a multiple linear regression of the observed performance for nearby lines against the most sensitive parameters. This is especially helpful when comparing lines with similar conductor geometry, tower style, and span length. Linear regression against remaining variables as insulation strength, footing resistance, local ground flash density, and TEM coupling coefficient can be as successful at predicting future performance as the most sophisticated treatment. In this context, equal weight is given to describing simplified and complex models for the lightning performance of transmission lines.

6.7.4 Digital Models for Backflashover

FLASH 1.8: Backflashover Aspects

The IEEE Working Group on Estimating the Lightning Performance of Transmission Lines studied various methods for calculating the line backflashover performance, including DCORTL (Sargent and Darveniza 1967), the methods of Brown (Brown 1978), and the method described in the second edition of the Red Book (EPRI 1982). After comparing calculation results with observations on a calibration set of more than 20 transmission lines, the Working Group published papers (IEEE 1985; IEEE 1993) recommending the following:

- Adoption of the Anderson simplified method (EPRI 1982), using evaluation of the volt-time curve at 2 μs (revised in 1993 to the span reflection time), and 6 μs along with traveling wave models of the tower, overhead groundwires that incorporate voltage-dependent coupling from corona effects.
- Elimination of the surge reduction factor in the Anderson method relating high-current footing resistance to measured low-current values. A constant factor of 0.6, applied to the calculation results to account for the reduced susceptibility of flashover for strokes to midspan compared to strokes to tower, should vary between 0.6 and 1.0 depending on footing resistance.

The Anderson method, as revised by the IEEE, was made available to the electrical industry in a variety of formats. With the difficulty of error-free completion of the schedule of calculations, even with scientific calculators, the program was converted to a series of computer languages, starting with FORTRAN, then Commodore BASIC, DOS (within a 64-k memory limit), C++, and most recently Excel. Versions of the DOS executable and BASIC versions are provided with IEEE Standard 1243 (IEEE 1997b). The Excel version, FLASH 1.8.1, is available online at www.ieee.org / pes-insulators.

The success of the FLASH program in predicting accurate transmission-line outage rates relates more to its use of accurate, but empirical, models than in its careful reproduction of every aspect of the complex lightning surge response. In particular, the use of the volt-time curve at 2-3 μs, just before the return of reflections from adjacent towers, is both technically correct and insensitive to error, compared to faster-front or slower-front times to flashover. The IEEE has been slow to adopt leader-progression models for flashover mainly because of the high sensitivity of the newer model to small errors in late-time voltage calculations, compared to the two-point evaluation recommended by Anderson at 2 μs and 6 μs.

DCORTL

Anderson and Thompson (Anderson and Thompson 1966) incorporated a digital weather model as the basis for calculating insulation performance of EHV transmission lines. This model built on Anderson's initial use of Monte Carlo methods strictly for lightning calculations. Sargent and Darveniza (Sargent and Darveniza 1967) refined and extended the use of Monte Carlo methods for dealing with the wide range of uncertainties in selecting parameters for analyzing double-circuit lightning performance of transmission lines. They sampled randomly from a range of parameter values, such as rise times from 2 to 6 μs and peak stroke current distribution of 13 kA median (5% level 60 kA, 1% 110 kA) from (AIEE 1950). The selected strokes were simulated in a traveling wave model, and calculations were repeated enough times to aggregate useful results. This work was supported by nanosecond models of the tower and phase conductor response, and was able to successfully predict the ratio of single-circuit to double-circuit outages on a number of 132-kV, 220-kV, and 230-kV lines in a wide range of grounding conditions and lightning exposure.

CIGRE Model

The CIGRE Technical Brochure 63 (CIGRE 1991) summarizes recommendations for calculating the lightning performance of transmission lines, and also facilitates modeling of the surges appearing at line terminals. A number of researchers have adapted parts or all of the CIGRE approach into calculation models, often using versions of the EMTP software package. Torres et al. (Torres et al. 2002) report the use of an implementation called DESCARGA, considering a concave front current, constant tower surge impedance, no corona effects, soil ionization, a leader progression model for insulation strength under nonstandard voltage impulse, and other important features in (CIGRE 1991). A comparison using data from four lines in Colombia was made among the IEEE FLASH program, DESCARGA, and the observed line performance. Both tools were found to be useful, but some adjustments, such as an appropriate relation between thunderstorm day and

ground flash density, were suggested for use in tropical regions.

Hileman DOS Programs

Hileman (Hileman 1999) accompanied his book *Insulation Coordination in Power Systems* with a diskette containing a group of MS DOS programs and help files for analysis of transmission-line and substation lightning performance. These include both CIGRE and IEEE programs for calculation of shielding failures and backflashovers, plus calculations of many of the parameters required in lightning analysis. Some of the initial versions of these programs were written for EPRI and are now updated.

EPRI TFLASH

In the years 1998-2003, EPRI developed a comprehensive transmission-line lightning simulation program TFLASH. This program evaluates all the aspects of lightning reliability of a large library of line geometries, insulator types, line arresters, conductor sizes, grounding arrangements, and transmission voltages. It is under continuous development, and is available to both EPRI and non-EPRI members through EPRI, 115 East New Lenox Road, Lenox, Massachusetts 01240, U.S. It accommodates multiple lines on the same right-of-way, distribution underbuild, branch circuits, and different exposures, and includes NLDN maps of regional ground flash densities over which a line can be located. It also permits economic evaluations of strategies for obtaining the best lightning performance of a line for a limited investment, or estimating how much investment would be necessary to attain a specified flashover rate of a proposed or existing line.

NEC2 and Other Electromagnetic Codes

The Numerical Electromagnetic Code (NEC) software program is a general-purpose routine that allows users to specify the endpoints of wire segments, and then to explore the response of this structure to electromagnetic fields at specified frequencies. The NEC code uses the method of moments (Harrington 1993). The original NEC2 was developed by Burke and Poggio (Burke and Poggio 1980) for the U.S. Navy. The code started as a "card image/batch run" operation initially designed for mainframe computers, similar to EMTP. It has been ported to many other machines with improved user interfaces as described at www.nec2.org. There are other public-domain electromagnetic codes, such as MININEC, that could also be used for this purpose. NEC2 uses the Sommerfield-Norton ground interaction for wire structures above lossy ground.

Baba and Ishii made excellent use of NEC2 in a series of analyses of transmission-line surge response to lightning (Baba and Ishii 1997, 1999, 2000, 2001), including a tutorial to describe the complete process of accurate frequency-domain modeling and conversion to time domain using Fourier transforms. The NEC2 code cannot be used to model nonlinear phenomena such as corona, ionization, or leader progression. This limitation can be addressed through the use of a "Thin Wire Time Domain" code, and research into this alternative for lightning electromagnetic effects has been initiated (Mozumi et al. 2003).

The electromagnetic models can give a detailed description of the potential difference across insulation without the approximations involved in adapting surge impedance models for this purpose. Properly-constructed computer models, validated in preferred research with experiments on full or reduced-scale models, have automatically dealt with causality and propagation effects that influence voltage coupling, and tower and ground plane surge response.

EMTP Codes

The Electromagnetic Transients Program (EMTP) was developed by Dommel (Dommel 1969) and was adopted at Bonneville Power Authority in the late 1960s. Some aspects of this development remain in the public domain through the Alternative Transients Program (ATP) program. The EMTP software proved to be a valuable tool for simulating power system transients in the frequency and time domain, using modules to describe system elements (lines, cables, transformers, lumped elements), their interconnections, and their interactions. Since that time, the following development dates are notable:

1982	The EMTP Development Coordination Group was founded.
1987	Version 1.0 released.
1989	Version 2.0 (DCG/EPRI EMTP) released.
1996	Version 3.0 (EMTP96) released.
2003	EMTP-RV released.

With improving computer processing power and memory, it is now practical to carry out simulations of lightning on multiple spans of transmission lines that include corona and frequency-dependent effects on wave propagation, (IEEE 1996), nonlinear tower and ground plane surge response, electromagnetic wave coupling (from an external source code such as LIOV), leader-progression models of insulator flashover, and accurate models for the response of line surge arresters.

One difficulty that still tends to limit the use of EMTP codes for lightning performance evaluation (Martinez and Castro-Aranda 2003) is the need to construct manual or supervisory routines (Zanetta 2003) to run multiple cases (for example, ramping up surge currents from 10 to 200 kA, and noting when flashover or arrester failure occurs) and to consolidate results. However, the new tools in later versions of EMTP for constructing the models, for visualizing the waveforms, and for saving results of case studies have facilitated many advanced research and analysis projects.

Web-based Resources

The recent development of online resources for retrieval of conference proceedings and journal articles offers a great wealth of new perspective to the lightning researcher. Recommended resources for further study include (but are not limited to):

- Search engines such as "Google" at www.google.com using keywords such as "lightning" and key phrases such as "transmission line" or "rolling sphere."
- Posted papers from conferences such as International Conference on Lightning Protection (ICLP).
- IEEE Xplore and Digital Library resources.
- *Electra* (four CD collection of papers from 1968 to 2002).
- Standards such as IEEE 1243, IEC 61024, and IEC 61312.
- EPRIweb resources, listing abstracts of important work.
- www.emtp.com.

6.7.5 Applet Descriptions

Two applets are provided with this book to help the user to integrate the technical descriptions in Sections 6.2 to 6.6.

Applet L-4

Applet L-4 attached to this chapter is a tutorial program to display the various voltage and current waveshapes created by a lightning flash to a tower top under different electrical and geometric conditions. Its operation is covered in more detail in the Applet Help File. The user selects a stroke waveshape—CIGRE first stroke, CIGRE subsequent stroke, Heidler waveshape stroke, or ramp function—and crest current. The general electrical parameters, including tower and shield wire characteristics, are keyed in as well as the low-frequency footing resistance. It assumes that the footing resistance dynamics can be described by the Korsuncev curve (Section 6.10.13), and—if ionization around the ground electrode is to be included—the Korsuncev *S* dimension must be specified. The applet then displays a table of values of some of the calculated variables as a function of time, followed by a graphic colored display of the voltage and current waveshapes created by the lightning strike and—if insulator performance is to be studied—a plot of the Disruptive Effect integration (Section 6.5.2) toward flashover is included. The applet is simplified and may not compare accurately with similar calculations made by EMTP or EPRI TFLASH, but should be sufficient for tutorial purposes.

Figure 6.7-1 shows, for a ramp function waveshape, the Disruptive Effect integrated waveshape calculated from the voltage across the insulator. When this waveshape reaches 100%, a flashover occurs.

Applet L-1

Applet L-1 attached to this chapter comprises a tutorial program to evaluate lightning performance of an idealized line for a variety of dimensional and grounding conditions. Procedures for using this applet are given in the Applet Help File. It is a traveling wave model for strikes to a tower top with two other equally spaced transmission towers on each side of it. CIGRE first-stroke current waveshapes are employed, but the user has the option of shifting the time to crest. Tower grounds can be ground rods, concrete foundations, or continuous or radial counterpoise. Radial counterpoise can consist of up to eight radials. Shielding failures

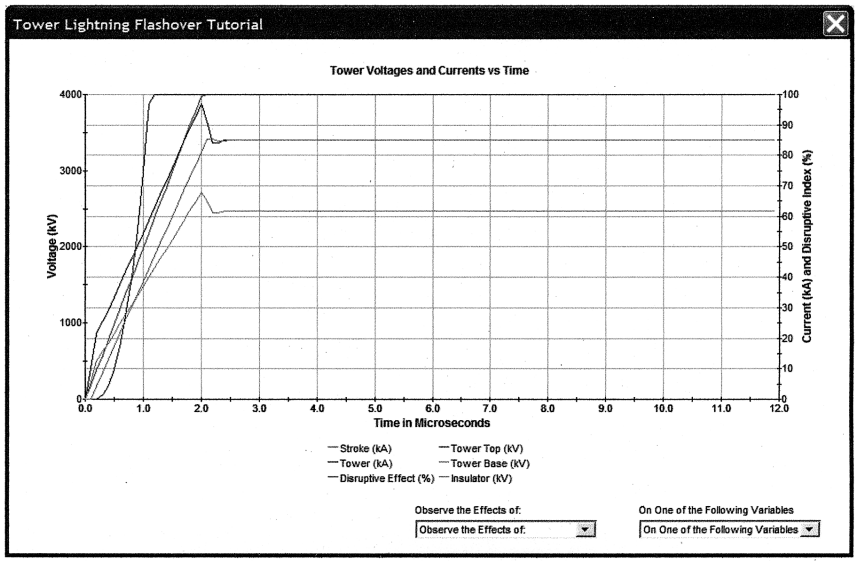

Figure 6.7-1 Example output waveforms of Applet L-4.

are calculated using the method of maximum heights (Section 6.6.5) and backflashovers as described in Section 6.7.1. Volt-time flashover of insulators is computed using the Disruptive Effect (DE) algorithm described in Section 6.5.2. When two or more insulators are equally stressed, the flashovers are shared equally between them. Simultaneous flashovers on more than one phase, as may often occur on a double-circuit line, are not reported. For any stroke, the calculation stops as soon as a flashover occurs, and the program then proceeds to the next stroke.

Ground rods can be in asymmetrical locations with respect to one another if desired, and their combined ground resistance is calculated as a dynamic value for every time step using the Liew-Darveniza algorithm (Liew and Darveniza 1974), with some conceptual modifications as described in Section 6.10.12.

Concrete foundations are assumed sufficiently large so that resistance reductions due to soil ionization can be neglected. If the total low-frequency ground resistance of the concrete foundations is unknown, the program provides an estimated value depending on the foundation surface area and soil resistivity, plus an adjustment for a fixed amount of metal reinforcing inside the concrete. The frequent practice of driving one or more ground rods adjacent to concrete foundations is not simulated, but should be recognized as providing additional reductions of Applet L-1 backflashover estimates.

For radial counterpoise, up to eight radial wires—all of the same length and diameter—can be utilized as the tower ground electrode. The low-frequency resistance of the counterpoise is calculated and displayed by Applet L-1 when earth resistivity is specified. The low-frequency counterpoise resistance is calculated using the Dwight equations (Dwight 1936) in Table 6.10-1. For any counterpoise subjected to a high-frequency transient, the initial impedance is the combined surge impedance of the counterpoise, but the counterpoise impedance rapidly decays down (or sometimes up) in approximately three round-trip travel times to the combined low-frequency resistance, or even lower when ionization is involved. For high currents, computer models show most earth ionization appears at the tower end of the counterpoise, because currents are depleted rapidly as they move along the wires. Applying travel times to the Applet L-1 counterpoise models is beyond the capability of the applet, and the approximate dynamic resistance is assumed similar to a set of horizontal ground rods modified by the presence of the earth's surface above them.

To more accurately represent surge impedance at high currents, corona envelopes are simulated on all shield wires and—for shielding failure analysis—on any phase conductor that is struck. The simulation follows Section 6.4.1 above.

Applet L-1 is intended as a tutorial model or rough estimation tool. It does not model:

- Multiphase flashovers
- Different tower footing resistances (all towers on either side of the struck tower must have the same footing resistance as the struck tower)
- Different tower exposures to lightning
- Arrester applications
- Subsequent stroke flashovers
- Distribution underbuild
- Counterpoise traveling wave effects
- Shielding failures on hillsides
- Corona attenuation of traveling waves

A much larger program, such as the EPRI TFLASH described in Section 6.7.4, would be necessary to make a thorough analysis of all the complexities inherent in the lightning flashover of all types of transmission lines.

6.8 INITIATION OF INDUCED FLASHOVERS

6.8.1 Induction from EM Fields of the Lightning Flash

The electromagnetic field coupling problem from a lightning flash near a conductor can be solved in three equivalent ways, using combinations of the electric and magnetic fields that illuminate the line. Near the lightning flash, these magnetic and electric source terms are not necessarily inter-related by the impedance of free space, 377 Ω. Rachidi (Rachidi 1993) showed the equivalence of these approaches, described generally in Appendix A2, and an excellent review of the entire induction process by Nucci and Rachidi is available in (Cooray 2003b, Chapter 8). These models predict that vertical lightning strokes terminating near, but not directly attaching to, overhead power lines and cables can still induce significant voltages and currents.

6.8.2 Simplified Model for Induced Overvoltages

Rusck (1958) described a simple model for the field-to-line coupling over perfectly conducting ground. For a linear leader charge q moving upward with velocity v:

$$I_o = vq_o \qquad 6.8\text{-}1$$

$$Z_o = \frac{1}{4\pi}\sqrt{\frac{\mu_o}{\varepsilon_o}} = 30\ \Omega \qquad 6.8\text{-}2$$

$$V_1(x,t) = Z_o I_o h \frac{v}{c} \frac{ct - x}{y^2 + (v/c)^2 (ct - x)^2} \left(1 + \frac{x + (v/c)^2 (ct - x)}{\sqrt{(vt)^2 + \left(1 - (v/c)^2\right)\left(x^2 + y^2\right)}} \right) \quad 6.8\text{-}3$$

$$V = V_1(x) + V_1(-x) \quad 6.8\text{-}4$$

Where:

q_o = the charge per unit length, C/m.
v = the return stroke velocity, m/s.
c = the speed of light, 3 x 10^8 m/s.
x = the coordinate along the horizontal conductor, with $x = 0$ at the point closest to the lightning.
y = the coordinate perpendicular to the horizontal conductor, with $y = 0$ at the lightning stroke.
h = the height of the horizontal conductor above perfect ground.

Figure 6.8-1 shows the induced voltages from a 10-kA flash at four locations along a 10-m-high conductor.

The highest voltage occurs at the conductor location nearest to the lightning stroke. The peak voltage for 10 kA is only 70 kV, well below the critical flashover level of high-voltage transmission lines. For this situation ($x = 0$), and with a typical return stroke velocity of $v = 0.3\ c$, Equation 6.8-3 simplifies to give a peak overvoltage estimate of:

$$V = 29 \frac{Ih}{y} \quad 6.8\text{-}5$$

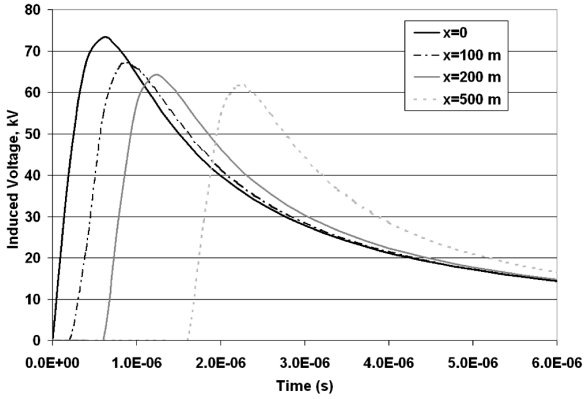

Figure 6.8-1 Induced voltage on horizontal conductor, h = 10 m above perfect ground, y = 50 m from I_o = 10-kA lighting stroke with $v = 0.3\ c$.

Field-measured induced voltages, such as the South African test line (Eriksson et al.1982) and an experimental line at Camp Blanding, Florida (Rubenstein –et al. 1989), the latter exposed to triggered lightning flashes, tend to verify Equation 6.8-5. The Rusck equation fails for small distances between the line and the flash or for the case of high earth resistivity.

6.8.3 Protection against Induced Flashovers

Generally, transmission lines have minimum insulation strength of at least 300 kV. This has led to a hypothesis (Gilman and Whitehead 1973) that induction cannot cause outages on transmission circuits. Any stroke with sufficient amplitude and close enough to cause an induced overvoltage flashover has a striking distance that is sufficiently high to terminate on the line.

There are cases where the induced overvoltage has a stronger engineering significance. First, a tall structure with large attractive radius can reduce the dimension y, which normally cannot be less than the striking distance of the lightning flash to the conductor. The return stroke velocity v will also equal the speed of light within the tall structure. These factors can combine to increase the overvoltage level.

In the case of tall transmission towers, the phase conductors are located below the tower top. The fraction of the lightning surge current in the tower can be within 3 m of the phases. Calculations (Baba and Ishii 2000) using an advanced electromagnetic program, NEC2, show that the resulting induced voltages have substantial peak amplitudes of up to 10% of the tower voltage, but tend to be bipolar. The bipolar-induced voltages with pulse widths corresponding to the tower travel time will not add to, or subtract from, the destructive index integral in any way that is substantiated by test results.

6.8.4 Importance for Subtransmission and Underbuilt Distribution

In some cases, joint-use imperatives force transmission-line towers to carry additional conductors for lower-voltage subtransmission, distribution, or communication systems. Since the transmission line receives many direct strokes over its life, the resulting exposure risk to attached equipment must be well managed. The transmission tower carries appreciable surge current, and this, combined with the physical proximity, can lead to severe induced overvoltage or side flashes. The term “backflow current” is generally applied to cases where lightning surges flow down a target (tower and overhead shield wire), through interconnected grounds, and back up into the susceptible system. The number of flashes to the overhead line often makes the use of line surge arresters effective on the lower-voltage system. The parallel impedance of the low-voltage network tends to reduce the surge impedance and improve the

coupling coefficient, either when it flashes over or when its surge arresters operate. However, the insulation strength on distribution lines can be much less than 300 kV, so significant (even high) induced overvoltage flashover rates can occur on such lines.

6.9 INITIATION OF MIDSPAN FLASHOVERS

Line flashovers caused by lightning strikes at or near midspan between two adjacent towers are infrequent for normal midspan clearances. Exceptions can occur if shield wire-to-phase spacings are small (as in distribution circuits), or if span distances are large (300 m or more). The high-voltage phenomena involved in these failures is well understood in principle, and has been confirmed by field tests (Wagner and Hileman 1964; Los 1980), but is highly nonlinear, and represents an interesting application of traveling wave theory.

6.9.1 The Failure Mechanism

In Figure 6.9-1, a high-magnitude stroke current is injected into a shield wire at midspan. The voltage at the strike point on the shield wire builds up according to the standard equation:

$$V_s = \frac{I_s Z_s}{2} \qquad 6.9\text{-}1$$

Where:

V_s = shield wire surge voltage to ground at the hit point, kV.

I_s = instantaneous stroke current, kA.

Z_s = shield wire surge impedance (modified by corona calculated from Equation 6.4-23), ohms.

6.9.2 Corona Coupling at Midspan

By the standard coupling equation, treating the self and mutual surge impedances as a coupled set of potential dividers with the phase current $I_p = 0$, the voltage V_p coupled onto the phase becomes:

$$V_p = \frac{Z_{sp} V_s}{Z_s} \qquad 6.9\text{-}2$$

Where:

Z_{sp} = mutual impedance between shield wire and phase conductor, ohms.

Equations for calculation of self and mutual surge impedances Z_s and Z_{sp} under corona conditions are given in Section 6.4.

Combining Equations 6.9-1 and 6.9-2, the voltage difference between phase and shield wire is

$$V_{sp} = V_s - V_p = \frac{I_s Z_s}{2}\left[1 - \frac{Z_{sp}}{Z_s}\right] \qquad 6.9\text{-}3$$

and the average gradient E_{sp} between shield wire and phase conductor is

$$E_{sp} = \frac{I_s Z_s}{2 S_{sp}}\left[1 - \frac{Z_{sp}}{Z_s}\right] \qquad 6.9\text{-}4$$

The ratio Z_{sp}/Z_s is called the "coupling factor." It normally has a value in the 0.2-0.3 range, increasing with voltage, as shown in Figure 6.4-7, and establishes the ratio of phase voltage to shield wire voltage for a hit to the shield wire.

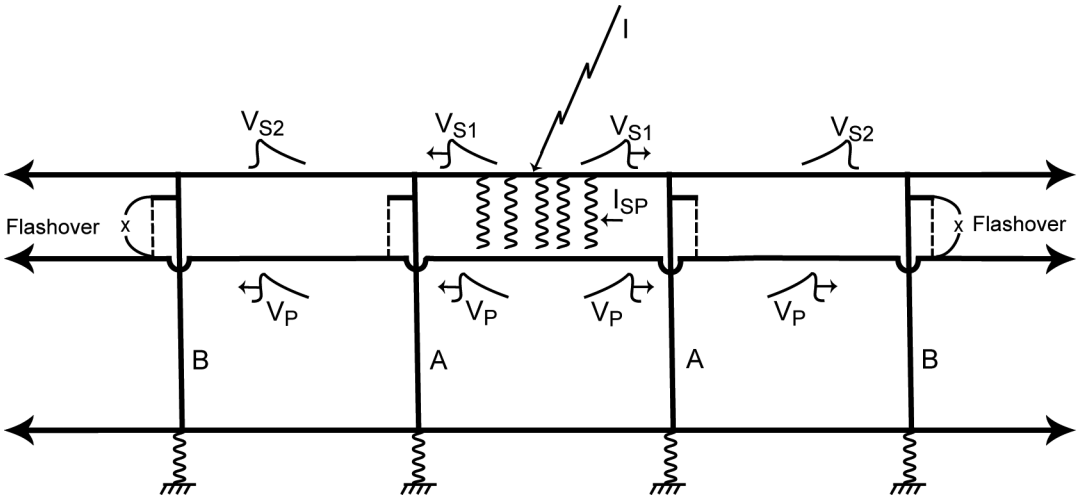

Figure 6.9-1 Lightning breakdown processes at midspan.

6.9.3 Current Injection into Phase Conductors

High-voltage tests (Wagner 1964; Wagner and Hileman 1964; Los 1980) have shown that the breakdown gradient E_{sp} between shield wire and phase occurs at approximately 610 kV/m for a standard 1.2 x 50 μs waveshape. This breakdown is observed to begin with strong predischarge currents flowing from the shield wire to the phase. This current flow into the phase can reach many hundreds of amperes before complete breakdown, increasing the phase voltage and maintaining the gradient between the two wires at its critical 610 kV/m value during the breakdown process. At a gradient of 610 kV/m between the two wires, the breakdown process is relatively slow, and can require many microseconds to complete. In the meantime, the stroke current injected into the shield wire (less the current flowing across the gap) splits and travels to the transmission structures at each end of the span (Figure 6.9-1). Here the currents reflect with reversed polarity off the structures (unless footing resistance is extremely high), and the reversed polarity currents return to the strike point where they combine, greatly reducing the shield wire voltage and stopping the breakdown before it can complete.

6.9.4 Tower Flashovers Caused by Midspan Strokes

Predischarge current injection into the phase conductor, as introduced above, can still cause flashovers at towers one or two spans away in some cases, even though the flashover process at midspan stalls before completion. As an example, in Figure 6.9-1, a 50-kA midspan stroke into a shield wire with a combined surge impedance (with corona) of 200 ohms would develop 10 MV on the shield wire at the strike point. If the spacing to the nearest phase is 7 m, then the voltage between the two wires at the critical gradient of 610 kV/m would be held to 4.3 MV during the breakdown process. This is equivalent to the total predischarge currents injecting a voltage onto the phase of 10 – 4.3 = 5.7 MV. This 5.7 MV transient, V_p, then travels in both directions along the phase conductor and appears an the line ends of the nearest insulators at towers *A* at the same time that shield wire voltages V_{s1} are arriving at the tower *A* tower tops (Figure 6.9-1). The difference created between the tower top voltage and the phase voltage may be insufficient to cause insulator flashovers at tower *A*, depending on footing resistance and difference between shield wire and phase voltages, but the phase voltage transients then continue to travel to the next set of towers where shield wire voltages V_{s2} are small and the difference between tower top and phase voltage is large, initiating phase flashovers at those locations.

The assumption is usually made that midspan flashovers do not make a significant contribution to the total backflash rate, but this assumption does not hold for some lines, particularly for lines with low basic insulation level (BIL), long spans, or tight clearances between shield wires and phases at midspan. Applet L-1 also does not determine if predischarge currents injected into phase conductors by a midspan hit are sufficient to cause flashovers at nearby towers. It operates on the assumption that approximately 60% of span hits are near enough to be considered as tower hits and that the other 40% are far enough out on the spans to not cause flashovers.

6.9.5 Cascading Flashovers at Adjacent Structures

Note also that if a midspan flashover does occur, the voltages arriving at insulators for towers *A* and *B* are usually sufficient to cause one or more insulator flashovers. The insulator flashover nearest to the generation source holds in, turning off or greatly limiting the voltage to the other flashovers. This can leave only failure evidence of burn marks on the insulator that held in, and no evidence whatsoever of the root cause at midspan.

6.9.6 Rules for Midspan Spacing

Generally, conductor clearances to other phase conductors, overhead shield wires, and grounded metallic objects should be specified to be sufficiently large that flashover at adjacent towers occur under lightning impulse conditions. Factors that influence the required spacing include:

- The conductor surge impedance, raising potential near the strike point relative to potential near the insulators.
- The number of nearby insulators in parallel with the gap; generally, only the two closest insulators should be considered.
- The presence of ac system voltage, unsynchronized with the lightning, and appearing essentially as a static bias voltage for the duration of the lightning surge.
- The wind speed, pressure on the conductor, and the horizontal displacement.
- The variability of wind gusts, which can get conductors swinging out-of-phase.
- The phasing of ac voltage on double-circuit lines, since reduced distance or contact between two conductors of the same phase and voltage are unlikely to cause outages.
- Special factors, such as the presence of ice and low torsional damping, which can cause a vertical “galloping” motion.

Electrical safety standards such as the NESC (IEEE/ANSI C2) generally use a linear relation between electrical guard distance and lightning impulse level (BIL) of 540 kV/m. Other details are discussed in Chapter 3.

6.9.7 Importance for Subtransmission and Underbuilt Distribution

If subtransmission or underbuilt distribution circuits are supported on transmission towers, very poor lightning performance on the former is a likely result. The insulation on these circuits is usually much weaker than the transmission circuit insulators, while the lightning transient voltages are usually as high or higher than those created across the transmission circuit insulators. In many cases, practically every lightning flash that hits the line (and being taller, more flashes are attracted to the line), as well as many flashes near the line, result in a subtransmission or distribution circuit flashover. Remedies can include liberal application of line arresters, installing the subtransmission or distribution circuits on separate poles, or using insulators with a BIL substantially above conventional practice.

6.10 TRANSMISSION-LINE GROUNDING

The grounding or earthing system is the total set of measures used to connect an electrically conductive part of the power system to earth. The grounding system is an essential part of both high- and low-voltage electric power networks, and has at least four important electrical roles:

1. To protect against lightning, eliminating hazards by:
   - Providing a mechanically and electrically robust path to ground
   - Limiting potential differences across electrical insulation on stricken towers
   - Reducing the number of flashovers that occur
2. For correct operation of the power system, minimizing energy by:
   - Providing unambiguous identification of faults, so that the correct protection systems operate.
   - Providing low zero-sequence impedance for return of unbalanced fraction of ac system currents
3. To ensure electrical safety, minimizing energy by:
   - Rapidly identifying system faults, leading to reduced fault duration
   - Limiting touch or step voltages to levels that restrict body currents to safe values
4. To contribute to electromagnetic compatibility, eliminating some hazards and reducing energy of others.

All these functions are provided by a single grounding system. Some elements of this system may have specific electrical purposes, but all elements are normally bonded or coupled together, forming one system to be designed or analyzed.

6.10.1 Mechanical Integrity

The main design challenges in transmission-line engineering are mechanical. The conductors must be sized to carry the load current, typically at a density of 1 A/kcmil (1000 circular mils or 0.001 sq. in.). National electrical safety standards define the necessary physical clearances to other electrical circuits and to ground for a variety of land uses. The towers are spotted at intervals of 200 to 400 m with sufficient strength to support the conductor weight, including possible ice loads, at attachment heights that will maintain adequate clearance at maximum conductor operating temperatures. The towers must also withstand some, but possibly not all, wind loads with well-controlled failure modes. Lines need sufficient margin for broken insulators or conductors over irregular terrain, with a wide range of soil load-bearing capabilities. There are, however, mechanical engineering solutions that have positive or negative impact on the effectiveness of overhead groundwires for grounding and lightning protection, such as:

- The spacing of the tower legs. Towers with a wide base, relative to the depth of the footings, perform better electrically because they have a larger contact patch to the earth. Steel pole towers tend to perform less effectively for the same reason.
- The use of guy wires. Towers with one or two central footings and four or more widely spaced guy wires have a large footprint and can perform well with adequate electrical grounding of each guy wire.

Designers often choose narrow-base towers for agricultural areas, then specify extensive buried ground conductors that are vulnerable to damage from agricultural machines. Steel poles, selected for appearance in areas of high public exposure, must also be specified with ground electrodes of sufficient size and shape to control risk of touch potentials.

6.10.2 Guy Anchors for Additional Strength

In areas where agriculture is less productive and the terrain is more rugged, tower designers tend to prefer the use of guyed V-type towers. These are economical, especially when helicopter installation is feasible. It is important to include analysis of the ground electrodes formed by the soil anchors for the guy wires. Also, the addition of four parallel guy wires to a conventional V-type lattice tower can reduce the tower surge impedance by a factor of two. The lower profile of guyed structures compared to free-standing towers also reduces lightning incidence, which is related to the attractive radius of overhead groundwire height, as described in Section 6.5.

6.10.3 Corrosion and End-of-Life Aspects

Buried wire electrodes, such as radial or continuous counterpoise, have a lifetime of 10 years or less in many applications. End of life can be accelerated when there is unrestricted public access to buried copper conductor, when there is acidic soil, or when there are appreciable steady-state neutral voltages.

6.10.4 Steady-State Tower Potentials

Currents induced in overhead groundwires can reach 30 A under normal load conditions. In lines where all spans are equal, the net current in each footing is zero. However, for lines with unequal span lengths, each tower has a different current that can reach a significant fraction of the total. Transmission tower ground electrodes provide steady-state dissipation of this current. The power dissipation can dry out the soil around concentrated electrodes such as rods, generally leading to higher local resistivity and contact resistance.

For an impressed current, the potential rise of a ground electrode relative to remote earth is obtained through the following analytical process:

- A distribution of the current is assumed, typically ignoring the resistance of the metallic parts of the buried electrode.
- The potential at distance *R* in the surrounding medium of resistivity ρ is calculated by superposition of potentials *dU* from the currents *dI* leaving each conductor element using $dU = \rho dI/(4\pi R)$.
- The potential is integrated (summing the contribution of each element of current *dI)* and evaluated at infinite distance (to obtain the rise in potential relative to remote earth) or at a close distance such as 1 m (to obtain touch or step potential exposures).

When an electrode consists of two or more components, the mutual resistance between the two elements is computed, often by using the average distance between the two. but sometimes using a double (Neumann) integral. The potential of an electrode buried in a half space is computed by considering a nearby image that makes a plane of symmetry at the surface of the earth.

Low-Frequency Ground Resistance Equations

Dwight (1936) and Sunde (1949) published expressions used to calculate the resistance to remote earth of electrodes for a number of practical shapes (see Tables 6.10-1 and 6.10-2).

Simple Model for all Smooth, Solid Electrode Shapes

While the tables of equations cover a wide range of situations, they do not provide particularly accurate estimates for fairly simple cases where vertical and horizontal electrodes are combined, such as two vertical rods connected together by a buried wire or a circular ring with a buried connection to a central tower. There is an approach that can treat an extremely wide range of electrode shapes with reasonable accuracy. This approach was developed from techniques for computation of electrode capacitance in free space with variational methods (Chow and Yovanovic 1982; Chisholm 2001). For a uniform half-space of resistivity ρ, the resistance of solid electrodes is accurately described by:

$$R_{geometric} \approx \frac{\rho}{2\pi g}\ln\left(\frac{11.8g^2}{A}\right) \qquad 6.10\text{-}1$$

Where:

$R_{geometric}$ = the electrode resistance to remote earth.
ρ = the resistivity in Ω-m.
g = the geometric sum of the length, width and depth of the electrode, $\sqrt{r_x^2 + r_y^2 + r_z^2}$
A = the surface area of the electrode.

The value 11.8 is theoretically $(2\pi e^{\sqrt{3}})/3$ or 11.838, but 12 is easier to remember.

The strength of the simple expression in Equation 6.10-1 is that it is adequately accuracy over an extremely wide range of electrode shapes. This means that geometric resistance for electrodes of any intermediate shapes (thick buried discs, fat cylinders, combinations of vertical rods and surface grids) can be estimated with similar accuracy using the same expression. Examples of the level of accuracy achieved, along with insight into the effect of electrode shape on resistance, follow by comparison to derived resistances of hemisphere, rod, disc, and arbitrary objects of revolution in the literature.

The *hemisphere* of radius *s* has a surface area of $A = 2\pi s^2$ and a value of $g = 1.732\ s$. For this important theoretical result, the geometric resistance from Equation 6.10-1 is:

$$R_{geometric} = \frac{\rho}{2\pi\sqrt{s^2+s^2+s^2}}\ln\left(\frac{11.8(\sqrt{s^2+s^2+s^2})^2}{2\pi\, s^2}\right)$$
$$= \frac{\rho}{2\sqrt{3}\pi s}\ln\left(\frac{11.8\cdot 3}{2\pi}\right) = \frac{\rho\cdot 1.73}{2\sqrt{3}\pi s} = \frac{\rho}{2\pi s} \qquad 6.10\text{-}2$$

This is in perfect agreement with the accurate value obtained by integrating the potential from the hemisphere surface to infinity.

Equation 6.10-1 gives a geometric resistance for a *rod* of length *s*, radius *r*, area $A = 2\pi rs + \pi r^2$ and $g \approx$ s for $s >> r$ of:

$$R_{geometric} = \frac{\rho}{2\pi s}\ln\left(\frac{11.8s^2}{2\pi rs}\right)$$
$$= \frac{\rho}{2\pi s}\left(\ln\left(\frac{11.8}{2\pi}\right) + \ln\left(\frac{s}{r}\right)\right)$$
$$= \frac{\rho}{2\pi s}\left(0.63 + \ln\left(\frac{s}{r}\right)\right)$$

Expressed in the same form as Equation 6.10-3, classical derivations of the resistance of a single rod of length s and radius r differ in the value of K_{rod}, as shown in Table 6.10-3.

$$R_{geometric} = \frac{\rho}{2\pi s}\left(K_{rod} + \ln\left(\frac{s}{r}\right)\right) \qquad 6.10\text{-}3$$

Generally, the value of $\ln(s/r)$ in Equation 6.10-3 will be about 6, leading to a ±9% change in $R_{geometric}$ from the variation in K_{rod} for different assumptions about the currents and fields around a vertical rod. Applet L-6 can be used to calculate the current and potential distribution along a vertical rod more accurately than any of the derivations in Tables 6.10-1, 2, or 3.

Table 6.10-1 Low-Frequency Ground Resistance of Electrodes (Dwight 1936)

Electrode	Dimensions	Equation
Single vertical rod	Length *L*, radius *a*	$R = \frac{\rho}{2\pi L}\left(\log_e \frac{4L}{a} - 1\right)$
Two vertical rods	Separation *s* with *s>L*	$R = \frac{\rho}{4\pi L}\left(\log_e \frac{4L}{a} - 1\right) + \frac{\rho}{4\pi s}\left(1 - \frac{L^2}{3s^2} + \frac{2}{5}\frac{L^4}{s^4} + \ldots\right)$
Two vertical rods	Separation *s* with *s<L*	$R = \frac{\rho}{4\pi L}\left(\log_e \frac{4L}{a} + \log_e \frac{4L}{s} - 2 + \frac{s}{2L} - \frac{s^2}{16L^2} + \frac{s^4}{512L^4} - \ldots\right)$
Buried horizontal wire	Length *2L*, depth *s/2*	$R = \frac{\rho}{4\pi L}\left(\log_e \frac{4L}{a} + \log_e \frac{4L}{s} - 2 + \frac{s}{2L} - \frac{s^2}{16L^2} + \frac{s^4}{512L^4} - \ldots\right)$
Right-angle turn of wire	Arm length *L*, depth *s/2*	$R = \frac{\rho}{4\pi L}\left(\log_e \frac{2L}{a} + \log_e \frac{2L}{s} - 0.2373 + 0.2146\frac{s}{L} + 0.1035\frac{s^2}{L^2} - 0.0424\frac{s^4}{L^4}\ldots\right)$
Three-point star	Arm length *L*, depth *s/2*	$R = \frac{\rho}{6\pi L}\left(\log_e \frac{2L}{a} + \log_e \frac{2L}{s} + 1.071 - 0.209\frac{s}{L} + 0.238\frac{s^2}{L^2} - 0.054\frac{s^4}{L^4}\ldots\right)$
Four-point star	Arm length *L*, depth *s/2*	$R = \frac{\rho}{8\pi L}\left(\log_e \frac{2L}{a} + \log_e \frac{2L}{s} + 2.912 - 1.071\frac{s}{L} + 0.645\frac{s^2}{L^2} - 0.145\frac{s^4}{L^4}\ldots\right)$
Six-point star	Arm length *L*, depth *s/2*	$R = \frac{\rho}{12\pi L}\left(\log_e \frac{2L}{a} + \log_e \frac{2L}{s} + 6.851 - 3.128\frac{s}{L} + 1.758\frac{s^2}{L^2} - 0.490\frac{s^4}{L^4}\ldots\right)$
Eight-point star	Arm length *L*, depth *s/2*	$R = \frac{\rho}{16\pi L}\left(\log_e \frac{2L}{a} + \log_e \frac{2L}{s} + 10.98 - 5.51\frac{s}{L} + 3.26\frac{s^2}{L^2} - 1.17\frac{s^4}{L^4}\ldots\right)$
Ring of wire	Diameters ring *D*, wire *d* depth *s/2*	$R = \frac{\rho}{2\pi^2 D}\left(\log_e \frac{8D}{d} + \log_e \frac{4D}{s}\right)$
Buried horizontal strip	Length *2L*, section *a* by *b*, (*a>8b),* depth *s/2*	$R = \frac{\rho}{4\pi L}\left(\log_e \frac{4L}{a} + \frac{a^2 - \pi ab}{2(a+b)^2} + \log_e \frac{4L}{s} - 1 + \frac{s}{2L} - \frac{s^2}{16L^2} + \frac{s^4}{512L^4} - \ldots\right)$
Buried horizontal round plate	Radius *a*, depth *s/2*	$R = \frac{\rho}{8a} + \frac{\rho}{4\pi s}\left(1 - \frac{7}{12}\frac{a^2}{s^2} + \frac{33}{40}\frac{a^4}{s^4} + \ldots\right)$
Buried vertical round plate	Radius *a*, depth *s/2*	$R = \frac{\rho}{8a} + \frac{\rho}{4\pi s}\left(1 - \frac{7}{24}\frac{a^2}{s^2} + \frac{99}{320}\frac{a^4}{s^4} + \ldots\right)$

Table 6.10-3 Value of K_{rod} for different assumptions about potential gradient around driven rod in half-plane of conducting soil

Researcher	Based On	K_{rod}
Liew and Darveniza 1974	Cylinder + Hemisphere Equation 6.10-11	0.003*
Dwight 1936	Table 6.10-1	0.38
Sunde 1949	Table 6.10-2 Average potential from constant current density	0.38
Chisholm 2001 using Oettle 1988	Equation 6.10-1	0.63
Rudenberg 1945, Sunde 1949	Ellipsoid of revolution Equation 6.10-5	0.69
Chisholm and Janischewskyj 1989	Deformed Hemisphere	1.00

*s = 3 m, r = 0.01 m

For a circular, solid *disc* of radius s, surface area $A = \pi s^2$ and $g = 1.414\,s$, Equation 6.10-1 gives:

$$R_{geometric} = \frac{\rho}{2\pi g}\ln\left(\frac{11.8\cdot 2s^2}{\pi s^2}\right) = \frac{\rho}{2\sqrt{2}\pi s}\ln(7.51) = \frac{0.226\rho}{s}$$

The "correct" theoretical derivation gives:

$$R_{geometric} = \frac{\rho}{4s} \qquad 6.10\text{-}4$$

Table 6.10-2 Footing Resistance Expressions from Sunde (1949)

Electrode	Dimensions	Equation
Single vertical rod	Length *L*, radius *a*	$R = \frac{\rho}{2\pi L}\left(\log_e\frac{4L}{a} - 1\right)$
Two vertical rods on circle of diameter *D*	Length *L*, radius *a*	$R = \frac{1}{2}\frac{\rho}{2\pi L}\left(\log_e\frac{4L}{a} - 1 + \frac{L}{D}\right)$
Three vertical rods on circle of diameter *D*	Length *L*, radius *a*	$R = \frac{1}{3}\frac{\rho}{2\pi L}\left(\log_e\frac{4L}{a} - 1 + \frac{2L}{D\sin\pi/3}\right)$
Four vertical rods on circle of diameter *D*	Length *L*, radius *a*	$R = \frac{1}{4}\frac{\rho}{2\pi L}\left(\log_e\frac{4L}{a} - 1 + \frac{2L}{D\sin\pi/4} + \frac{L}{D}\right)$
Six vertical rods on circle of diameter *D*	Length *L*, radius *a*	$R = \frac{1}{6}\frac{\rho}{2\pi L}\left(\log_e\frac{4L}{a} - 1 + \frac{2L}{D\sin\pi/6} + \frac{2L}{D\sin\pi/3} + \frac{L}{D}\right)$
n vertical rods on circle of diameter *D*	Length *L*, radius *a*	$R = \frac{1}{n}\frac{\rho}{2\pi L}\left(\log_e\frac{4L}{a} - 1 + \frac{2nL}{\pi D}\log_e\frac{2n}{\pi}\right)$
n rods in line, separation *s*	Length *L*, radius *a*	$R = \frac{1}{n}\left[\frac{\rho}{2\pi L}\left(\log_e\frac{4L}{a} - 1\right) + \frac{\rho}{\pi s}\left(\frac{1}{2} + \frac{1}{3} + \frac{1}{4} + \ldots + \frac{1}{n}\right)\right]$
Buried horizontal wire	Length *L*, radius *a*, depth *d*	$R = \frac{\rho}{\pi L}\left(\log_e\frac{2L}{\sqrt{2ad}} - 1\right)$
n buried horizontal radial wires	Length *L*, radius *a*	$R = \frac{\rho}{n\pi L}\left[\log_e\frac{2L}{a} - 1 + \sum_{m=1}^{n-1}\left(\log_e\frac{1+\sin(\pi m/n)}{\sin(\pi m/n)}\right)\right]$

The resistance of an *ellipsoid of revolution* with major semi-axis *s* and minor semi-axis *r* was derived by (Sunde 1949, Equation 3.12) as follows:

$$R_{geometric} = \frac{\rho}{4\pi s}\frac{\alpha+1}{\alpha-1}\ln(\alpha)$$
$$\alpha = \frac{\alpha_o}{2}\left[1+\sqrt{1-\frac{4}{\alpha_o^2}}\right] \qquad 6.10\text{-}5$$
$$\alpha_o = \left(\frac{2s}{r}\right)^2 - 2$$

For ellipsoids that are wider than they are long, α in Equation 6.10-5 becomes complex, and evaluation must use complex arithmetic. Figures 6.10-1 shows the overall effect of electrode shape. Figure 6.10-2 shows that the simple expression of Equation 6.10-1 is significantly closer to the Sunde derivation than either rod or disc expressions 6.10-3 or 6.10-4 for a wide range of electrode shapes that have roughly equal depth and radius.

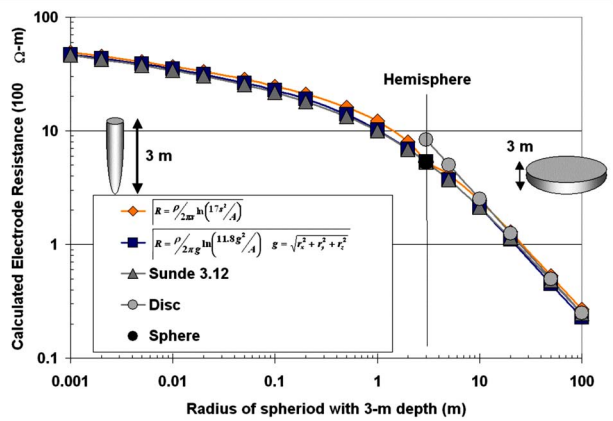

Figure 6.10-1 Comparison of expressions for resistance of rod, hemisphere, and disc electrodes.

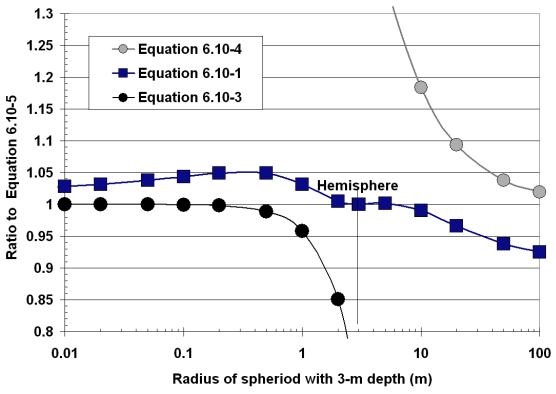

Figure 6.10-2 Ratio of expressions for geometric resistance to Sunde (Equation 6.10-5).

Correction from Solid to Wire-Frame Electrodes

The difference in resistance between solid electrodes and wire-frame approximations to the same shape is often small. This difference is called a "contact resistance." One estimate for contact resistance can be derived from the difference between the resistance of a circular ring of diameter *D,* wire diameter *d,* and burial depth *s/2*:

$$R = \frac{\rho}{2\pi^2 D}\left(\log_e\frac{8D}{d} + \log_e\frac{4D}{s}\right) \qquad 6.10\text{-}6$$

and the resistance of a circular plate of identical dimensions *D* and *s*:

$$R = \frac{\rho}{2D}\left(0.5 + \frac{D}{2\pi s}\right) \qquad 6.10\text{-}7$$

Figures 6.10-3 and 6.10-4 show the contact resistance for practical transmission tower ring and radial electrodes.

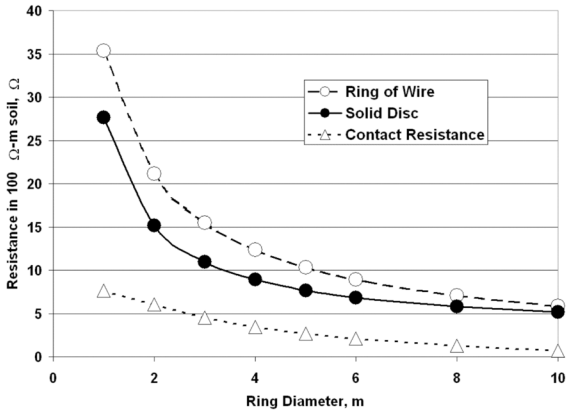

Figure 6.10-3 Contact resistance: Difference between ring and solid circular plate electrode resistances, buried at 1.5 m.

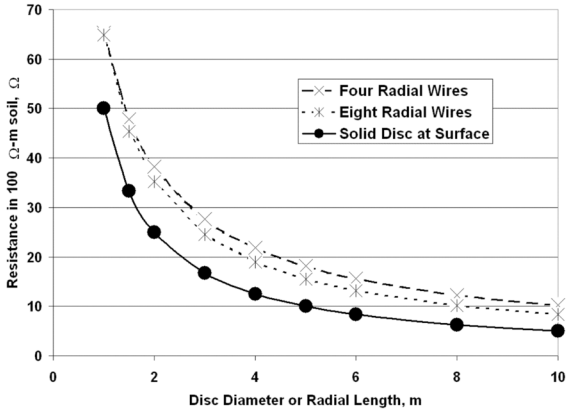

Figure 6.10-4 Contact resistance: Difference between radial wire and solid circular plate electrode resistance for shallow 0.5-m burial.

For buried grids of total length L, it is common to estimate the contact resistance using a simple expression:

$$R_{contact} \leq \frac{\rho}{L} \qquad 6.10\text{-}8$$

This upper bound is accurate for practical radial electrodes and too high for ring electrodes.

6.10.5 Earth Resistivity—Its Importance and Measurement

Soil resistivity has a direct influence on the potential rise from lightning flashes. Uncertainties in estimates of resistivity dominate our ability to compute transmission-line backflashover rates. Electrical resistivity ρ, with units of Ω-m, is a physical property of all materials that relates the electric field E (V/m) to the current density J (A/m^2) using $E = \rho J$.

The electrical resistivity of different materials at room temperature can vary by over 20 orders of magnitude. There are strong dependencies on temperature, moisture content, and frequency for many materials, including most soils and rock types. No single technique or instrument can measure resistivities over this wide range. This section focuses on techniques and instruments for practical measurement of soil resistivities and an assessment of the related experimental errors.

Since it is difficult to measure current density J in the soil, measurement techniques tend to use geometries that allow accurate calculation of current density as a function of source current I. This allows the use of an accurate four-terminal resistance meter, which accommodates a wide range of resistance in the excitation current source without affecting the high-impedance potential readings on inner terminals. A Wenner array, consisting of four, equally-spaced surface probes, is recommended for most work in uniform or layered soil. Figure 6.10-5 shows this configuration.

Equation 6.10-9 is used to convert the resistance measurements to resistivity at each probe spacing s, correcting for probe length l_w:

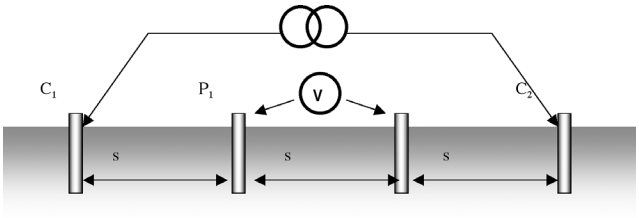

Figure 6.10-5 Wenner probe technique for measurement of resistivity.

$$\rho_a(s) = \frac{4\pi s \cdot R_{measured}}{1 + \frac{2s}{\sqrt{s^2 + 4l_w^2}} - \frac{s}{\sqrt{s^2 + l_w^2}}} \qquad 6.10\text{-}9$$

While it gives good accuracy, especially when used with a wide range of probe spacing 1 m < s < 200 m, the Wenner measurements are relatively slow to carry out and are more common in substation site selection and design. Transmission-line designers can review other sources of earth resistivity data in the design and site selection stage, and can also rely on airborne electromagnetic survey methods to establish design data for specific routes.

One important starting point for resistivity data is in the public domain. With every AM broadcast antenna, a "Proof of Performance" has been filed, consisting of measurements of radiated power as a function of distance from the antenna. This data can be used to estimate the earth resistivity over the path. If the earth resistivity is low, then the signal strength falls off uniformly with distance. For poorly conducting soil, the decay rate can increase to nearly 1/d^2. In the U.S., the Federal Communications Commission (FCC) has generated contour maps of conductivity σ (= 1/ρ) that give an approximation to the surface-layer resistivity and its variability. Applet G-2 can be used to explore the strong variation in resistivity across North America. The screen capture in Figure 6.10-6 shows resistivity of more than 1000 Ω-m in an area of Canadian Shield (granite). Resistivity of 100 Ω-m is reported for much of the central USA, with higher values in the Appalachian and Rocky mountain ranges.

6.10.6 Influence on Dielectric Strength of Soils

Certain soils contain more air pockets and are more prone to ionization effects as a consequence. This shows up as variations in the electric field gradient E_o, with values of 100-300 kV/m being low and 1000 kV/m being an upper limit. Oettle (Oettle 1988) studied the relationship of dielectric strength with resistivity, and reported a weak relationship that can be neglected. The median gradient of 300 kV/m was recommended by (Mousa 1994) after a literature review.

6.10.7 Vertical and Horizontal Layering

One method for estimating the effect of layering is to compare the very low frequency (VLF) (< 30 kHZ) and MF (1 MHz) conductivity maps for a region (see Figure 6.10-7). From the skin effect, the lower-frequency signals have deeper penetration, and the attenuation derived for those frequencies tend to represent a thicker layer than the 1-MHZ values.

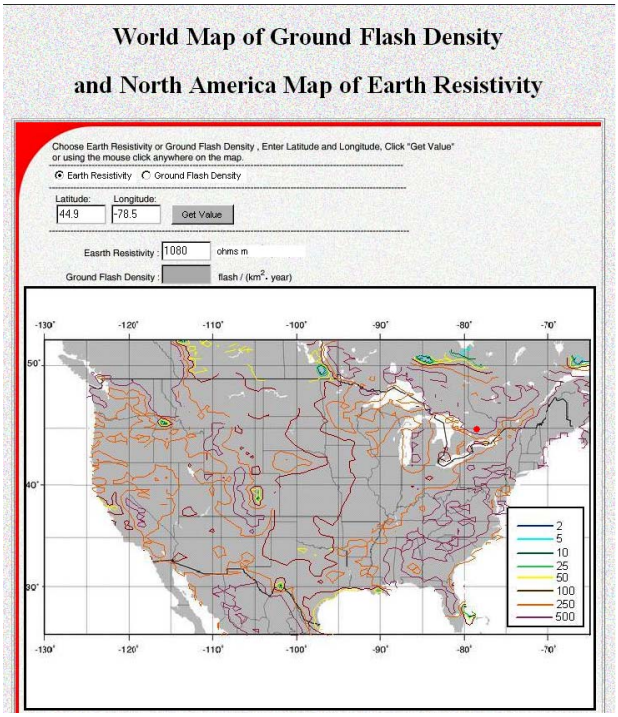

Figure 6.10-6 Screen capture from Applet G2. Estimates of resistivity based on the FCC records of AM broadcast can be obtained by clicking elsewhere on the map in Applet G2 or by entering the local latitude (a positive number) and longitude (a negative number) and clicking the "Get Value" button.

6.10.8 Measurement Techniques and Typical Results of Field Tests

The variation of surface layer depth and resistivity over horizontal distances of 300 m can be quite remarkable.

In cases where there is a pronounced change in soil resistivity with probe separation, the apparent resistivity $\rho_a(s)$ for the probe spacing s equal to the tower electrode diameter is a good approximation to the effective resistivity of the multi-layer earth. Alternately, the data can be interpolated with two-layer or multi-layer soil models, and the resulting values of upper-layer resistivity, depth, and lower-layer resistivity can be used along with an infinite series of reflection coefficients to compute an effective resistivity. Dawalibi (Dawalibi 1982, Chapter 4) provides guidance for this calculation process.

6.10.9 Capacitance, Electrolytic and Dielectric Effects

Bewley (Bewley 1963) observed a transient counterpoise capacitance of about 8 x 10^{-11} F/m. For a 50-m counterpoise, if soil conditions are such that the total leakage resistance is 20 ohms, this corresponds to a leakage resistance per meter of 1000 ohms. The RC time constant is 8 x 10^{-11} x 1000 = 8 x 10^{-8} s or 0.08 μs. This extremely small time constant indicates that resistance effects quickly swamp out capacitance effects during counterpoise current

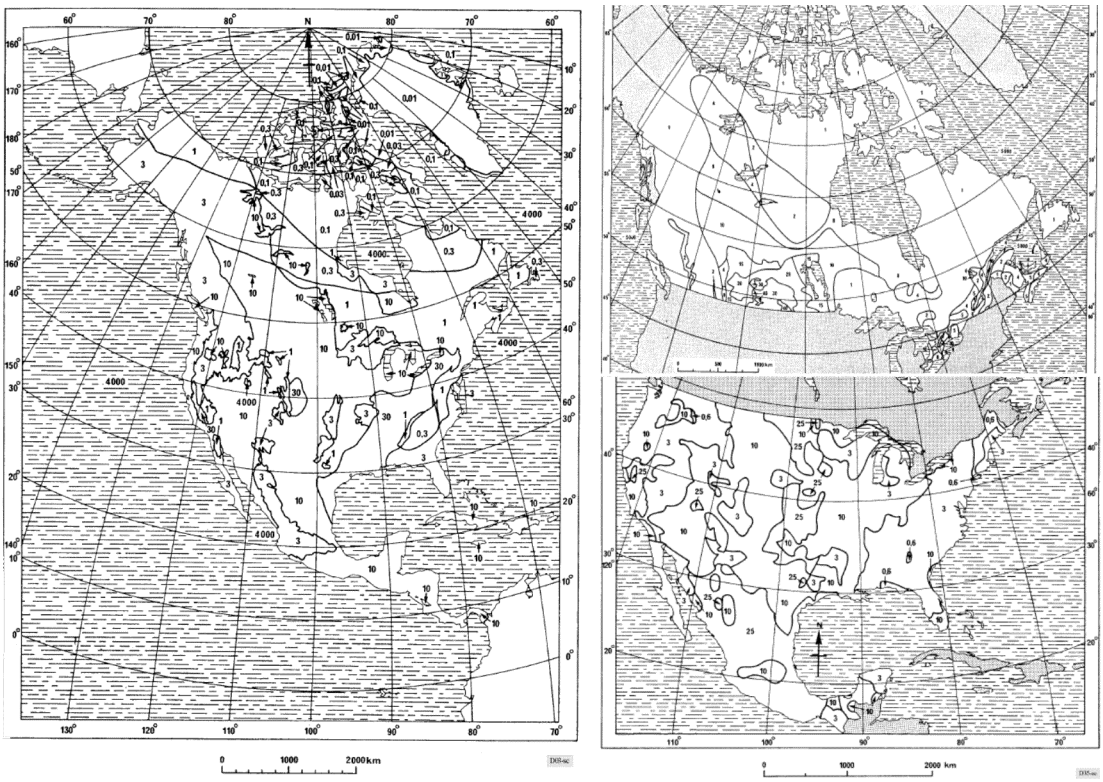

Figure 6.10-7 *Left*: ELF (deeper penetration) conductivity map. *Right*: MF (surface layer) conductivity maps for North America (CCIR 1982) (Reproduced with the kind permission of ITU).

propagation. A general measure of this is the "relaxation time" τ of the earth:

$$\tau = \varepsilon \times \rho \qquad 6.10\text{-}10$$

Where:

τ = earth relaxation time, s.
ε = earth permittivity, F/m.
ρ = earth resistivity, ohm-m.

A typical earth permittivity of 8 x 10^{-11} F/m and a resistivity of 300 ohm-meters yield a relaxation time of 2.4 x 10^{-8} s, or 0.024 μs. Hence resistance quickly dominates as a current wave propagates along the counterpoise.

6.10.10 Dynamics of Ground Resistance (Applets L-1 and L-3)

Applet L-1 (Transmission Line Lightning Performance) and Applet L-3 (Tower Dynamic Footing Resistance) are closely related. One of the mathematical difficulties that L-1 has to face is the nonlinearity of tower ground resistance at high stroke currents, brought about by the fact that earth is a poor dielectric. For large concrete foundations, surface areas are sufficient to maintain current densities at the surface of the concrete to values low enough to limit dielectric failures in the earth, but for ground rods and counterpoise wires, large currents have to flow from small surface areas, and the current density multiplied by the soil resistivity can create voltage gradients higher than the soil can endure. The resulting ionization appears as reduced resistivity of the soil (Oettle 1988). This effect can significantly reduce the voltage created at the base of a tower from what would be anticipated using the normal low-frequency resistance, and hence the lightning flashover rate.

6.10.11 Nonlinear Dynamics of Ground Rods

At high dielectric stresses, air spaces in many types of ground ionize and break down. This tends to increase the effective size of electrodes, in the same way that a corona envelope forms around overhead conductors. The limiting gradient in soils tends to be in the range of 100 to 1000 kV/m, compared to the recommended corona envelope in air of 1500 – 2000 kV/m used in Section 6.4.1. The increased radius of the corona envelope reduces the resistance of small or thin electrodes such as ground rods or counterpoise. The nature and the extent of this reduction in resistance are important research aspects into lightning response of small ground electrodes (EPRI 2002a; EPRI 2002b).

Figure 6.10-8 shows a typical test series, with increasing currents injected into a single ground rod. For 1-kA current, there is no effect, but as current increases to 7 kA, the impedance is halved late in the current wave.

For 1-kA current, there is no effect, but as current increases to 7 kA, the impedance is halved late in the current wave. The test levels of 7-34 kA are important, because there are typically two to four ground rods at each tower, each sharing a fraction of the impressed lightning current. Also, reflections from adjacent towers tend to shorten the tail of the impressed current, an effect that can be estimated using a ladder network of adjacent tower footing impedances connected by the overhead groundwire surge impedances.

An important nonlinear characteristic of multiple ground rods appears when they are all impulsed with the same voltage, as is usually the case. If the rods are asymmetrically located (for example, three rods in a row, so that the earth voltage coupling of the center rod to the other two is different from that of the outermost rods), the outer rods initially draw more current than the center rod. This, in turn, causes the outer rods to ionize sooner and their resistance drops more rapidly, causing them to draw still more current compared to the center rod. The situation is somewhat similar to an attempt to parallel several surge arresters when one has a different volt-ampere characteristic from another—the arrester with the lowest volt-ampere characteristic draws practically all the current.

6.10.12 The Liew-Darveniza Calculation of Rod Dynamic Resistances

In 1974, Liew and Darveniza (Liew and Darveniza 1974) published an important paper describing their development of theoretical models of the dynamic response of ground rods to high currents and comparisons with field tests.

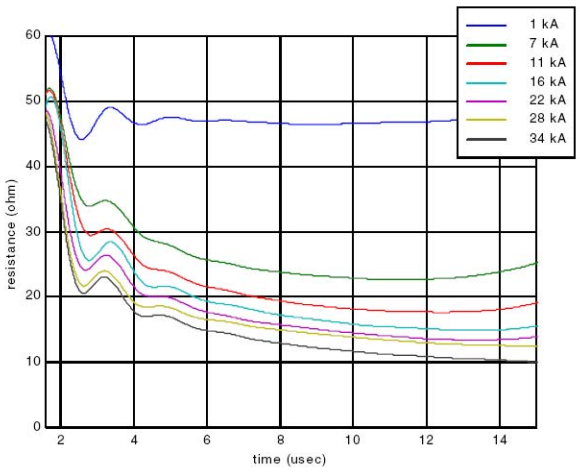

Figure 6.10-8 Resistance of 48-Ω driven rod for various impulse currents for 2.5 / 15 μs impulse current (typical of subsequent stroke).

Basically, they assumed each ground rod to be surrounded with a series of concentric shells (Figure 6.10-9).

Impulse current applied to the rod flows radially outward through each shell. Depending on the resistance of each shell and the current density, the soil in the shell starts ionizing and the shell resistance drops. Assuming uniform current flow out of the rod, the current density in each shell is easily calculated. If this current density is sufficient to create a shell gradient greater than E_0, where E_0 is the critical dielectric ionizing gradient of the soil, the shell resistance decays exponentially with time. When the surge current eventually decays, the gradient across one or more of the shells falls below E_0, and those shells start deionizing, their resistances increasing exponentially with time to their original low-current values.

Liew and Darveniza derived an equation for the sum of the nonionizing resistance of an infinite number of shells surrounding a single rod, and compared the result with the classical formula for the resistance of a single rod. The result was close to the theoretical value, demonstrating that the shell algorithm met the theoretical requirements. The resulting Liew-Darveniza equation for low-frequency resistance of a single rod is:

$$R = \frac{\rho}{2\pi L} \ln\left(\frac{r_0 + L}{r_0}\right) \qquad 6.10\text{-}11$$

Where:
R = rod low-frequency resistance, ohms.
ρ = earth resistivity, ohm-m.
L = rod length, m.
r_0 = rod radius, m.

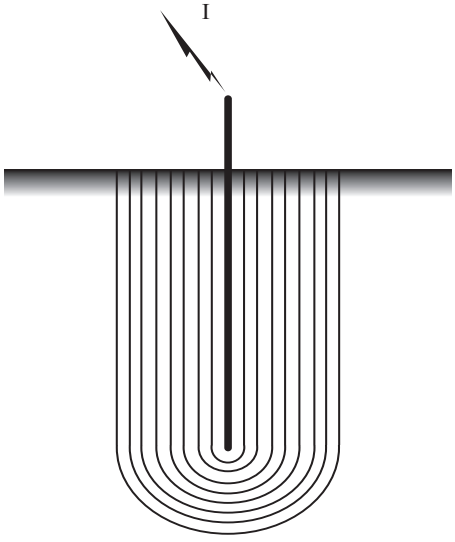

Figure 6.10-9 Liew-Darveniza ground rod surrounded by concentric shells of earth.

The relation between Equation 6.10-11 and other estimates of rod resistance was discussed previously in Table 6.10-3.

Shell ionization of any shell occurs when

$$J_C = \frac{E_0}{\rho_0} \qquad 6.10\text{-}12$$

Where:
J_C = critical current density, amperes/ m^2.
E_0 = earth critical ionizing gradient, volts/m.
ρ_0 = earth resistivity, ohm-m.

Ionization is marked by an exponential decay in resistivity:

$$\rho = \rho_0 \exp\frac{-t}{\tau_1} \qquad 6.10\text{-}13$$

Where:
ρ = shell resistivity during ionization, ohm-m.
ρ_0 = low current soil resistivity, ohm-m.
t = time in μs after start of ionization.
τ = a soil ionization time constant, μs (assumed 2.0 μs for many tests).

During the later deionization process of the shells, the deionization resistivity ρ of any shell increases exponentially, and Liew-Darveniza suggests the equation:

$$\rho = \rho_i + (\rho_0 - \rho_i)\left(1 - \exp\frac{-t}{\tau_2}\right)\left(1 - \frac{J}{J_C}\right)^2 \qquad 6.10\text{-}14$$

Where:
J = current density, ohm-m.
τ_2 = deionization time constant, μs.
ρ_i = value of resistivity when $J = J_C$ on current decay.
t = time measured from onset of deionization, μs.

Liew-Darveniza found reasonably good correlation between published ground rod volt-time data and their theoretical calculations using the concentric shells model, and the concentric shells model is used in all applets in this edition of the Red Book where analysis of ground rod response is required.

6.10.13 Use of the Korsuncev Criterial Curve

Korsuncev (Korsuncev 1958) carried out a dimensional analysis of the nonlinear behavior of ground electrodes of several different shapes, using what is known in North America as the Buckingham "Pi" method. Dimensionless ratios of relevant parameters in a complex problem are manipulated to give insight. Familiar dimension-less ratios used in thermodynamics are the Reynolds and Nusselt

numbers. Korsuncev recommended the following ratios Π_1 and Π_2:

$$\Pi_1 = \frac{s\,R}{\rho} \qquad \Pi_2 = \frac{\rho\,I}{E_o s^2} \qquad \text{6.10-15, a, b}$$

Where:

s = the characteristic distance from the center of the electrode to its outermost point.

ρ = the earth resistivity in the ionization zone near the electrode.

E_o = the critical breakdown gradient, typically 400 kV/m.

I = the instantaneous value of current, kA.

R = the footing resistance in Ω.

Chisholm and Janischewskyj (1989) consolidated observed relations between Π_1 and Π_2, as shown in Figure 6.10-10 for a variety of electrode shapes, ranging from hemisphere to thin rod. There are two separate regions of response. For low values of Π_2 at the left side of Figure 6.10-10, there is insufficient current to cause ionization, and the resulting resistance is independent of current. There is a unique value of Π_1 for each electrode shape, given closely by:

$$\Pi_1^o \approx \frac{1}{2\pi}\ln\left(\frac{2\pi\, e\, s^2}{A}\right) \approx \frac{1}{2\pi}\ln\left(\frac{2\pi e^{\sqrt{3}}\, g^2}{3A}\right) \qquad \text{6.10-16}$$

Π_1^o ranges from 0.159 for a hemisphere to about 1.26 for a 10-m long, 10-mm radius rod. The second expression is valid for smooth objects of revolution, using the dimension g as used by Oettle: $g = \sqrt{(r_x^2+r_y^2+r_z^2)}$.

The value of Π_1 to use in Equation 6.10-15a is the lesser of Π_1^o or an empirical expression relating Π_1 and Π_2 in the region of interest:

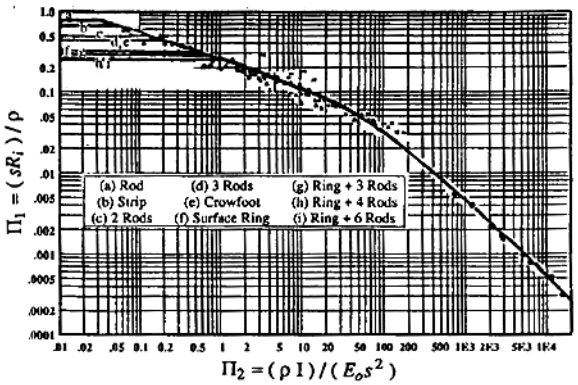

Figure 6.10-10 Observed relation between dimensionless parameters for ionized resistance of ground electrodes from Popolansky and Korsuncev.

$$\Pi_1 = \min\left(\Pi_1^o,\ 0.263 \cdot \Pi_2^{-0.308}\right) \qquad \text{6.10-17}$$

An EPRI study (EPRI 2002a) showed that the simple Korsuncev model provides good dynamic tracking of the voltage-current relationship for simple ground electrodes under lightning impulse conditions up to 40 kA. The shape of the ionized zone can be estimated from the resulting value of Π_1, knowing that the area A increases, but dimension s does not change if $\Pi_1 > 0.159$. For $\Pi_1 < 0.159$, the footing is fully ionized, the zone is hemispherical, and the zone radius can be calculated from the expression for the resistance of a hemisphere.

A step-by-step procedure using the Korsuncev relations to calculate dynamic resistance at high currents is as follows:

1. Calculate Π_2 for the required I current using Equation 6.10-15b.
2. Calculate Π_1 Equation 6.10-15a using g or s as appropriate.
3. Check that $\Pi_1 < \Pi_1^o$ from Equation 6.10-17 and then calculate the dynamic resistance using Equation 6.10-15.

6.10.14 Metal Tower and Reinforced Concrete Foundations

A basic calculation using the resistivity and relative permittivity of steel compared to copper shows that, at low currents, the surge impedance of a steel structure can be substantially higher than the impedance of an equivalent nonmagnetic structure.

$$L = \frac{1}{4\pi r}\sqrt{\frac{\mu_0}{\pi\sigma}}\,\frac{1}{\sqrt{f}} \qquad \text{6.10-18}$$

For copper:
Resistivity $\rho_{copper} = 1/\sigma_{copper} = 1.55 * 10^{-8}$ Ω-m.
Relative magnetic permeability = $\mu_r = 1$.

For reinforcing steel such as bare rebar:
Resistivity $\rho_{steel} = 1/\sigma_{steel} = 9*10^{-8}$ Ω-m at room temperature.
Relative magnetic permeability = μ_r = 100 to 1000 at low current.

$$\frac{L_{Steel}}{L_{Copper}} = \frac{\frac{1}{4\pi r}\sqrt{\frac{\mu_0\mu_{rs}}{\pi\sigma_s}}\,\frac{1}{\sqrt{f}}}{\frac{1}{4\pi r}\sqrt{\frac{\mu_0\mu_{rc}}{\pi\sigma_c}}\,\frac{1}{\sqrt{f}}} = \sqrt{\frac{\rho_{steel}\,\mu_{r\,steel}}{\rho_{copper}}} = 24-76 \qquad \text{6.10-19}$$

The capacitance per unit length of steel and copper wires would be equal, so the surge impedance of a pure steel wire would be five to nine times higher than the surge impedance

of a bare copper wire. However, several mitigating factors lead to lower inductance for steel wires:

- **Galvanizing.** Most steel wires are not exposed directly to the environment. The outer surfaces are galvanized with zinc or clad with aluminum or copper.
- **Saturation.** The current density is high in steel elements near the point of lightning attachment, and they tend to saturate. The current density at the surfaces is also elevated due to the skin effect, which tends to limit the cross-sectional area available to the lightning strike current by forcing the current to the perimeter of the member. This high current density saturates the steel near the surface of the conductor and significantly lowers the relative permeability. In the vicinity of the strike point, the relative permeability is much closer to that of free space (1.0) than it is to the maximum value of 1000 for unsaturated steel rebar at low currents. Since the permeability is much reduced, the inductive component is similarly reduced, reducing the surge impedance.
- **Corona**. As described in Section 6.4, the tower members are usually not sufficiently large to limit the electric field gradient to less than 1500 kV/m, so an impulse corona envelope forms, at least for small towers. This envelope increases the effective radius of the members and reduces their surge impedance.

For lightning strokes, the surge impedance of a structural rebar grid is found to be much lower than that of the conventional external copper or aluminum down-conductor system. In cases where the rebar is encased in concrete, the resulting electrode has a low inductance, and this makes the metal/concrete cross-section the preferred path for lightning surge currents.

In rocket-triggered natural lightning strike tests on instrumented reinforced concrete structures, (Schnetzer 1995) found that 75 to 90% of the strike current was carried by the steel rebar, and the remainder was carried by the external Lightning Protection System (LPS) down-conductors. This was true during the entire lightning waveform, even during the high *dI/dt* early-time phase, where the inductive component of the rebar would prevail. This clearly indicates that the surge impedance of the rebar grid is substantially lower than that of the LPS down-conductors during lightning strikes.

In an extreme example, the CN Tower is a 553-m reinforced-concrete structure with three 80-mm by 10-mm copper bars as an internal lightning protection system. Measurements by (McComb et al. 1980) with a current shunt in the lightning protection system and a Rogowski coil around the entire tower show that the copper carries less than 0.03% of the total current.

Generally, steel rebar in concrete foundations of transmission towers should be electrically continuous, and an external connection should be welded to the tower steel. The large surface area and relatively low resistivity of the concrete make the tower foundations preferred electrodes. Lightning will find its way into and out of the footings, with or without the bonds. A pre-engineered conductive path mitigates any concerns related to cracking or spalling.

The resistance of an individual concrete footing is formed by two terms: the contact resistance of the rebar length in the concrete, using a value of $\rho_{Concrete}$ = 70 to 250 Ωm in Equation 6.10-8, and the geometric resistance of the concrete electrode, given by Equation 6.10-1. Four concrete footings in parallel can be treated with the use of Applet L-6.

6.10.15 Radial and Continuous Counterpoise

An extensive compilation of low-frequency ground resistance formulas was published by Dwight (Dwight 1936) for rods, counterpoise, rings of wire, and buried strips and plates. His equations are reproduced in Table 6.10-1. Radial counterpoise, consisting of one or more horizontal buried wires, is similar in lightning response to one or more ground rods, the difference being that the proximity of the earth's surface to the horizontal wires increases the low frequency and dynamic resistance. For long wires (25 m or more), propagation times are also involved, so that—for very fast transients—the counterpoise impedance is initially governed by the combined surge impedances of all the wires (approximately 200 ohms per wire) and rings down or up exponentially to the final low-frequency resistance of all the wires in approximately three round-trip travel times. The addition of ionization brush discharges around the wires at high currents, particularly near the input end, further complicates the analysis.

Continuous counterpoise, wherein a buried conductor runs continuously from tower to tower, shows zero low-frequency footing resistance when conventional measurements are made. However, for high-frequency lightning transients, propagation times along the counterpoise render it ineffective for distances exceeding 60 to 90 m (Bewley 1963). Several radial wires of the same combined length have a much better transient response. The L-1 applet in this chapter assumes that a continuous counterpoise has the same high-frequency transient response as two radial wires, each with a length of 75 m.

6.10.16 Recommendations for Line Flashover Calculations

The strongest advantage of simple, empirical methods for calculating lightning flashover rate is that they can be applied efficiently to vectors of footing resistance data. For example, the FLASH program accepts a distribution of

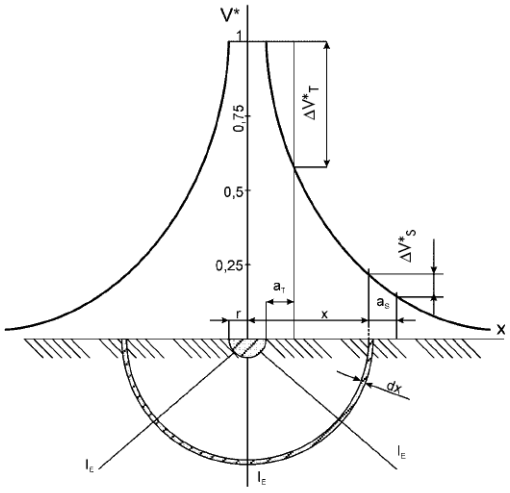
footing resistance values as a histogram, and computes a composite flashover rate by summing the contributions of each element. It is now feasible to assemble the footing resistance or resistivity data in a spreadsheet, and to calculate the outage rate span by span. If additional line parameters, such as structure heights and conductor spacing, are also available electronically, these values can also be included.

User experience with the FLASH program, in the calibration process based mainly on outage data reported by Whitehead (Whitehead 1983), showed that aggregation of footing resistance into 10 or more subsets gave significant improvement in the predicted transmission outage rates.

6.10.17 Step, Touch and Transferred Potentials

Ground resistance calculations normally assume that the earth is an infinite, uniform half-plane with a given value of resistivity. With these assumptions, it is possible to derive exact equations for the ground resistance of some important electrode shapes. These exact theoretical equations are used in this section to illustrate the relationships among voltage, current, and potential distribution along the earth surface, using the variables shown in Figure 6.10-11.

With uniform resistivity ρ, there is spherical symmetry, and the current flows radially away, uniformly in every direction. The surface of the hemisphere, as well as any hemispherical cross-sections *dx* of the ground centered at the hemisphere, is an equipotential, and the current lines are perpendicular to these surfaces.



The current density is highest at the surface of the electrode (thinking of an uninflated balloon) and becomes thinner as the distance *x* increases (as the balloon inflates). The total current (weight of the balloon) remains constant at any inflation level, so the current density is given by the current divided by the surface area of the hemisphere, $A = 2\pi x^2$.

Under these conditions the resistance of the hemispherical element of thickness *dx* and the radius *x*:

$$dR = \frac{\rho}{2\pi \cdot x^2} dx \qquad 6.10\text{-}20$$

The electrode resistance is the integral of dR from the hemisphere surface to infinity:

$$R = \frac{\rho}{2\pi} \int_r^{\infty} \frac{dx}{x^2} = \frac{\rho}{2\pi r} \qquad 6.10\text{-}21$$

r = Electrode radius.
x = Distance from the center of the electrode.
a_T = Touch distance (normally 1 m).
a_S = Step distance (normally 1 m).
ΔV_T = Touch Voltage from the electrode itself to a position near the electrode.
ΔV_S = Step Voltage between two points, both remote from the electrode.

Figure 6.10-11 Potential profile of hemispherical electrode in uniform soil, showing parameters for calculating ground resistance, step and touch potentials.

The potential of any point located at distance *x* from the center of the hemisphere electrode, in which an earth current I_E flows, is given by:

$$V_X = \frac{\rho I_E}{2\pi x} \qquad 6.10\text{-}22$$

The shape of the potential profile for hemisphere electrodes gives a benchmark for comparing profiles of other electrode shapes. Ring or mesh electrodes have potential profiles that fall off less rapidly than $1/x$, while vertical driven rods have a greater change in surface potential with distance.

The potential difference between the electrode ($x = r$) and a point on the earth surface, one at distance $x = r + \Delta x$, is given by:

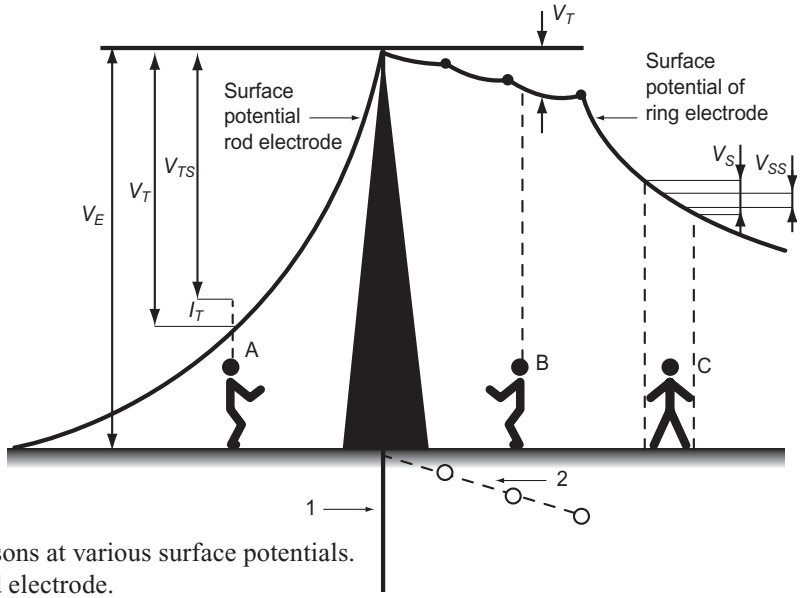
$$V_T = \frac{\rho I_E}{2\pi} \left(\frac{1}{r} - \frac{1}{r + \Delta x} \right) \qquad 6.10\text{-}23$$

In many electrical safety standards, such as IEEE Guide 80, Δx = 1 m, representing the reach of a 2-m (6 ft, 7-in.) person. A similar calculation can be carried out to determine the step potential V_S, existing between the feet of a person standing at a position x with foot separation Δx:

$$V_S = \frac{\rho I_E}{2\pi}\left(\frac{1}{x} - \frac{1}{x+\Delta x}\right) \qquad 6.10\text{-}24$$

where $x > r$.

Figure 6.10-12 shows a practical illustration of touch and step voltages. Persons at locations *A* and *B* are subject to the touch potentials V_T, while the person at C is subject to a step potential V_S.



The left side of Figure 6.10-12 shows the situation for a rod electrode, while the right side shows the potential profile of a ring electrode. The rod electrode (1) may have a low resistance, but it also has the steepest (most unfavorable) potential distribution. The ring electrode (2) has a much flatter earth potential profile. The touch potential for person *A*, near the rod electrode, is considerably larger for person *B*, near the meshed electrode. Step potentials for person *C* are higher near the edge of the ring, but not as high as the step potential at an equal distance away from the rod.

The electrode resistance determines the value of potential rise, and its configuration establishes how the potential rise distributes along the earth surface. The configuration also influences the grounding resistance, as described by the geometric resistance and effective resistivity. Adequate design needs to consider both resistance and configuration, usually in an iterative process.

A ring electrode has some important benefits for many grounding conditions. The ring is has large dimension *g* and area *A*, giving a lower resistance, and the ring shape has a lower surge impedance than a long vertical rod or horizontal counterpoise. Also, within the ring is an area of approximate equipotential, but at the edges of the electrode there is a strong potential gradient. The touch potential is limited, because practical rings extend beyond several meters beyond any metal structure, but high step voltages can still occur.

Risk of exposure to step voltage is much preferred to touch voltage, because several of the following mitigation factors are present:

- Higher body path impedance (and the two feet appear in series rather than in parallel).

A,B,C = Persons at various surface potentials.
1 = Rod electrode.
2 = Mesh (grid or radial / ring) electrode.
V_E = Potential rise of composite electrode relative to remote ground.
V_T, V_{TS} = Touch voltage (open circuit) and shocking touch voltage (into body impedance).
V_S, V_{SS} = Step voltage (open circuit) and shocking step voltage (into body impedance).
I_T = Shocking touch current (V_{TS} / (impedance of body path + two feet in parallel).
I_S = Shocking step current (V_{SS}/(Impedance of body path + two feet in series).

Figure 6.10-12 Comparison of surface potential distribution for rod and mesh electrodes.

- Lower fraction of heart current for leg-to-leg electrocution compared to arm-to-legs contact.
- High resistivity of many common surface layers, including grass, asphalt, and gravel.

There are other disadvantages to ring electrodes: it is not practical to bury them deeply, so they are more susceptible to changes in soil moisture content and more easily damaged or vandalized. Improved stability of resistance can be achieved by including a number of long vertical rods in the mesh.

6.10.18 Coordination With Safe Body Withstand Levels

The risk of electrocution increases with duration of exposure, as shown for two standard models in Figure 6.10-3. At typical transmission-line clearing times of 3 ac cycles (50 ms), the graph shows that Biegelmeier (Biegelmeier and Lee 1980) recommends a safe limit of 500 mA for all short-duration surges. The level calculated from the Dalziel electrocution equation (Dalziel and Lee 1968) will be 116 mA divided by the square root of time in seconds, giving 519 mA.

A body impedance of 1000 Ω is used at 60 Hz to convert electrocution current into tolerable step and touch potentials. Additional factors, such as the foot-to-surface contact resistance, are also described in the IEEE Guide 80 (IEEE 2000a). A wide range of bioelectric impedance measurements shows that this impedance is also reasonable at 50 kHz for a wide range of body shapes, including children and the elderly.

For particularly fast exposure, such as the 100-µs "monophasic" (one-sided pulse) lightning surge current, Figure 6.10-14 shows a factor of 30 increase in ventricular fibrillation current relative to the 500-mA level of Biegelmeier, shown as level (2). An impulse current of 15 A from hand to foot would require an impulse potential of about 15 kV.

6.10.19 Calculation of Surface Potentials Using L-6 Applet

One excellent tool for evaluating the touch and step potentials around typical transmission tower electrodes is the L-6 applet. Using a sophisticated three-point moment method, this tool allows efficient modeling of foundation components as large or small cylinders, horizontal buried wires or rings. A screen capture for the demonstration electrode, a tower with ring and radial wires, is shown in Figure 6.4-15.

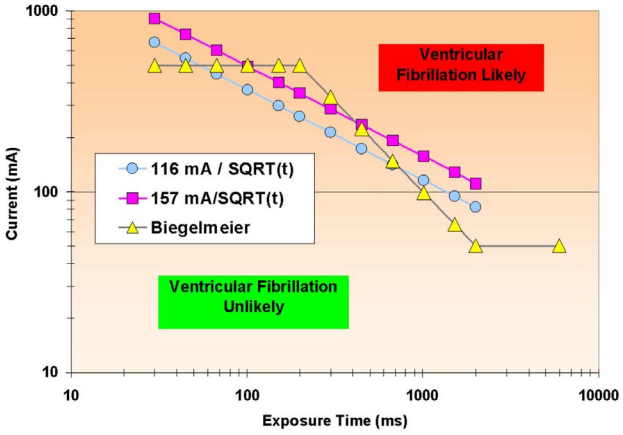


Figure 6.10-13 Comparison of IEC and IEEE Guide 80 Standards for electrocution current.

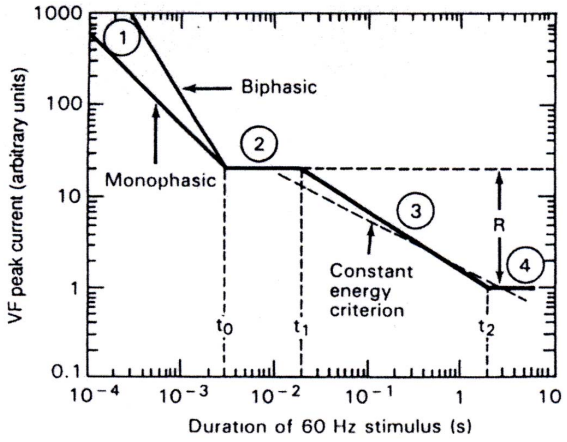

Figure 6.10-14 Ventricular fibrillation current versus duration of 60-Hz stimulus for wide range of exposure duration (Reilly 1998)

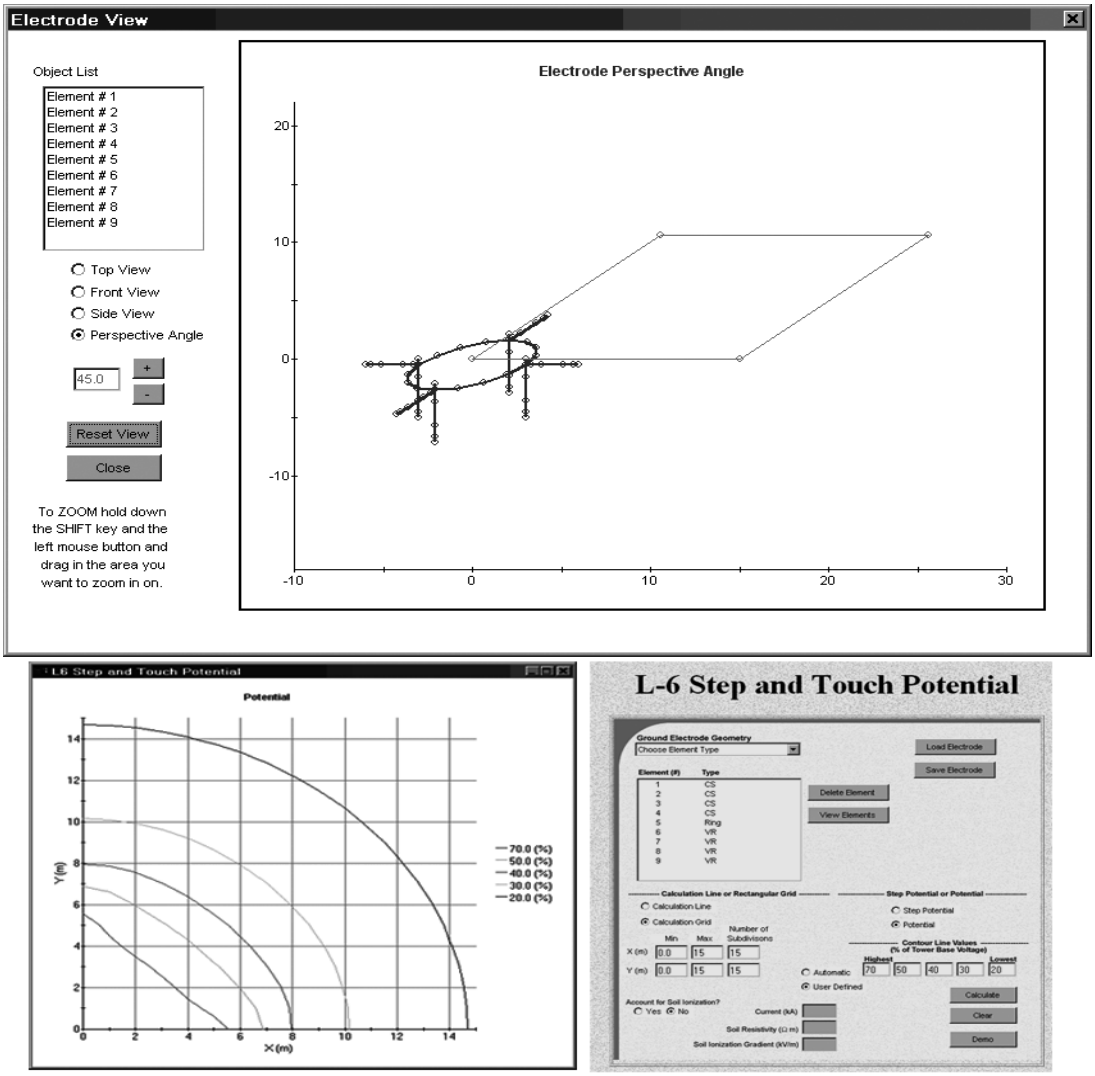

Figure 6.10-15 Screen Capture showing input geometry and calculation results for L-6 Applet.

APPENDIX 6.1 THEORY OF THE DISRUPTIVE EFFECT ALGORITHM

The disruptive effect algorithm was originally developed by Witzke and Bliss (1958) to evaluate impulse failures of transformers. In the quasi-uniform fields of power transformers, the formative time lag of a breakdown (the time required for a discharge to bridge a gap once it starts) is quite small compared to the statistical time lag which has to wait for the weak links (free electrons, ions, contaminating particles, etc.) to start the process, so the statistical time lag dominates the breakdown process and it becomes a matter of probability when the breakdown will begin. Once it begins, the formative time lag is practically instantaneous.

Disruptive Effect as a Probability Equation

In Figure A6.1-1, an impulse wave is simulated by a series of voltage impulses, each of a width t. Let the probability of withstand P_N of the gap for impulse *n* be approximated by:

$$P_N = \varepsilon^{-\alpha(V-V_0)\Delta t} \quad \text{A6.1-1}$$

Then the total probability of withstand of all the impulses is the product of all the individual probabilities and if this total probability is 0.5 for critical flashover, then:

$$0.5 = P_1.P_2.P_3 \ldots\ldots.P_N \quad \text{A6.1-2}$$

and substituting Equation A6.1-1 into Equation A6.1-2:

$$0.5 = \varepsilon^{-\varepsilon(V_1-V_0)\Delta t}.\varepsilon^{-\alpha(V_2-V_0)\Delta t}.....\varepsilon^{-\alpha(V_N-V_0)\Delta t} \quad \text{A6.1-3}$$

Taking the log of both sides of Equation A6.1-3:

$$-0.6931 = -\alpha\sum_{V_1}^{V_N}(V_K - V_0)\Delta t \quad \text{A6.1-4}$$

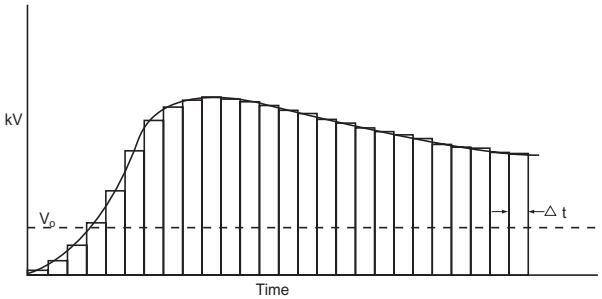

Figure A6.1-1 Voltage waveshape as contiguous impulses.

which in the limit becomes:

$$DE = \int_{V_1}(V(t) - V_0)dt \quad \text{A6.1-5}$$

Where:

$DE = 0.6931/\alpha$

Equation A6.1-5 is the "equal-area: criterion." A better fit to empirical data is often attained if $(V(t) - V_0)$ is raised to some exponent *n*.

Disruptive Effect as a Formative Time Lag Equation

The disruptive effect equation can also be viewed as a description of the flight of the breakdown streamer across a gap (a leader progression model). If the distance *x* that the streamer travels during a time *t* is given by:

$$\Delta x = \alpha(V(t) - V_0)^n \Delta t \quad \text{A6.1-6}$$

and then the gap is completely bridged when:

$$S = \sum_{t_0}^{t_S} \alpha(V(t) - V_0)^n \Delta t \quad \text{A6.1-7}$$

where *S* = gap length and t_S is the time to bridge the gap.

and once again in the limit:

$$DE = \int_{t_0}^{t_S}(V(t) - V_0)^n \Delta t \quad \text{A6.1-8}$$

where for this condition, $DE = S/\alpha$.

In Equation A6.1-8, α is a function of gap length, as is *DE*. *DE* does not vary so widely if gradient is used in the equations instead of voltage. The starting time t_0 in Equation A6.1-8 is the time at which the voltage just reaches the V_0 value. Values of *n* ranging from 1 to 4 have been proposed for the exponent.

Summary

The disruptive effect equation appears to simulate either a statistical time lag or a formative time lag (leader progression), and it seems reasonable to apply it for some combination of both. In practice it is easier to apply than a standard CIGRE leader progression model, and as long as the experimental parameters *n* and V_0 can be determined in advance, it should provide reasonably acceptable results for a variety of waveshapes.

APPENDIX 6.2 ELECTROMAGNETIC FIELDS FROM LIGHTNING

Source Strength

Electromagnetic radiation occurs whenever charge is accelerated. Current is the time derivative of charge flow, so a high rate of current rise *dI/dt* from lightning generates strong electromagnetic fields. An elegant model for this electromagnetic radiation (Uman et al. 1975) treats the lightning channel as a vertical transmission line of constant impedance in free space. Lightning is assumed to propagate upwards with a uniform return stroke velocity, often $v = c/3$, where c is the speed of light. With this model, the distant electric and magnetic fields, coupled by the 377-Ω impedance of free space, will be faithful copies of the return stroke current waveform, delayed in time and attenuating linearly with distance as follows:

$$H(D,t + D/c) = \frac{v}{2\pi cD} i(t) \qquad \text{A6.2-1}$$

Where:

$H(D,t+D/c)$ = the magnetic field (A/m).
$E(D,t+D/c)$ = 377 Ω x $H(D,t+D/c)$.
$i(t)$ = the lightning stroke current (A).
D = the distance from the flash to the receiver (m).
v = the return stroke velocity (m/s).
c = the velocity of light (3.0×10^8 m/s).
t = time (s).

At close range, Equation A6.2-1 has limitations, but still provides a good estimate of the peak incident energy for calculating induced overvoltages into horizontal conductors near ground. The average fields of 16 mA/m or 6 V/m at 100 km can be measured with good signal-to-noise ratio using wideband loop or plate antennas of dimension 0.1 to 1 m.

Measuring Lightning Locations

Wideband Gated Direction Finding (DF)

Several technologies have taken advantage of the strong source radiation for real-time detection of lightning ground flashes. The first gated, wideband receivers in commercial use (Krider et al. 1976) measured horizontal magnetic fields in north-south and east-west orientation, along with vertical electric field. Since the measured magnetic field is perpendicular to the direction from the source, its orientation can be used to determine a bearing towards the source. With two or more bearings, a source location can be placed on the surface of the earth. Peak magnetic field strengths were also reported. Networks with these LLP receivers were extended across the U.S. and operated until 1995, when a combined technology was implemented.

Site-to-site installation variations were significant limitations in the original networks. Nearby loop structures also introduced systematic site errors in bearing and amplitude. Continuous identification and elimination of these site errors led to satisfactory operation of extensive networks.

Wideband Time-of-Arrival Methods

The Global Positioning System (GPS) is a network of 24 Rockwell Navstar satellites. Each 900-kg satellite orbits the earth every 12 hours in a constellation that keeps every point on the planet in radio contact with at least four satellites. The first operational GPS satellite was launched in 1978, and the system reached full 24-satellite capability in 1993. Figure A6.2-1 shows the performance after "Selective Availability", a deliberate degradation of the signals, was discontinued.

The GPS achieves 5-m Standard Error Probable (SEP) or 3-m Circular Error Probable (CEP) through the use of time signals with 20-ns accuracy. Inexpensive GPS receivers can thus allow precise synchronization of waveform recorders for accurate location of remote electromagnetic transients, including power system faults and lightning strokes.

In a time-of-arrival (TOA) lightning location network, the time difference between two received signals establishes a hyperbola along which the lightning has occurred. With three received signals, it is usually possible to define a unique stroke location. An LPATS (Lightning Position And Tracking System) technology, using simple electric field antennas, operated with this approach until 1995. At that time, a combined technology, taking advantage of both DF and TOA data, was implemented (Cummins, Murphy et al. 1998).

Limitations of the TOA approach relate mainly to differences in the rate of signal attenuation at low and high frequencies, leading to an increase in signal rise time to peak with distance.

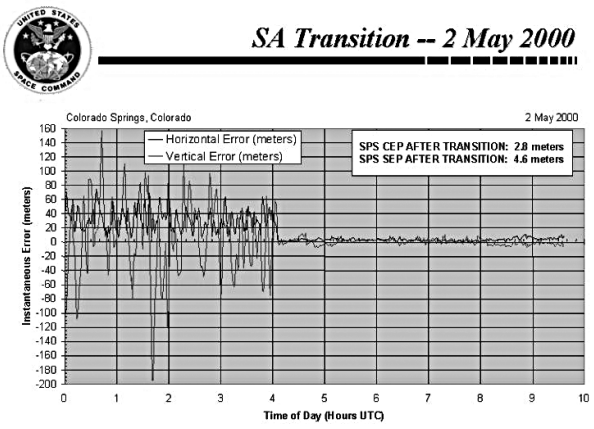

Figure A6.2-1 Reduction of GPS location error after removal of "Selective Availability" degradation on 2 May 2000.

Measuring Lightning Amplitudes

The principles for computing the effective radiated power from a vertical monopole antenna are well established (IEEE 1991). A measurement of signal power at a remote location can be inverted to give the source power. While the Sommerfeld-Norton approach is formulated for sinusoidal waves, it is relatively simple to implement the procedure using a Fourier transform of the lightning current impulse. This gives a lossy-earth correction that can be applied to the basic Equation A6.2-1 above.

Lightning is an impulse with a broad frequency spectrum, but peak features of interest have equivalent frequencies given by:

$$f_{equivalent} = \frac{dI/dt}{2\pi I} \qquad \text{A6.2-2}$$

For first strokes, 24 kA/μs and 31 kA give 120 kHz. For subsequent strokes, 40 kA/μs and 12 kA give 500 kHz. At frequencies below 5 MHz, the ground-wave propagation is most important. The following empirical process implements the ground-wave model in (IEEE 1991), supplemented by (Jordan and Balmain 1968) and (Volland 1968). The process is valid for distances:

- greater than five times the vertical height of the lightning channel
- less than 8000 km/(Hz)$^{1/3}$

Inputs:

ρ = soil resistivity (Ω-m)
ε_r = the relative permittivity of the earth
D = the path length (m)
f = the frequency (Hz)
λ = the free space wavelength = (3 x 10^8 m/s)/f (m)

$$x = \frac{1.8 \cdot 10^{10}}{\rho\, f}$$

$$b = \tan^{-1}\frac{\varepsilon_r + 1}{x} \text{ (Degrees)}$$

$$p = \frac{\pi D}{x\,\lambda}\cos(b)$$

$$A_0 = \frac{2 + 0.3p}{2 + p + 0.6p^2}$$

$$A_1 = 0.0143353\,b - 0.000143317\,b^2 + 5.94888 \cdot 10^{-7}\,b^3$$

$$n = 2.967 - 0.024719\ b + 0.00027614\ b^2 - 1.3469 \cdot 10^{-6}\,b^3$$

$$A_2 = \frac{37}{38 + \left|p - 2\right|^n}$$

$$\begin{cases} p < 1, & A_3 = p^{(0.252 - 0.00151b - 0.1 \cdot \log_{10} p)} \\ p \geq 1, & A_3 = 1 \end{cases}$$

$$A_{total} = A_0(1 - A_1 A_2 A_3)$$

$$F(p) = A_{total} \times \exp\left[j\pi \frac{(1.4 + p)\sqrt{p}}{2.5 + (1 + p)\sqrt{p}} \right]$$

The complex attenuation function *F(p)* is the difference in attenuation of the signal propagation over lossy ground, compared to that of a signal in free space. The function *F(p)* is multiplied by the Fourier transform of the lightning return stroke waveshape, and an inverse Fourier transform gives the distorted waveform. Table A6.2-1 shows the calculated loss of peak signal strength for a 1.2 x 50μs surge waveform.

Table A6.2-1 Signal Attenuation over 500-km Path for 1.2 μs x 50 μs Wave

ρ, Soil Resistivity	ε_r, Relative permittivity	Attenuation
0.2 Ω-m	81	0.999
100 Ω-m	81	0.990
100 Ω-m	10	0.992
1,000 Ω-m	5	0.912
1,000 Ω-m	10	0.911
1,000 Ω-m	20	0.909
10,000 -m	10	0.708

Generally, within the range of validity of the Sommerfeld-Norton approach and for most terrain, the attenuation of signal strength with distance introduces small 10% (or less) corrections into the field-source inversion process. At present, distance normalization to 100 km using an exponent of $D^{-1.12}$ rather than D^{-1} is used to provide attenuation correction for lightning location data in the continental U.S. and Canada (Cummins, Murphy et al. 1998).

Illumination of Nearby Power Lines

The strong electromagnetic field from lightning will induce voltages and currents in nearby horizontal conductors. The electromagnetic field coupling problem from a lightning flash near a conductor can be solved in three equivalent ways, using combinations of the electric and magnetic fields that illuminate the line. Near the lightning flash, these magnetic and electric source terms are not necessarily inter-related by the impedance of free space, 377 Ω. Rachidi (Rachidi 1993) showed the equivalence of these approaches, described generally in Table A6.2-2, and an excellent review of the entire induction process by Nucci and Rachidi is available in (Cooray 2003b, Chapter 8). These models predict that vertical lightning strokes terminating near, but not directly attaching to, overhead power lines and cables can still induce significant voltages and currents.

Table A6.2-2 Models for Traveling Waves on Horizontal Conductor under External Electromagnetic Field Illumination

Model	Basis	Wave Equation 1	Wave Equation 2
Taylor et al. 1965	Total Voltage V(x)	$\frac{dV(x)}{dx} + j\omega LI(x) = -j\omega \int_0^h B_y^i(x,z)dz$	$\frac{dI(x)}{dx} + j\omega CV(x) = -j\omega C \int_0^h E_z^i(x,z)dz$
Agrawal et al. 1980	Scattered Voltage $V_{Sxat}(x) = V(x) + \int_0^h E_z^i(x,z)dz$	$\frac{dV_{sxat}(x)}{dx} + j\omega LI(x) = E_x^i(x,h)$	$\frac{dI(x)}{dx} + j\omega CV_{scat}(x) = 0$
Rachidi 1993	Scattered Current $I_{Sxat}(x) = I(x) - \frac{1}{L}\int_0^h B_y^i(x,z)dz$	$\frac{dV(x)}{dx} + j\omega LI_{scat}(x) = 0$	$\frac{dI_{sxat}(x)}{dx} + j\omega CV(x) = \frac{1}{L}\int_0^h \frac{\partial B_x^i(x,z)}{\partial y}dz$
Rusck 1957	Total Voltage $V_1(x) + V_1(-x)$	See Equation 6.8-3	Assumes $E_x=0$ For perfect ground
Chowdhuri 1989	Total Voltage	$\frac{\partial^2 V(x)}{\partial x^2} - \frac{1}{c}\frac{\partial^2 V(x)}{\partial t^2} = -\frac{1}{c^2}\frac{\partial^2 V_i(x)}{\partial x^2} = F(x,t)$	Refer to Chowdhuri 1989 for V_i and $F(x,z)$

The model of (Agrawal et al. 1980) is formulated in terms of horizontal and vertical electric fields, coupled as source terms to a surge impedance description of a line over ground. The peak vertical electric fields can be obtained from distance-normalized signal strength. The peak horizontal electric field, which is small compared to the vertical field except over lossy ground, must be estimated using a wavetilt formula. This approach is most common in the electric power industry, particularly for evaluation of lightning performance of distribution lines. Generally, induced overvoltages from nearby lightning are roughly unipolar with narrow pulse width, corresponding to the stroke current rise time, and they do not often exceed 300 kV, except over poorly conducting earth (Borghetti et al. 2001). For special cases of tall objects near transmission lines, induced surges can be large, but they would also be bipolar with narrow pulse width corresponding to the height of the conductor above ground. The bipolar surges will not contribute much stress to insulator flashovers.

CHAPTER 7

Electric and Magnetic Fields

Luciano Zaffanella

This chapter presents engineering issues related to electric and magnetic fields produced by high-voltage transmission lines and to their effects. Methods of calculations and measurements are described. Evaluations of currents, voltages, and energies induced on objects and assessments of their effects are discussed. While the emphasis in previous editions was on electric field, magnetic field is also covered in detail in this edition. Methods of field reductions are illustrated and the analytical tools for their design are provided.

Dr. Luciano E. Zaffanella is one of the original authors of the *EPRI Transmission Line Reference Book*. When the first and second editions were published, he was directing General Electric's staff that was operating Project UHV on behalf of EPRI. Under his direction this project became a High Voltage Transmission Research Center, an internationally renowned facility for the study of overhead high voltage transmission lines with HVAC voltages up to 1500 kV three-phase, and HVDC voltages of + and – 1200 kV, including their environmental impact. He pioneered engineering studies of electric and magnetic fields, the development of low magnetic field lines, and methods of field reduction of existing lines. Prior to joining project UHV, he was the Head of the Research Section of the High Voltage Department of CESI, in Milan, Italy. He is currently Vice President of Research of Enertech, a company well known for its EMF expertise.

7.1 INTRODUCTION

Overhead transmission lines generate electric and magnetic fields at power frequency. These fields play an important role in transmission-line design and operation. This chapter presents practical methods for calculating and measuring electric and magnetic fields, discusses the effects of these fields, and presents the criteria by which the fields are to be evaluated.

The previous edition of this book, written at a time when there was a rapid increase in the use of higher voltage lines and there was a prospect of transmission lines with voltages above 1000 kV, emphasized electric fields. Electric fields are still to be considered in many aspects of line design and operation. They are important in terms of induction on vehicles and other conductive objects, shocks caused by spark discharges, interference with pacemakers, and pole fires. Some jurisdictions have electric field limits, so an electric field analysis is required to obtain permits for construction of new lines or upgrading of existing lines. This is true for all voltage levels considered in this book. At 230 kV, electric fields are of marginal interest, but must still be addressed in a permit application.

The emphasis today has shifted to magnetic fields. Magnetic field induction in parallel wires is one aspect. Interference with the proper operation of computer monitors is another. However, the major focus of attention is on the level of magnetic fields outside the right-of-way where long-term exposure of people to magnetic field and its possible health effects is of concern. Concern for health effects from exposure to power frequency electric and magnetic fields surfaced in the 1960s with the introduction of Extra High Voltage (EHV) transmission systems (Kowenhoven et al. 1967). These concerns were highlighted by a 1972 report of Russian workers becoming ill as they worked in high-voltage substations (Korobkova et al. 1972). Later in the decade, a report was published detailing an epidemiological study correlating a surrogate for 60-Hz magnetic fields with childhood leukemia (Wertheimer and Leeper 1979). This report triggered a massive research effort to find answers to the question: "Can power frequency magnetic fields of the type generated by transmission lines have an adverse effect on people's health?" Some jurisdictions have introduced magnetic field limits for transmission lines, so transmission-line magnetic fields must be analyzed in order to obtain permits for new lines or for uprating of existing lines. Magnetic field depends on the line current and remains a significant issue even when the voltage is 220 kV or lower.

The efforts to determine whether there are health effects associated with electric and magnetic fields have generated an abundant literature but are not discussed in this book, which is about engineering issues. At the time this reference book is being written, health effects due to long-term exposure to electric fields are generally considered irrelevant, but long-term exposure to magnetic fields is still a subject of investigations (NIEHS 1998; NRPB 2001).

As a result of the emphasis on magnetic fields, there have been significant advancements in the development of instrumentation for measuring these fields, advanced methods of calculations, and techniques for reducing magnetic fields. This chapter presents the different practical options that are available for reducing electric and magnetic fields. Because construction of new lines or modification to existing lines is subject to review in the regulatory process and to intense public scrutiny, the transmission-line design process often includes efforts to minimize electric and magnetic fields compatibly with safety and reliability.

Electric and magnetic fields and several related quantities can be calculated using simple software applications provided in the electronic version of this book. The user may exercise the following applets:

- EMF-1: "Field Ellipse." This applet calculates the maximum and minimum axes of the field ellipse given the orthogonal field components.
- EMF-2: "Transmission Line Electric Field (2-D)." This applet may be used to calculate the electric field and the space potential at any desired location near a transmission line and also to draw contour lines to separate regions with different electric fields or space potentials. This applet considers two-dimensional line geometry.
- EMF-3: "Single Conductor Equivalent to a Bundle." This applet may be used to calculate the diameter of the single conductor that has the same capacitance to ground as a bundle with a given geometry.
- EMF-4: "Transmission Line Electric Field (3-D)." This applet may be used for three-dimensional geometry. Applet EMF-4 also considers objects with various shapes at ground potential and may be used to assess the shielding effect of these objects.
- EMF-5: "Electric Field Shielding by Grid." This applet may be used to calculate the electric field reduction that is obtained with either vertical or horizontal grids of grounded wires.
- EMF-6: "Transmission Line Magnetic Field (2-D)." The user may exercise this applet to calculate the magnetic field at any desired location near a transmission line and also to draw contour lines to separate regions with different magnetic fields. This applet considers two-dimensional line geometry.
- EMF-7: "Transmission Line Magnetic Field (3-D)." This applet may be used for the calculation of magnetic

fields with three-dimensional geometry. In fact, the user may consider any combination of straight cylindrical segments, catenaries, busses, and coils.

- EMF-8: "Induction in Parallel Wires." This applet may be used to calculate the current induced in shield wires grounded at every tower, or the currents and voltages induced in shield wire sectionalized, transposed, and grounded at given intervals, or the voltage induced in long wires grounded at one end and isolated from ground at the other end.
- EMF-9: "Distant Field Equations for Parallel Lines." This applet may be used to find the equations giving the distant magnetic field from any set of infinitely long conductors with known current and position in space.
- EMF-10: "Electric Field Induction In Objects." This applet may be used to calculate the short-circuit current of objects to ground induced by the electric field produced by high-voltage conductors.
- EMF-11: "Magnetic Field Reduction Using Cancellation Loops." This applet may be used to design cancellation loops for the purpose of reducing magnetic field of transmission lines. The geometry of the line and of the loop are described in three dimensions. The results of the calculations include the current in the cancellation loop wires, and the magnetic field before and after the introduction of the loops.
- EMF-12: "Magnetic Field Reduction with Fourth Wire Scheme." This applet calculates the magnetic field reduction resulting from a special line design, called the "fourth wire scheme" (see Section 7.17.7).

7.2 BASIC ELECTRIC AND MAGNETIC FIELD PRINCIPLES

7.2.1 EMF: Electric and Magnetic Fields

Electric and magnetic fields (EMF) are generated by electrical charges and by their movement (electric currents).

The term *electromagnetic fields* refers to electric and magnetic fields that are coupled, as in high-frequency radiating fields. When the rate of change (frequency) of these fields is sufficiently low, as for power system fields, EMF can be separated into electric (related to voltages) and magnetic (related to currents) fields. In this case, the word EMF should be understood as meaning *Electric and Magnetic Fields*, as opposed to *Electromagnetic Fields*.

There is a spectrum of frequencies of electromagnetic fields. The product of frequency and wavelength of an electromagnetic wave equals the speed of propagation of the wave, which, in free space, is equal to the speed of light: $c \approx 3 \times 10^8$ m/s. The wavelength associated with 60 Hz is 5000 km and that associated with 50 Hz is 6000 km. By comparison, the wavelength of FM broadcast transmission at 100 MHz is 3 m. When the distance to the source is large compared to the wavelength, electric and magnetic fields are linked and considering them together is justified. In this case, the electric field, E (V/m), and the magnetic field strength, H (A/m), are related to each other through the intrinsic impedance, η, of the medium where the electromagnetic wave travels at a speed, v. This is called the "far field" or radiation field.

$$E = \eta H \quad \eta = \sqrt{\frac{\mu}{\varepsilon}} \quad v = \frac{1}{\sqrt{\mu\varepsilon}} \qquad 7.2\text{-}1$$

In free space, $\mu = 4\pi 10^{-7}$ H/m.
$\varepsilon \approx 8.85 \times 10^{-12}$ F/m.
$\eta \approx 377\ \Omega$.

However, when the distance from the source is small, such as in the case of electric and magnetic fields near power transmission lines, the fields are independent and should be considered separately as electric and magnetic fields, not as electromagnetic fields. These near fields form the "quasistatic" region, where the time variation of the fields is sufficiently slow that static formulas can be applied for many purposes. Effects related to coupled voltages and currents predominate in the quasistatic region. The radiation field is negligible in the quasistatic region.

The electromagnetic spectrum has been divided into several portions. Most of the electric and magnetic fields associated with the power system are within the "extremely low frequency" (ELF) band, which goes from 3 Hz to 3 kHz. This range encompasses both the fundamental frequency and its measurable harmonics.

Ionizing and Nonionizing Fields

This chapter discusses fields that are sufficiently low in magnitude and in frequency not to cause ionization. Power system electric and magnetic fields belong to the nonionizing portion of the electromagnetic spectrum. Fields are ionizing when they are capable of ejecting electrons from their orbits around a normal atom. Electromagnetic fields capable of producing ionization have frequencies that fall between 10^{16} and 10^{22} Hz. These include ultraviolet light, X rays, and gamma rays. Electromagnetic fields at frequencies below 10^{16} Hz are nonionizing, but may be capable of producing energy in the form of heat.

AC and DC Electric and Magnetic Fields

Power frequency ac electric and magnetic fields are also quite different both in nature and in their effects from dc electric and magnetic fields, like those occurring in natural ambient conditions or near HVDC power transmission lines. The main difference consists in the ability of ac fields to induce currents, the ac electric field through capacitive coupling and the ac magnetic field through inductive coupling. On the other hand, dc electric fields have other

effects, such as the ability to affect the trajectory of air ions and to affect the deposition of charged particles on surfaces, phenomena that have little significance for ac electric fields. The dc magnetic field of the earth has a nearly constant intensity and direction at any given location. Its intensity and direction are primarily a function of the latitude. Its intensity is generally much greater than the maximum instantaneous value of the ac magnetic field generated by transmission lines at points accessible by the general public, but the two fields cannot be compared on the basis of their magnitude alone because ac fields can induce currents in circuits and conductive bodies, whereas dc fields cannot (unless a conductive body is moving).

7.2.2 Phasors and Vectors

Electric and magnetic fields near transmission lines are described using phasors and vectors. A vector is characterized by a magnitude and an angle in space, whereas a phasor is a quantity with a sinusoidal time variation described by a magnitude and a phase angle. The three orthogonal components of a vector may be phasors with different magnitudes and phase angles. In this chapter, a vector is indicated with an arrow ($\vec{E}, \vec{B}$) and a phasor with a wave sign ($\tilde{E}, \tilde{B}$) or with a sinusoidal function of time.

7.2.3 Electric Field

Definition

The magnitude and direction of the force exerted on a stationary electrical charge define an *electric field*. The electric field is a vector. If a unit electric charge, one coulomb, is in a unit electric field, one volt per meter, it will be subjected to a unit force, one newton, in the direction of the field.

A more intuitive visualization of an electric field is obtained by considering two parallel conductive plates separated by an insulating medium, such as air. If a voltage is applied between the two plates, an electric field will be created between them, directed from one plate to the other. If the plates are sufficiently large with respect to their separation, *S*, the electric field is uniform and its magnitude is equal to $E = V/S$.

The unit of measurement of the electric field is the volt per meter (V/m).

The electric field is defined by its space components along three orthogonal axes. Each space component is a function of time.

$$\vec{e}(t) = e_x(t) \cdot \vec{u}_x + e_y(t) \cdot \vec{u}_y + e_z(t) \cdot \vec{u}_z \qquad 7.2\text{-}2$$

$\vec{u}_x$, $\vec{u}_y$, $\vec{u}_z$ are the unit vectors in the directions of the *x, y,* and *z* axes, respectively. $e_x(t)$, $e_y(t)$, and $e_z(t)$ are periodic functions of time, and each can be expressed as the sum of sinusoidal electric fields at the power frequency and its harmonics. Transmission-line electric fields have very little harmonic content because voltages are usually close to sinusoidal. For instance, the amplitude of the component along the *x* axis may be written:

$$e_x(t) = \sqrt{2} E_x \sin(\omega t + \alpha_x) \qquad 7.2\text{-}3$$

E_x is the rms (root-mean-square) value, $\sqrt{2}E_x$ is the maximum amplitude, and α_x is the phase angle of the electric field component along the *x* axis, and $\omega = 2\pi f$, with *f* being the frequency. Similar expressions can be written for the other two axes.

Electric Field Ellipse

In an electric field created by a three-phase system, the vector $\vec{e}$ changes in magnitude and direction with time. If the field is represented by an arrow anchored at a point, the tip of the arrow describes an ellipse, the "electric field ellipse."

The field ellipse (see Figure 7.2-1) can be characterized by its major and minor axes. When the axes are equal in magnitude, the ellipse becomes a circle, the field is constant in magnitude, but its direction varies with time. On the other hand, when the minor axis becomes very small with respect to the major axis, the ellipse becomes very narrow, until it eventually collapses into an oscillating vector. In this case, the field is represented by a vector with constant direction, but with a magnitude that varies with time.

When the field vector has a constant direction in space, the field is "linearly polarized." This occurs, for instance, on the surface of the transmission-line conductors, on the surface of conductive objects, and at or near a conductive ground.

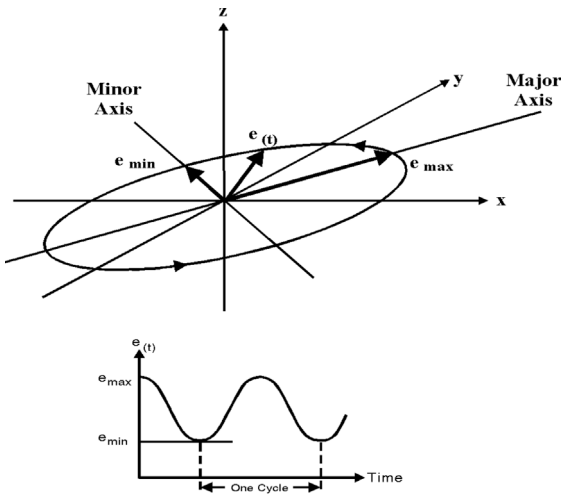

Figure 7.2-1 Electric field ellipse and variation of electric field with time.

If the field vector describes an ellipse, the field is "elliptically polarized." Away from the surface of conductive objects, a system of 50- or 60-Hz voltages not in phase with each other, such as three-phase transmission lines, will, in general, generate elliptically polarized fields. The degree of polarization is defined by the axial ratio. The axial ratio can range from zero to one. When the axial ratio is equal to zero, the field is linearly polarized. When the axial ratio is equal to one, the field is "circularly polarized."

$$\text{Degree of polarization} = \text{axial ratio} = e_{min}/e_{max} \qquad 7.2\text{-}4$$

RMS Value

The rms (root-mean-square) value of the electric field is used to characterize the intensity of the field, despite its possibly complicated variations in space and time. This is the quantity used to characterize the electric field, unless otherwise specified. In mathematical terms, the rms value can be derived from the function expressing the amplitude of the electric field vector versus time as follows:

$$E_{rms} = \sqrt{\frac{1}{T}\int \left[e(t)\right]^2 dt} \qquad 7.2\text{-}5$$

The variable t is the time; the integration must be performed for the duration of one period, T, of the time function (e.g., 1/60 s for a 60-Hz field). The rms value of the field has a simple relationship with the rms values of the three orthogonal space components:

$$E_{rms} = \sqrt{E_x^2 + E_y^2 + E_z^2} \qquad 7.2\text{-}6$$

The above equation is valid no matter what the periodic time functions are—i.e., it is valid also if the field contains harmonics of the power frequency. If the field is purely sinusoidal, the rms value is related to the minimum and maximum axes of the field ellipse by Equation 7.2-7.

$$E_{rms} = \sqrt{E_{\max}^2 + E_{\min}^2} \qquad 7.2\text{-}7$$

E_{max} and E_{min} are the rms values of the components of the electric field measured in the directions of the major and the minor axis of the field ellipse, respectively. The minimum and maximum axes of the field ellipse can be calculated from the three orthogonal components as shown in Appendix 7.1.

Spatial Characteristics of the Electric Field

The electric field is perpendicular to the surface of conductive bodies. In particular, it is perpendicular to the surface of the ground. When the ground is flat and without disturbing objects, the electric field caused by a distant source (high-voltage equipment, high-voltage conductors) is vertical and relatively uniform. In general, however, the electric field is rather nonuniform. This is especially true near conductive objects like the human body. The electric field is greatly perturbed by the presence of the body.

The effects of the electric field, such as induced currents and voltages on objects, are often expressed in terms of the *unperturbed field*, which is the field at the location of the object if the object were not there to perturb it. Because conductive objects perturb the field, special techniques are needed for electric field measurements (see Section 7.5).

Temporal Stability of Electric Fields

Electric field magnitudes have practically no variations in time. This reflects the fact that voltages are usually constant, even when the electrical loads are variable. Electric fields away from high-voltage conductors are affected very little by corona. The space charge generated by a conductor in foul weather, when the conductor is in corona, affects its equivalent capacitance, but the effect is small, particularly for a bundle of two or more subconductors.

Harmonic Content of Electric Fields

Power system voltages and electric fields have little harmonic content. Electric fields near transmission lines generally have a total harmonic distortion less than 1%. The largest harmonic is generally the 5th.

Electric Field Transients

Voltage surges in overhead transmission lines cause electric field transients characterized by a large rate of change of the electric field, *dE/dt*. Electric field transients occur also in nature, due to lightning.

Space Potential

An electric field region can be characterized not only by the electric field but also by the potential of each point, which is the voltage between the point and a reference, usually the electrical ground whose potential is taken equal to zero. The space potential is a phasor. Space potentials at the power frequency are characterized by an rms value and a phase angle. The following relation exists between electric field and space potential:

$$\vec{E} = -\nabla \tilde{V}_{sp} \qquad 7.2\text{-}8$$

The electric field is equal to the gradient of the space potential. For example, the component, $\tilde{E}_x$, of the vector electric field in the x direction is equal to the partial derivative of the space potential in that direction.

$$\tilde{E}_x\vec{u}_x = -\frac{d\tilde{V}_{sp}}{dx}\vec{u}_x$$
$$\tilde{E}_y\vec{u}_y = -\frac{d\tilde{V}_{sp}}{dy}\vec{u}_y \qquad 7.2\text{-}9$$
$$\tilde{E}_z\vec{u}_z = -\frac{d\tilde{V}_{sp}}{dz}\vec{u}_z$$

$\vec{u}_x$, $\vec{u}_y$, and $\vec{u}_z$ are the unit vectors in the directions of the *x, y,* and *z* axes, respectively. The voltage difference between two points is the difference in space potential between the two points and can be obtained by integrating the electric field along any line connecting the two points:

$$\tilde{V}_{AB} = \tilde{V}_{sp,A} - \tilde{V}_{sp,B} = \int_A^B -\vec{E}\cdot d\vec{l} \qquad 7.2\text{-}10$$

Coulomb's Law - Electric Flux Density - Surface Charge

Electric fields are caused by electric charges. *Coulomb's law* states that the electric field created by a charge, $\tilde{Q}$, at a distance, *R*, is given by:

$$\tilde{E} = \frac{\tilde{D}}{\varepsilon} = \frac{\tilde{Q}}{4\pi\varepsilon R^2} \qquad 7.2\text{-}11$$

$\tilde{D}$ is the magnitude of the electric flux density vector, $\vec{D}$. The total flux exiting a volume is equal to the sum of all the charges inside that volume (Gauss' law). The flux emanating from a point charge is uniformly distributed over the surface of a sphere centered on that charge, hence Equation 7.2-11. ε is the dielectric constant of the medium. For air, $\varepsilon = 8.854\cdot10^{-12}$ (F/m).

The electric flux through a surface is equal to the integral of the component of $\vec{D}$ normal to the surface. When the surface is that of a conductive object, the electric flux density vector is perpendicular to the surface and its magnitude, $\tilde{D}$, is equal to the charge density, $\tilde{q}$ (C/m²), which is equal to the ratio between the charge, $\tilde{Q}$, and the area, *A*, over which the charge is distributed. Thus, the electric field on the surface of conductive object is related to the surface charge density by Equation 7.2-12:

$$\tilde{q} = \tilde{Q}/A = \tilde{D} = \varepsilon\tilde{E} \qquad 7.2\text{-}12$$

Line Charge

The charge on a transmission-line conductor may often be considered uniformly distributed over the length of a line section. The geometry may be considered two-dimensional. The charge per unit of length is expressed using the unit of coulomb/meter. Although the charge is distributed on the surface of the conductor, for the purpose of calculating the electric field outside the conductor, the charge is often treated as a "line charge" located at the center, as if the conductor consisted of a line with zero dimensions. The electric flux emanating from a line charge is distributed over a cylindrical surface. The electric flux density and the electric field at a distance, *R*, from the line conductor are vectors directed away from the line charge and with magnitudes given by:

$$\tilde{E} = \frac{\tilde{D}}{\varepsilon} = \frac{\tilde{Q}}{2\pi\varepsilon R} \qquad 7.2\text{-}13$$

Potential Coefficients

The calculation of electric fields is relatively straightforward when the charge values and locations are known. Equation 7.2-11 is used for point charges and Equation 7.2-13 for line charges. In practice, however, the voltages rather than the charges are known. The voltage, $\tilde{V}_i$, on an object (*i*) is related to the charge, $\tilde{Q}_j$, on another object (*j*) through the potential coefficient, P_{ij}:

$$\tilde{V}_i = P_{ij}\tilde{Q}_j \qquad 7.2\text{-}14$$

Potential coefficients have different expressions, depending on the geometry of objects. The calculation of electric fields in two dimensions makes use of the potential coefficients between cylinders, as described in Section 7.3. For three-dimensional problems, complex expressions of potential coefficients are available for the case of sphere-to-sphere (EPRI 1999) and cylindrical segments-to-cylindrical segments (see Appendix 7.6), when spheres or cylindrical segments are used to simulate the geometry of objects.

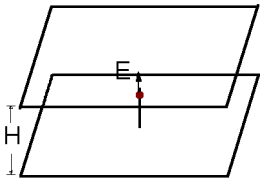
Grounded and Floating Objects

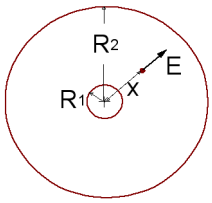
Most objects near transmission lines may be considered conductive for the purpose of electric field calculations. Conductive objects include cars, trucks, the body of people and animals, live vegetation, moist surfaces, and the ground itself. Very dry wood, dry gravel, dry clothes and shoes, and rocky soil may be considered insulators. Conductive objects that rest on a conductive ground are "grounded"—i.e., at the potential of the ground, normally taken as the zero reference potential. Conductive objects that are well insulated from ground are considered "floating," because their potential floats between ground potential and the line potential. The total charge on a floating object is zero, although charges may be located on different parts of its surface. Many objects are neither grounded nor floating, because they are connected to ground through a resistance. This is, for example, the case of cars and trucks connected to the electrical ground through tires and dry pavement, of people connected to ground through partially conductive shoes, and of gutters connected to ground through not perfectly insulating wooden surfaces.

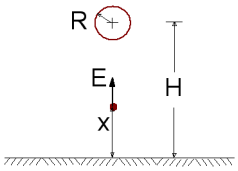
Electric Field for Simple Geometry

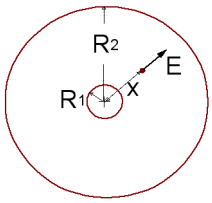
Electric field expressions are provided in Table 7.2-1 for pairs of electrodes with simple shapes. *V* is the voltage between electrodes. When the geometry is even slightly

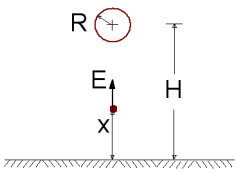
more complex, such as for transmission line conductors parallel to each other above a flat ground, there are no simple closed-form solutions and more complex calculation methods, such as those described in Section 7.3 must be employed.











7.2.4 Magnetic Fields

Definition

The magnitude and direction of the force exerted on a moving electric charge define the magnetic field. If an electric charge is moving into a magnetic field, or if a field moves past the charge, the charge will be subjected to a force. If the unit electric charge—i.e., 1 C (one coulomb)—moves at a unit velocity—i.e., 1 m/s (one meter per second)— perpendicular to a magnetic field of a unit flux density— i.e., 1 T (one tesla)—it will be subjected to a unit force—i.e., 1 N (one newton)—in a direction orthogonal to both the direction of the motion and the direction of the magnetic field. The quantity described is the *magnetic flux density*, which is the magnetic flux in the unit area perpendicularly traversed by the flux.

The above definition, although correct, is not very intuitive. To gain better physical insight into the meaning of magnetic flux density, consider a single long wire carrying a current, I. The magnetic flux density in the surrounding air at a distance R from the wire is equal to $2 \cdot 10^{-7}\ I/R$ tesla. For

Table 7.2-1 Electric Field for Simple Geometry

Geometry		Capacitance	Charge on Electrode	Electric Field
Plate-to-plate		$C=\frac{\varepsilon}{H}$ (F/m²)	$Q=\frac{\varepsilon V}{H}$ (C/m²)	$E=\frac{V}{H}$ (V/m)
Concentric spheres		$C = 4\pi\varepsilon\frac{R_1R_2}{R_2-R_1}$ (F)	$Q = 4\pi\varepsilon V\frac{R_1R_2}{R_2-R_1}$ (C)	$E = V\frac{R_1R_2}{x^2(R_2-R_1)}$ (V/m)
Sphere above ground (for H>>R)		$C = 4\pi\varepsilon R$ (F)	$Q = 4\pi\varepsilon RV$ (C)	$E = V\frac{2R(H^2+x^2)}{(H^2-x^2)^2}$ (V/m)
Concentric cylinders		$C = \frac{2\pi\varepsilon}{\ln(R_2/R_1)}$ (F/m)	$Q = \frac{2\pi\varepsilon V}{\ln(R_2/R_1)}$ (C/m)	$E = \frac{V}{x\cdot\ln(R_2/R_1)}$ (V/m)
Cylinder above ground (for H>>R)		$C = \frac{2\pi\varepsilon}{\ln(2H/R)}$ (F/m)	$Q = \frac{2\pi\varepsilon V}{\ln(2H/R)}$ (C/m)	$E = \frac{2VH}{(H^2-x^2)\cdot\ln(2H/R)}$ (V/m)

instance, if the wire carries 1 ampere at the distance of 1 meter, the magnetic flux density is equal to $2 \cdot 10^{-7}$ tesla. The magnetic flux density is a vector that, in this example, is tangential to the circle with radius *R*. If the current is a phasor, the magnitude of the magnetic flux density is also a phasor.

Units of Measurement

Magnetic flux is measured in weber (Wb). The "magnetic flux density," often indicated by the letter B, is the magnetic flux per unit area. Magnetic flux density is measured in weber per square meter, or tesla. 1 T = 1 Wb/m^2.

$$\Phi = B \cdot A \qquad 7.2\text{-}15$$

The "magnetic field strength," indicated using the letter H, is measured in ampere per meter (A/m). $\vec{B}$ and $\vec{H}$ are related to each other through the permeability of the medium:

$$\vec{B} = \mu \vec{H} \qquad 7.2\text{-}16$$

The permeability, μ, is a characteristic that gives an indication of how a material affects the magnetic flux density that penetrates it. The permeability of vacuum, air, and biological matter is nearly the same: $\mu = \mu_0 = 4\pi\ 10^{-7} = 1.257 \cdot 10^{-6}$ henry/meter (H/m).

When engineers talk about a magnetic field, they refer to the rms value of the magnetic flux density, B. The international unit for magnetic flux density is the tesla (T). The unit commonly used in the United States is the CGS unit gauss (G). 1G = 0.0001T = 10^{-4}T. However, since most magnetic fields experienced by people are much lower than one tesla and one gauss, more commonly used units are the microtesla (μT), used in European publications, and the milligaus (mG), used in the U.S.: 1 mG = 0.001G = 10^{-7}T = 0.1 μ T

Like electric fields, magnetic fields can have constant direction (dc) or a direction that varies during the power frequency cycle (ac). The earth has a dc magnetic field ranging from about 280 to 660 mG (0.28 to 0.66 gauss), depending upon the location on the earth (the continental United States has a dc field of about 480 to 560 mG).

Magnetic Field Components, Magnetic Field Ellipse, RMS Value

The same concepts and definitions illustrated for the electric field are applicable to the magnetic field as well. The quantity used to characterize the magnetic field is the rms value, unless otherwise specified.

Harmonics of the Magnetic Field

The magnetic field of transmission lines has a low harmonic content, contrary to the field of most sources of magnetic field that can be encountered in common environments. Typical values inside and outside the right-of-way are shown in Table 7.2-2.

Table 7.2-2 Harmonic Content of Magnetic Fields from Transmission Lines (as a Percentage of the Fundamental)

Harmonic	2	3	4	5	7	9	11	13
Transmission Line (within ROW)	0.1	0.5-0.9	0.0	0.6-1.3	0.2	0.0-0.1	0.1	< 0.1
Transmission Line (outside ROW)	0.2-1.4	0.5-3	0.1-0.4	0.5-1.1	0.1-0.3	0.1-0.3	0.1-0.2	0.1

Temporal Stability of Magnetic Fields

The magnetic field from a power transmission line has the same variability as the transmission-line load current.

The Current Carrying Wire, Biot-Savart Law, Ampere's Law

The most familiar source of magnetic field is the current carrying wire, usually treated as a "line current"—i.e., the current travels along a line whose thickness can be ignored. A line current can, in general, follow any contour through space. A simple case of line current is the straight infinitely long line current. The magnetic field at a distance, *R*, from an infinitely long line current, *I*, forms circles around the wire, and its magnitude is given by:

$$B = \frac{\mu_0 I}{2\pi R} \qquad 7.2\text{-}17$$

The field direction is given by the right-hand rule (see Figure 7.2-2). The *right-hand rule* states that if the right thumb points along the wire in the direction of current flow, the fingers will encircle the wire in the direction of the magnetic field. The current, *I*, can be alternating, and Equation 7.2-17 indicates that the magnetic field produced by an ac current is in phase with the current.

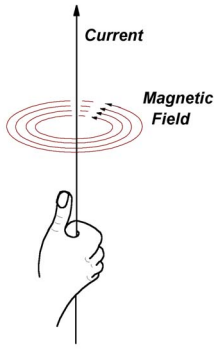


Figure 7.2-2 The right-hand rule.

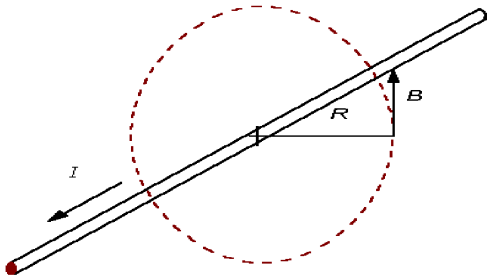
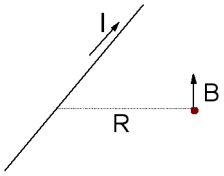
For a line current following any contour through space, the magnetic field is given by the Biot-Savart law (see Section 7.4.4). Application of the Biot-Savart law leads to the development of equations for simple wire geometry as shown in Table 7.2-3.

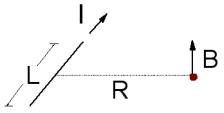
Another fundamental law is Ampere's law, expressed by:

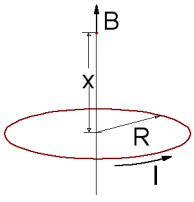
$$\int \vec{B} \cdot d\vec{l} = \mu_0 I_{enclosed} \qquad 7.2\text{-}18$$

Ampere's law states that the integral of the component of the magnetic field vector along any closed contour line equals μ_0 times the net current passing through the contour. As an example of its application, consider an infinitely long wire carrying a current *I*. The application of Ampere's law is illustrated in Figure 7.2-3, where an imaginary circular contour is drawn symmetrically around the current carrying wire. Note that at every point on the contour, the vector $d\vec{l}$ points along the contour. It is known from the right-hand rule that $\vec{B}$ also points along the contour. Therefore, at every point on the contour, $\vec{B}$ and $d\vec{l}$ are parallel. The integration of the scalar product around the contour gives: $B \cdot 2\pi R$. The total current enclosed by the contour of Figure 7.2-3 is the current in the wire, *I*. Therefore, Equation 7.2-18 becomes:









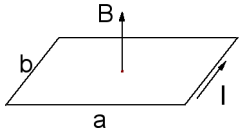


Figure 7.2-3 Magnetic field of an infinitely long current-carrying wire.

$$B = \mu_0 I / (2\pi R) \qquad 7.2\text{-}19$$

Faraday's Law of Induction, Induced Currents

Time-varying magnetic fields induce currents in conductive objects. These currents can flow in wires, or are induced as circulating currents in bulk matter. The latter are sometimes called "eddy currents." The physical law governing this phenomenon is called *Faraday's law.* This law states that there is an induced voltage around any closed path (loop) that equals the time rate of change of

Table 7.2-3 Magnetic Field for Simple Geometry

Geometry (Current in ampere, distances in meter)		Magnetic Field (tesla)	Magnetic Field (milligauss)
Infinitely long line		$B = \mu_0 \frac{I}{2\pi R}$	$B = \frac{2I}{R}$
Line segment (measurements in the axial plane)		$B = \frac{\mu_0 LI}{2\pi R\sqrt{L^2 + 4R^2}}$	$B = \frac{2LI}{R\sqrt{L^2 + 4R^2}}$
Circular Loop (measurements along loop axis)		$B = \frac{\mu_0 R^2 I}{2(R^2 + x^2)^{3/2}}$	$B = \frac{2\pi R^2 I}{(R^2 + x^2)^{3/2}}$
Rectangular Loop (measurements at the loop center)		$B = \frac{2\mu_0\sqrt{a^2 + b^2}}{\pi ab} I$	$B = \frac{8\sqrt{a^2 + b^2}}{ab} I$

magnetic flux through the loop (adjusted by a negative sign to give the correct direction). In mathematical form:

$$\tilde{V} = -\frac{d\tilde{\Phi}}{dt} \qquad 7.2\text{-}20$$

As an example of Faraday's law, consider a circular loop of wire one meter in radius (see Figure 7.2-4). The loop is placed in a region that has a uniform 60-Hz magnetic field with an rms value of 100 mG in the vertical direction, perpendicular to the plane of the loop. The field varies with time according to equation $\tilde{B} = \sqrt{2} \cdot 100 \cdot \sin(\omega t)$.

The flux through the loop is:

$$\tilde{\Phi} = \int \vec{B} \cdot d\vec{a} \qquad 7.2\text{-}21$$

The integration is over the area enclosed by the loop, and *da* is the elemental area vector.

Since the vectors $\vec{B}$ and $d\vec{a}$ are parallel everywhere over the area of integration, the scalar product in Equation 7.2-21 becomes simply the product of the magnitudes of $\vec{B}$ and $d\vec{a}$. Since the magnitude of $\vec{B}$ is constant,

$$\tilde{\Phi} = \pi \cdot \sqrt{2} \cdot 100 \cdot 10^{-7} \cdot \sin(\omega t) \text{ Wb}$$

The voltage induced in the loop is:

$$\tilde{V} = -d\tilde{\Phi} / dt = -\pi \cdot \sqrt{2} \cdot 10^{-5} \cdot \omega \cdot \cos(\omega t) \quad \text{V}$$

and in polar notation

$$= 0.012 \angle -90$$

where 0.012 is rms value.

In conclusion, the voltage induced in the loop by the magnetic field has an rms value equal to 0.012 V at a phase angle of 90° with respect to the field.

The loop will, in general, have an impedance formed by an inductance and a resistance as shown schematically in Figure 7.2-4. This impedance, along with the induced voltage, determines the current that flows in the loop.

Positive, Negative, and Zero Sequence Currents

The system of alternating currents of a three-phase transmission line can be considered as the geometric sum of a three symmetrical phasor system: positive, negative, and zero sequences, which are called *symmetrical components* (Grainger and Stevenson 1994). A positive sequence, the principal sequence for working current of power networks, is formed from three phasors of equal magnitude and with phase angles between the first phasor and the other two equal to 120° and 240°. A negative sequence is formed by three phasors equal in magnitude and with phase angles between the first phasor and the other two equal to -120° and -240°. Zero sequence current is formed from three phasors, equal in magnitude and in phase. Figure 7.2-5 presents an example of a phasor diagram of positive, negative, and zero sequence phase currents. Although the power system is designed for the positive sequence component, small negative and zero sequence components may exist.

Consideration of the symmetrical components is important for the assessment of methods of magnetic field reduction. Effectively reducing the magnetic field produced from transmission lines primarily requires dealing with the positive sequence currents. The negative sequence currents are of little importance because they are small. Furthermore, magnetic field reduction methods that apply to positive sequence currents apply to the negative sequence as well. The magnetic field produced by zero sequence currents, however, is not suppressed by the same measures effective for positive sequence currents. This concept is further discussed in Section 7.17, where different options for reducing transmission-line magnetic fields are examined.

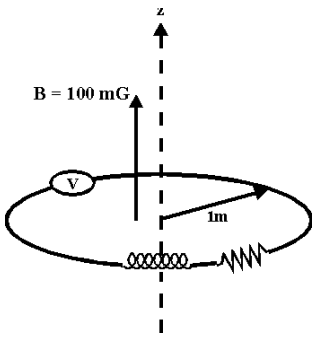

Figure 7.2-4 Voltage induced in a loop by an ac magnetic field.

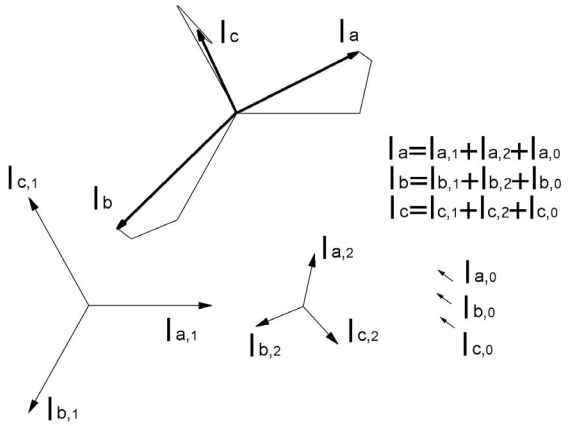

Figure 7.2-5 System of three nonsymmetric phase currents (I_a, I_b, I_c) presented as a sum of three symmetric components: (1) positive sequence, (2) negative sequence, and (0) zero sequence.

7.3 CALCULATION OF ELECTRIC FIELDS

7.3.1 General Method for Transmission Lines

The focus of this section is the electric field some distance from the conductors. In general, the methods described here do not apply to the electric field at the surface of the conductors, for which the reader is referred to Chapter 2. In most cases, the electric field generated by power transmission lines may be calculated with sufficient accuracy using a two-dimensional simplified analysis. The assumptions on which this analysis is based are the following:

- Electric fields in proximity to ac transmission lines are calculated assuming that there is no space charge, the charges being only on the surfaces of the conductors, on the ground, and on grounded objects. Corona, when present, creates a space charge near the conductor that affects the electric field but in an insignificant way, even in foul weather when corona is greater.
- Power line conductors may be simulated with a set of infinitely long cylindrical conductors, parallel to each other above a flat earth.
- The earth is assumed to be a perfect conductor because the time required for charges to redistribute on the earth surface under the action of a change in applied field (relaxation time, $\tau = \rho\varepsilon$) is extremely small (0.1 to 100 ns) compared to the period of the power frequency. The dielectric medium between conductors and earth is air, whose permittivity is practically independent of weather conditions and is equal to the permittivity of free space, $\varepsilon = 8.854 \cdot 10^{-12}$ F/m.
- Once the presence of the earth is accounted for using the images of the conductors, the time-varying electric field generated by a power transmission line may be treated as quasistatic—i.e., as essentially a static field because the wavelength is much larger than the dimensions under consideration.

The problem is two-dimensional and can be solved quite accurately using the charge simulation method. The electric field can be calculated using Applet EMF-2. The charges distributed on the surface of a conductor are simulated by a charge placed at the center of the conductor. The charges on the earth surface are simulated by image charges equal in magnitude but with opposite polarity to the charges on the conductors. These image charges are placed below the surface of the earth as if the earth were a perfect mirror reflecting the conductors. This system of charges creates electric fields in the space between conductors and earth that are equal to those created by the actual charges distributed on the surfaces of conductors and earth. The electric field at a point in space can be calculated from the charges. The charges are calculated knowing the voltage, V_k, applied to each conductor, k, and the geometry of the problem. It is required to solve the matrix equation:

$$[Q] = [P]^{-1}[V] \qquad 7.3\text{-}1$$

Where:

$[Q]$ is the array of the line charges (coulomb/meter).
$[V]$ is the array of the conductor voltages (volt).
$[P]$ is the array of the Maxwell potential coefficients (meter/farad).

Charges and voltages are alternating quantities at the power frequency and may be expressed by complex numbers, with a real and an imaginary part. For instance, the voltage of a conductor: $v(t)=\sqrt{2}V\cos(\omega t+\varphi)$ can be written as $\tilde{V}=\tilde{V}_r+j\tilde{V}_i$. V_r is the rms value of the real component (phase angle equal to zero) and V_i is the rms value of the imaginary component (phase angle equal to 90°):

$$v_r(t) = \sqrt{2}V\cos(\varphi)\cos(\omega t)$$
$$v_i(t) = \sqrt{2}V\sin(\varphi)\cos(\omega t + 90)$$

Equation 7.3-1 can be written for both real and imaginary quantities.

$$[Q_r] = [P]^{-1}[V_r] \quad \text{and} \quad [Q_i] = [P]^{-1}[V_i] \qquad 7.3\text{-}2$$

Conductors can be at any voltage including zero. Conductors with zero voltage include wires for lightning protection or wires intentionally used for electric field shielding.

The potential coefficients for a system of parallel conductors have simple expressions:

$$P_{kk} = \frac{1}{2\pi\varepsilon}\ln\left(\frac{4H_k}{d_k}\right) \qquad 7.3\text{-}3$$

$$P_{kl} = \frac{1}{2\pi\varepsilon}\ln\left(\frac{S'_{kl}}{S_{kl}}\right) \qquad 7.3\text{-}4$$

Where:

P_{kk} is the self potential coefficient of conductor k.
P_{kl} is the mutual potential coefficient between conductors k and l.
d_k is the diameter of conductor k.
H_k is the height above ground of conductor k.
S_{kl} is the distance between conductor k and conductor l.
S'_{kl} is the distance between conductor k and the image of conductor l (see Figure 7.3-1).
ε $= 8.854 \cdot 10^{-12}$ F/m.

The matrix of potential coefficients is symmetric: $P_{kl} = P_{lk}$.

In the case of a bundle of conductors, rather than considering each conductor separately, an equivalent single conductor may be considered. The equivalent conductor is a

conductor that would hold the same charge as the bundle when the same voltage is applied to it. The equivalent conductor can also be thought of as the conductor with the same capacitance to ground.

The diameter of a single conductor equivalent to a regular bundle—i.e., to a bundle of identical conductors disposed on the vertices of a regular polygon, is:

$$d_{eq} = d_b \cdot \sqrt[n]{\frac{nd}{d_b}}; \quad d_b = \frac{s}{\sin(\pi / n)} \qquad 7.3\text{-}5$$

Where:

d_b is the bundle diameter.
n is the number of subconductors in the bundle.
d is the diameter of the subconductors.
s is the spacing between subconductors.

The equivalent diameter of an asymmetric bundle—i.e., when the subconductors are not disposed on the vertices of a regular polygon, or of a bundle with subconductors with different diameters can be calculated using Applet EMF-3, "Single Conductor Equivalent to a Bundle."

Solution of Equations 7.3-2 yields the line charges on each conductor. Once the line charges are obtained, the desired electric fields and space potentials are calculated.

Each conductor's charge contributes to the electric field. The electric field is calculated by adding the contributions of all the charges. With reference to Figure 7.3-2, the electric field, $\vec{E}_k$, at point *M* caused by the line charge, $\tilde{Q}_k$, on conductor *k*, is the vectorial sum of the fields, $\vec{E}_{k1}$, due to $\tilde{Q}_k$, and $\vec{E}_{k2}$ due to the image, $-\tilde{Q}_k$, of $\tilde{Q}_k$ inside the earth.

The horizontal distance from conductor *k* and the height above ground of the measuring point, *M*, are indicated with X_M and H_M, respectively, while H_k indicates the height of the conductor. The magnitude of the horizontal and vertical components of the electric field caused by the charges on conductor *k*, $\tilde{E}_{kx}$ and $\tilde{E}_{ky}$, are given by Equations 7.3-6 and 7.3-7.

$$\tilde{E}_{kx} = \frac{\left(\tilde{Q}_{rk} + j\tilde{Q}_{ik}\right)}{2\pi\varepsilon} \cdot \left[\frac{X_M}{X_M^2 + (H_k - H_M)^2} - \frac{X_M}{X_M^2 + (H_k + H_M)^2}\right] \qquad 7.3\text{-}6$$

$$\tilde{E}_{ky} = \frac{\left(\tilde{Q}_{rk} + j\tilde{Q}_{ik}\right)}{2\pi\varepsilon} \cdot \left[\frac{H_M - H_k}{X_M^2 + (H_k - H_M)^2} - \frac{H_M + H_k}{X_M^2 + (H_k + H_M)^2}\right] \qquad 7.3\text{-}7$$

The vertical and horizontal components of the electric field vector are calculated by adding the contributions of all the conductors:

$$\tilde{E}_x = \sum_k \tilde{E}_{kx} = E_{rx} + jE_{ix} \qquad 7.3\text{-}8$$

$$\tilde{E}_y = \sum_k \tilde{E}_{ky} = E_{ry} + jE_{iy} \qquad 7.3\text{-}9$$

The rms value of the real and imaginary, horizontal and vertical components, E_{rx}, E_{ix}, E_{ry}, and E_{iy}, fully characterize the vector field. For instance, the rms value of the electric field is given by:

$$E_{rms} = \sqrt{E_{rx}^2 + E_{ix}^2 + E_{ry}^2 + E_{iy}^2} \qquad 7.3\text{-}10$$

The electric field vector describes an ellipse. The parameters of the field ellipse can be calculated as shown in Appendix 7.1 or using Applet EMF-1.

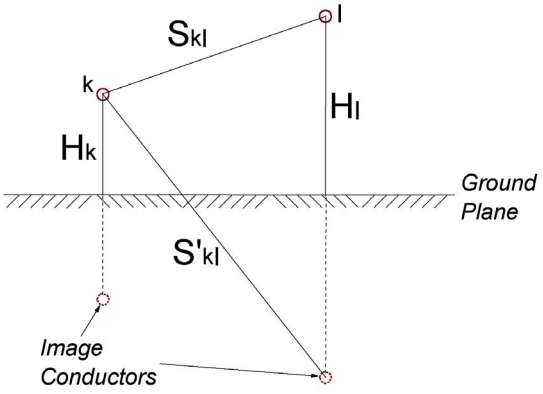

Figure 7.3-1 Conductors and their images.

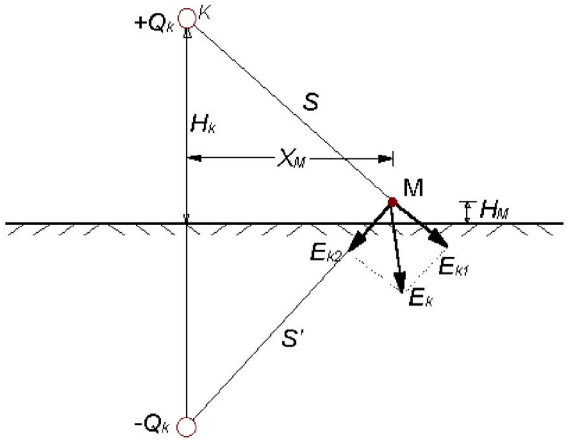

Figure 7.3-2 Calculation of the electric field from a line charge.

The space potential at the measuring point, *M*, may be evaluated by adding the contribution of each charge:

$$V_{sp} = \sum_k \frac{(Q_{rk} + jQ_{ik})}{2\pi\varepsilon} \cdot \ln\left(S_k / S'_k\right) \qquad 7.3\text{-}11$$

Where: S_k is the distance between conductor *k* and the measuring point.

S'_k is the distance between the image of conductor *k* and the measuring point.

Example

The following example guides the reader through the calculation of potential coefficients, charges on the conductors, electric field (real, imaginary, vertical, and horizontal components and resultant), and space potential (magnitude and phase angle). Consider a three-phase 525-kV line with the phases (*a*, *b*, *c*) in a flat configuration, 10 m between phases, 10.6 m height above ground, and bundles of three conductors, 3.3 cm in diameter, with 45 cm spacing. The electric field is calculated at a point 20 m from centerline and 2 m above ground.

Each phase is reduced to a single equivalent conductor, whose diameter is calculated with Equation 7.3-5:
d_b = 0.52 m, d_{eq} = 0.30 m.

The self-potential coefficients are calculated using Equation 7.3-3, using the conductor height of 10.6 m and the equivalent single conductor diameter of 0.30 m.

$P_{aa} = P_{bb} = P_{cc} = 8.91 \cdot 10^{10}$ m/F

The mutual potential coefficients are calculated using Equation 7.3-4.

$P_{ab} = P_{ba} = P_{bc} = P_{cb} = 1.53 \cdot 10^{10}$ m/F

$P_{ac} = P_{ca} = 6.77 \cdot 10^{9}$ m/F

The potential coefficients form a 3 by 3 square matrix, [P].

$$[P] = \begin{bmatrix} 8.91 & 1.53 & 0.68 \\ 1.53 & 8.91 & 1.53 \\ 0.68 & 1.53 & 8.91 \end{bmatrix} \cdot 10^{10} \quad \text{m/F}$$

Solution of Equations 7.3-2 requires the inversion of [P]. The elements of the matrix [C] = $[P]^{-1}$ are:

$C_{aa} = C_{cc} = 11.6 \cdot 10^{-12}$ F/m

$C_{bb} = 11.9 \cdot 10^{-12}$ F/m

$C_{ab} = C_{ba} = C_{bc} = C_{cb} = -1.90 \cdot 10^{-12}$ F/m

$C_{ac} = C_{ca} = -0.56 \cdot 10^{-12}$ F/m

$$[C] = [P]^{-1} = \begin{bmatrix} 11.6 & -1.90 & -0.56 \\ -1.90 & 11.9 & -1.90 \\ 0.56 & -1.90 & 11.6 \end{bmatrix} \cdot 10^{-12} \quad \text{F/m}$$

The real and imaginary components of the voltages to be used in Equations 7.3-2 are evaluated by assuming that the three-phase voltages are 120° apart and by referring the phase angles to that of the center-phase voltage. If the phase-to-phase voltage is 525 kV, the voltage to ground is 303.1 kV.

$V_{ra} = -0.5 \cdot 525 / \sqrt{3} = -151.6$ kV $\quad V_{ia} = 0.5 \cdot 525 = 262.5$ kV

$V_{rb} = 525 / \sqrt{3} = 303.1$ kV $\quad V_{ib} = 0$

$V_{rc} = -0.5 \cdot 525 / \sqrt{3} = -151.6$ kV $\quad V_{ic} = 0.5 \cdot 525 = -262.5$ kV

The charges can now be calculated with Equations 7.3-2:

$Q_{ra} = -2.25 \cdot 10^{-6}$ C/m $\quad Q_{ia} = 3.19 \cdot 10^{-6}$ C/m
$Q_{rb} = 4.18 \cdot 10^{-6}$ C/m $\quad Q_{ib} = 0$
$Q_{rc} = -2.25 \cdot 10^{-6}$ C/m $\quad Q_{ic} = -3.19 \cdot 10^{-6}$ C/m

The horizontal and vertical components of the field vector at a measuring point, *M*, can now be calculated with Equations 7.3-6 and 7.3-7 for each conductor and then added according to Equations 7.3-8 and 7.3-9. Point *M* is at a distance of 20 m from centerline and at a height of 2 m above ground. Equations 7.3-8 and 7.3-9 give:

$$\tilde{E}_x = (-100 + j\,141) + (481) + (-762 - j\,1080)$$
$$= -381 - j\,939 \quad \text{V/m}$$
$$\tilde{E}_y = (838 - j\,1189) + (-3055) + (3967 + j\,5627)$$
$$= 1750 + j\,4438 \quad \text{V/m}$$

The rms value of the electric field is given by Equation 7.3-10:

$$E_{rms} = \sqrt{381^2 + 939^2 + 1750^2 + 4438^2} = 4877 \quad \text{V/m}$$

The space potential at the measuring point, *M*, is calculated with Equation 7.3-11:

$$V_{sp} = \frac{1}{2\pi\varepsilon}\cdot(-2.25\cdot10^{-6} + j3.19\cdot10^{-6}) \cdot(-0.0417) + \frac{1}{2\pi\varepsilon}\cdot(-4.18\cdot10^{-6} + j0)\cdot(-0.081) + \frac{1}{2\pi\varepsilon}\cdot(-2.25\cdot10^{-6} - j3.19\cdot10^{-6})\cdot(-0.198) = (1687 - j\,2393) + (-6179) + (8026 + j\,1138) = 3535 + j\,8991 \quad \text{V}$$

The rms value of the space potential is

$$E_{rms} = \sqrt{3535^2 + 8991^2} = 9661 \quad \text{V}$$

The electric field and space potential can be calculated using Applet EMF-2, "Transmission Line Electric Field -2D."

7.3.2 Lateral Profile of Electric Field at Ground Level

Standards and guidelines prescribe measurements at 1-m height. However, there is very little difference between the electric field values calculated at 1 m and those calculated at ground level. The calculation of the electric field at ground level is a considerable simplification of the general method. The charges on the conductors and the image charges create field vectors with the same values but different orientation, with the resulting vector being vertical, as shown in Figure 7.3-3. The field caused by conductor *k* is given by Equation 7.3-7 with $H_M = 0$.

$$\tilde{E}_k = \frac{\left(Q_{rk} + jQ_{ik}\right)}{2\pi\varepsilon}\cdot\frac{2H_M}{X_M^2 + H_M^2} \qquad 7.3\text{-}12$$

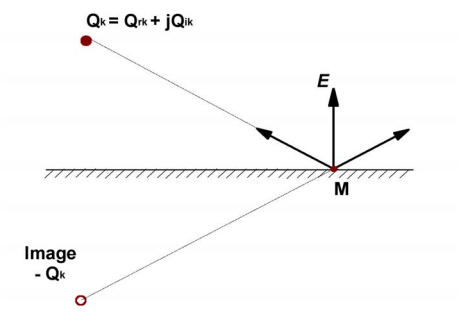

Figure 7.3-3 Electric field at ground caused by a line charge.

The field caused by the line is calculated by adding the contributions of all the conductors. The result is a phasor:

$$\tilde{E} = \sum_{k=1}^{n}\tilde{E}_k = E_r + jE_i \qquad 7.3\text{-}13$$

The magnitude of the field is:

$$E = \sqrt{E_r^2 + E_i^2} \qquad 7.3\text{-}14$$

The phase angle, θ, is:

$$\theta = \tan^{-1}(E_i / E_r) \qquad 7.3\text{-}15$$

The analysis of electric field effects on long objects that are not parallel to transmission lines requires the evaluation of both amplitude and phase angle of the electric field at different points.

If the calculation of the electric field at ground is repeated at different points in a cross-section of the transmission line, the *lateral profile* of the transmission line electric field is obtained. For an actual line with sag, the lateral profile is calculated at the section where the line has the lowest clearance to ground.

An example of lateral profile is shown in Figure 7.3-4. The maximum value of the electric field (the peak of the lateral profile) and the electric field at the edge of the right of way are particularly important for line design. The peak of the lateral profile generally occurs within the right-of-way, even though for flat configurations the lateral profile has two peaks occurring slightly outside the outer phases.

Figure 7.3-4 Example of lateral profile of electric field at ground. 525-kV line with flat configuration, 10-m phase spacing, 10.6-m height above ground, regular 3-conductor bundles, 3.3-cm diameter, 45-cm spacing.

7.3.3 Maximum Electric Field at Ground – Generalized Curves

Figures 7.3-5 to 7.3-9 show nomograms using nondimensional quantities. These curves are relatively simple to use and, even with easily accessible software, they may be preferable for a preliminary evaluation of the maximum electric field at ground for different single-circuit line types.

The use of Figure 7.3-5 is illustrated by the following example. Consider a single-circuit line with flat configuration, phase-to-phase voltage V = 525 kV, phase conductors consisting of regular three-conductor bundles with 3.3-cm diameter conductors and 45-cm spacing between conductors, phase spacing S = 10 m, and height above ground H = 10.6 m. The equivalent single-conductor diameter, calculated with Equation 7.3-5 is D = 0.3 m. In correspondence to H/D = 10.6/0.3 = 35.3 and S/H = 10/10.6 = 0.94, Figure 7.3-5 gives HE/V = 0.179. Therefore, the maximum field at ground is E = 0.179 × 525 / 10.6 = 8.8 kV/m, which is confirmed in Figure 7.3-4. Figures 7.3-5 – 7.3-9 do not consider the presence of overhead ground wires, which have a negligible effect on the field at ground level (see Section 7.3.4).

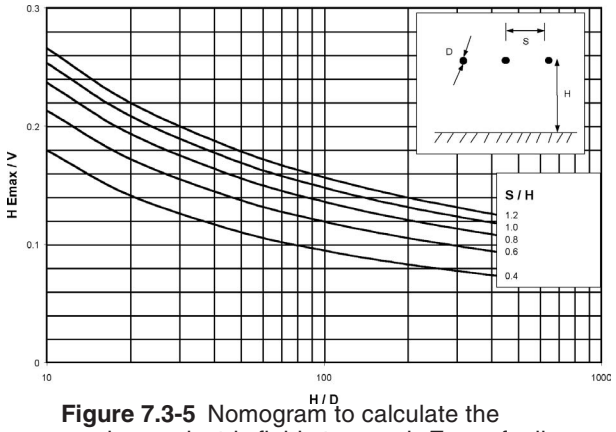

Figure 7.3-5 Nomogram to calculate the maximum electric field at ground, *Emax*, for lines of flat configuration.

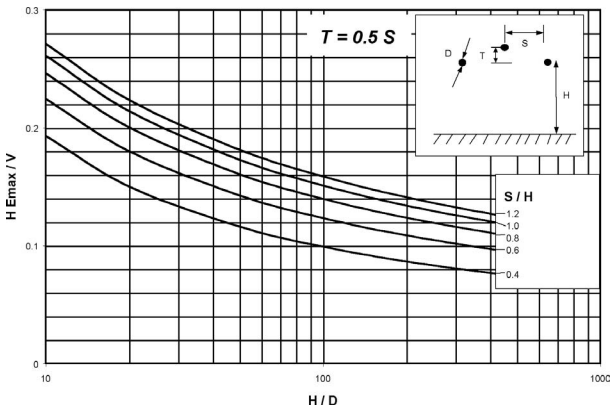

Figure 7.3-6 Nomogram to calculate the maximum electric field at ground, *Emax*, for lines of delta configuration (with T/S = 0.5).

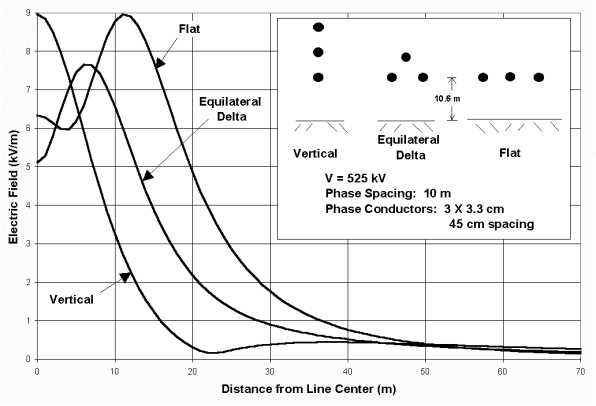

Figure 7.3-10 Effect of line configuration on the electric field at ground level.

7.3.4 Effect of Line Parameters

Effect of Line Configuration

Figure 7.3-10 shows the electric field profiles of three different single-circuit line configurations: flat, equilateral delta, and vertical. Voltage, phase spacing, conductor diameter, and clearance to ground are the same. The maximum electric field at ground is the lowest for the equilateral delta configuration. The electric field of the vertical line is the lowest at the edge of the right-of-way and beyond, while the field of the flat configuration is the highest.

Effect of Line Height

The line height is the parameter that has the greatest influence on the maximum field at ground. However, increasing the line height requires taller or more frequent towers. The effect of line height cannot be easily observed from the curves of Figures 7.3-5 – 7.3-9. The vertical axis variable implies an inverse proportionality between maximum field at ground, E_{max}, and height, H. However, H is contained also in the horizontal axis variable and in the parameter S/H. The relation between H and E may be expressed by the empirical equation:

$$\frac{E_1}{E_2} = \left(\frac{H_1}{H_2}\right)^m \qquad 7.3\text{-}16$$

E_1 and E_2 are the maximum fields for lines of minimum heights H_1 and H_2, respectively. The value of m depends on the line configuration. For single-circuit lines with a flat configuration $m \approx -1.4$ and for lines with an equilateral delta configuration $m \approx -1.6$. For instance, assume that the maximum field of a line with flat configuration is 8.8 kV/m for a 10.6 m height above ground. An increase of 1 m to a height of 11.6 m, will reduce the maximum field at ground to $8.8\ (11.6 / 10.6)^{-1.4} = 7.8$ kV/m.

The field at ground outside the transmission-line corridor is influenced by a change in line height in a completely different way. An example is shown in Figure 7.3-11. An increase in line height causes a decrease in the electric field up to a critical distance, L_c, but causes an increase in electric field at greater distances. Thus, increasing the line height is not desirable if the greatest concern is the electric field outside the transmission corridor. As a corollary of this discussion, the electric field outside the transmission corridor is generally greater toward the towers than at midspan.

The critical distance, L_c, at which a change in line height does not cause a change in electric field, is a function of the line parameters, particularly the line height. For lines of horizontal configuration, $L_c \approx (1.8 – 2.6)$ times the height H.

Effect of Sag

The effect of sag is normally neglected if the lateral profile is taken at the lowest point of the catenary. In this case, the difference in the calculation of the electric field near ground with and without accounting for the sag is less than 1% within the transmission corridor. This difference, expressed as a percentage of the field, increases with the distance from the line, but in absolute value is always negligible. For instance, for the 525-kV line of Figure 7.3-4, the field at 76 m from the line center at midspan calculated accounting for the sag is 128 V/m, while it is 116 V/m when the sag is not taken into account. This result was obtained using a 3-D electric field computer program (see Appendix 7.6) for an example in which the sag was 16.8 m and the span was 300 m. The effect of sag is negligible, not only at the point of minimum clearance, but also when the lateral profile is calculated with Equations 7.3-6 – 7.3-10 in the middle third of the catenary (middle third of the span when the two suspension points are at the same level), provided the height used in the calculations is the height of the conductors at the cross section where the profile is calculated. Closer to the suspension points, however, electric

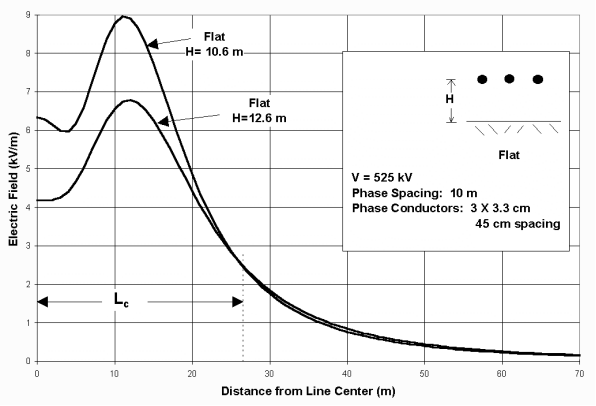

Figure 7.3-11 Effect of line height on the electric field at ground level.

field calculations made with 2-D algorithms may be significantly in error because of the cusp formed by the conductor at the suspension point and because the tower has a shielding effect. Both these factors may be taken into account using a 3-D electric field computer program.

Effect of Conductor Dimensions

The ground level electric field increases with conductor size. The effect of conductor size is practically independent of location. The field is approximately proportional to *log(P/D)* where *P* is the phase spacing and *D* the conductor diameter (equivalent diameter in the case of conductor bundles).

Effect of Phase Spacing

More compact lines produce lower electric fields at ground level. The electric field is approximately proportional to *log(P/D)* where *P* is the phase spacing and *D* the conductor diameter (equivalent diameter in the case of conductor bundles). Depending on the level of compaction, the line design may be controlled by support structure design, corona, radio and audible noise, insulation, maintenance, and other considerations.

Effect of Shield Wires

The overhead shield wires used for lightning protection and increasingly for communications do not have any appreciable effect on the ground-level electric field. Their presence causes a reduction of only 1 - 2% of the ground-level electric field.

Effect of Voltage

The electric field is proportional to the power line voltage. For the purpose of calculating electric fields, the voltages of a three-phase line may be considered perfectly symmetric (at 120° phase angle with each other).

Effect of Soil Conductivity

The conductivity of the soil is the least influential parameter. Even relatively dry soil has a conductivity much greater than that of air. Compared to air, the soil may be considered a perfect conductor. Extremely dry gravel or rock may lower the effective location of the ground plane representing the conductive earth only by a few tens of centimeters, which has a negligible effect on the electric field. If there is grass or other compact vegetation, the effective ground plane rises to be near the top of the vegetation.

Effect of Line Bends

Calculation of the electric field near line bends requires computational procedures for 3-D geometry (see Appendix 7.6 and Applet EMF-4). An example of electric field contour lines calculated for a 345-kV line making a 45° angle is shown in Figure 7.3-12. The field outside the right-of-way is increased inside the bend and decreased outside the bend.

Effect of Uneven Terrain

Calculation of the electric field above an uneven terrain requires advanced analytical techniques (Simpson and Brice 1987; Appendix 7.6). If the terrain is rolling, the electric field will be increased at the top of the roll and decreased at the bottom of the roll. The terrain factor, defined as the ratio between the electric field with the actual terrain and the electric field with a flat ground is shown in Figure 7.3-13. The terrain factor is a function of the terrain and not of the type of line. The maximum terrain factor, TF_{max}, at the top of the roll, and the minimum terrain factor, TF_{min}, at the bottom of the roll, can be estimated (for $B/A < 0.3$) as indicated in Equations 7.3-17 and 7.3-18.

$$TF_{max} = 1 + 1.6\ B/A \quad (7.3\text{-}17)$$

$$TF_{min} = 1 - 1.6\ B/A \quad (7.3\text{-}18)$$

First, calculations should be made for a flat terrain at the bottom of the rolls, and then the field at the top and at the bottom of the rolls should be calculated multiplying the flat-terrain electric field by the terrain factor.

Effect of Trees and Objects

The presence of conductive objects at ground potential has a significant effect on the electric field. In general, the effect consists in a field reduction. Shields consisting of grounded wires can be specifically designed for that purpose. Shielding caused by trees and other objects is discussed in Section 7.16.

7.3.5 Electric Field of Double-Circuit Lines

The relative phasing of the two circuits has a profound effect on the electric field at ground level. Figure 7.3-14 shows an example of the electric field lateral profile of a 525-kV double-circuit line with the conductors of each circuit configured vertically with different phase arrangements. Figure 7.3-15 shows an example of a 345-kV double-circuit line consisting of two delta circuits side by

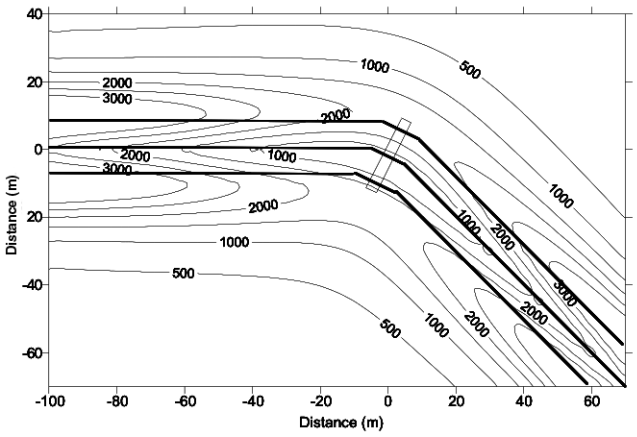

Figure 7.3-12 Electric field contour line near a line bend. Example of a 345-kV vertical line and a 45° angle.

side. If the phasing of one circuit is kept the same, there are six combinations of the phases of the other circuit, of which five result in different electric field profiles (arrangement ABC/CAB gives a profile symmetric to that of arrangement #4: ABC/BCA). Phase arrangement #1 in both cases is called "superbundle," because phase A and A^l, B and B^l, C and C^l in Figure 7.3-14 and phases A and A^l, B and B^l in Figure 7.3-15, may be considered as one large bundle of conductors at the same voltage. The superbundle arrangement corresponds to the highest electric fields (and also magnetic fields) at ground and to the lowest electric field at the conductors. Therefore, the superbundle corresponds to the lowest possible level of corona effects: corona loss, radio noise, and audible noise.

Phase arrangement # 5 corresponds to the lowest electric (and magnetic) fields at ground and to the highest electric field at the conductors and, therefore, produces the highest level of corona effects. This arrangement is called "low-reactance," because it also corresponds to the lowest reactance of the transmission line should this be composed of the two circuits tied together and carrying power in the same direction. Phase arrangement #6 consists of one circuit energized and the other grounded.

All the field values plotted in Figures 7.3-14 and 7.3-15 were calculated accounting for the presence of shield wires. Their influence on the electric field, however, was found negligible.

7.3.6 Electric Field in Substations

Electric field effects in substation are of the same type as those close to transmission lines. Induced currents and spark discharges depend on the particular situation and on the intensity of the electric field. The electric field at one meter above ground is a useful parameter to characterize the electric field environment of a substation as well.

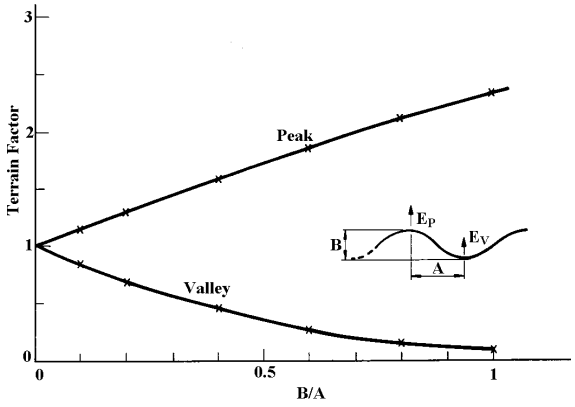

Figure 7.3-13 Terrain factor for rolling terrain.

In designing a new substation, the electric field of existing substations is a useful reference. The electric field at one meter above ground may be conveniently described by electric field contour lines traced on the plan view of the substation (EPRI 1982). Contour maps are a convenient way to show how the electric field at ground level is distributed within the substation area. For example, in a 500-kV substation, the maximum measured electric field at ground level was 8.5 kV/m. Typically, electric fields of about 2 kV/m were measured close to breakers and disconnects between phases, whereas values close to 6 kV/m were measured off the outside phases, where access roads or walk areas may be present.

Working areas usually have lower electric fields. For instance, if the breaker heads are de-energized for servicing, the fields around the heads will be lower unless they are close to an energized bus. The electric field near substation structures is very nonuniform. All the support structures are at ground potential and shield the region near ground.

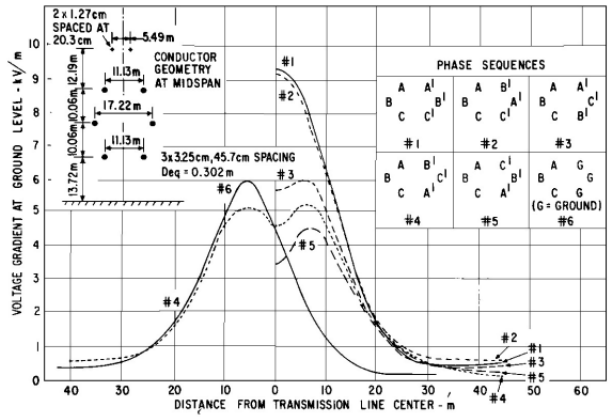

Figure 7.3-14 Electric field at ground level for a double-circuit 525-kV line consisting of two vertical circuits, different phase arrangements.

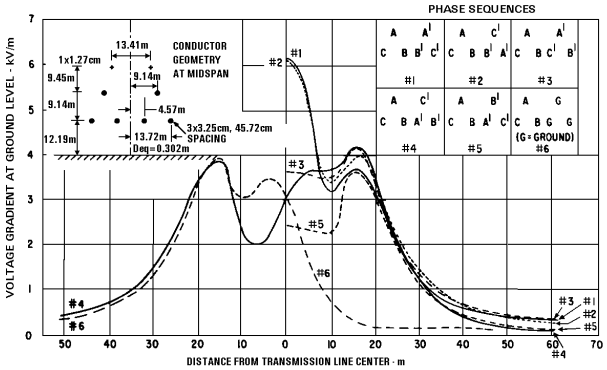

Figure 7.3-15 Electric field at ground level for a double-circuit 345-kV line consisting of two delta circuits, different phase arrangements.

The maximum values of the electric field at one meter above ground and typical geometrical characteristics of substation buses in North America are listed in Table 7.3-1. A limited amount of data on maximum electric field at ground measured in substations in different countries is available (Vinh and Yi 1982).

Table 7.3-1 Electric Field at One Meter Above Ground in Substations

Voltage	Max. Measured Electric Field	Typical Values Off Outer Phase[1]	Bus Height	Bus Phase Spacing	Base Height
(kV)	(kV/m)	(kV/m)	(m)	(m)	(m)
230		5.0	5.5	3.5	3.5
345	7.5	6.5	7	4.5	4.0
500	8.5	6.0	9	5.0	5.0
765	9.0	8.5	12	6.5	6.5

1. Representative maximum electric fields at ground level encountered along buses far from terminations and discontinuities.

The maximum electric field occurs at a distance of a few meters off the outer phases. The electric field may be reduced by designing substations with a large value of the bus height. Simpler procedures, however, may reduce the field even more. For instance, a grid of grounded wires strung off the outer phases at the height of the base will easily reduce the electric field by a factor of two or more, depending on the number and separation of the wires (see Section 7.16).

Air model facilities, using both power-frequency or high-frequency (24-kHz) voltages, have been used in the past to assess the electric field of substations (Sebo 1978; EPRI 1982). The use of calculation techniques for three-dimensional geometry, discussed in Appendix 7.6 and used in Applet EMF-4, makes the use of these models obsolete.

7.4 CALCULATION OF MAGNETIC FIELDS

7.4.1 General Method for Transmission Lines

In most cases, the magnetic field generated by transmission lines may be calculated with sufficient accuracy using a two-dimensional simplified analysis. Magnetic fields can be calculated using Applet EMF-6. The assumptions on which this analysis is based are the following:

- The conductors form infinitely long straight lines parallel to each other.
- The earth is a poor conductor for magnetic fields. The presence of the earth can be simulated by images of the conductors placed at a complex depth, which may be approximated by a real depth. The image depth is usually so large that, for calculations near transmission lines, the images may be neglected without loss of accuracy.
- Once the presence of the earth is accounted for using the images of the conductors, the time-varying magnetic field generated by a transmission line may be treated as quasistatic—i.e., as essentially a static field because the wavelength is much larger than the dimensions under consideration.

Consider the cross section of a conductor above the earth shown in Figure 7.4-1.

The figure shows the conductor and its image, placed at the image depth. For a detailed discussion of image depth, see Appendix 7.5. The image depth is approximately equal to 1.31 δ, where δ is the skin depth of the earth given by Equation 7.4-1.

$$\delta = \sqrt{\frac{\rho}{\pi f \mu}} \qquad 7.4\text{-}1$$

Where:

f is the frequency.
ρ is the resistivity of the soil.
μ is the permeability of the soil.

In most practical cases, the permeability of the soil is close to that of air ($\mu = 4\ \pi\ 10^{-7}$ H/m). For example, for a frequency of 60 Hz and a soil resistivity of 100 Ω m, the image depth is 850 m. This is such a large distance that, for many practical purposes, the contribution of the image conductor to the magnetic field may be neglected.

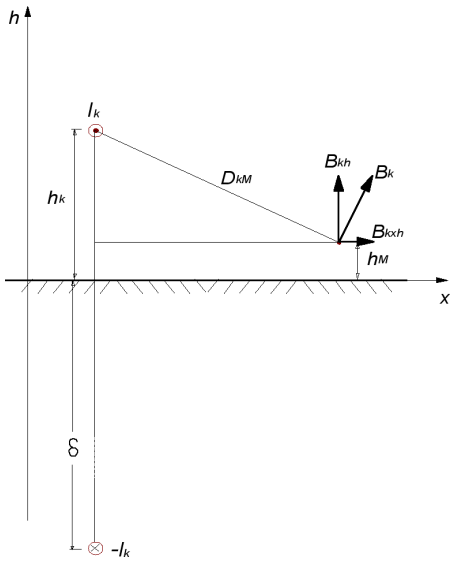

Figure 7.4-1 Magnetic field of an infinitely long conductor above the earth.

The calculation of the magnetic field is relatively straightforward if the amplitude and phase angle of the currents in all the conductors are known.

Consider a conductor, k, with the current I_k and phase angle ϕ_k. The current can be expressed as the sum of its real and imaginary components:

$$\tilde{I}_k = I_{kr} + jI_{ki} \quad 7.4\text{-}2$$

The magnetic field produced by this current has a real and an imaginary component. The real component of the magnetic field, B_{kr}, is caused by the real component of the current, I_{kr}, and is evaluated as indicated in Figure 7.4-1 and Equation 7.4-3. The field, B_{kr}, at a point M is represented by a vector that lies in the plane perpendicular to the conductor k and perpendicular to the line connecting M with the conductor k.

The magnitude of B_{kr} is given by Equation 7.4-3.

$$B_{kr} = 2 \cdot 10^{-7} I_{kr} / D_{kM} \quad 7.4\text{-}3$$

D_{kM} is the distance between conductor k and point M. The field is expressed in tesla, the current in ampere, and the distance in meter. If the field were expressed in mG, Equation 7.4-3 would become the simple expression 7.4-4.

$$\tilde{B}_{kr} = 2\tilde{I}_{kr} / D_{kM} \quad 7.4\text{-}4$$

Equation 7.4-4 neglects the contribution to the field by the image of conductor k in the ground. The image of a line current is not a mirror reflection (see Appendix 7.5). For practical purposes, the earth current can be lumped at an equivalent image location inside the earth as discussed above. The field contributed by the image of conductor k is calculated in the same fashion as for the conductor itself, except that the current in the image conductor should have the opposite direction. Even so, the image depth is usually so large that, for many practical purposes, the contribution of the image conductors to the magnetic field at a point near a transmission line can be neglected.

Using a system of orthogonal coordinates, x (lateral distance) and h (height above ground), as indicated in Figure 7.4-1, the magnitude of the magnetic field, B_{kr}, and of its horizontal and vertical components, B_{krx} and B_{krh}, are given by:

$$B_{kr} = \frac{2 \cdot 10^{-7} I_{kr}}{\sqrt{(x_M - x_k)^2 + (h_M - h_k)^2}} \quad 7.4\text{-}5$$

$$B_{krx} = \frac{2 \cdot 10^{-7} I_{kr}(x_M - x_k)}{(x_M - x_k)^2 + (h_M - h_k)^2} \quad 7.4\text{-}6$$

$$B_{krh} = \frac{2 \cdot 10^{-7} I_{kr}(h_M - h_k)}{(x_M - x_k)^2 + (h_M - h_k)^2} \quad 7.4\text{-}7$$

It should be noted that there is no field in the direction parallel to the conductor.

The same calculations are made to calculate the imaginary part of the magnetic field, B_{ki}, and its horizontal and vertical components, B_{kix} and B_{kih}. The imaginary component of the current, I_{ki}, should be used instead of the real component.

If a power line contains n conductors, with currents I_k and phase angles ϕ_k $(k = 1,n)$, the real and imaginary components of the horizontal and vertical magnetic field at point M are calculated separately for each conductor and then added. The resulting real and imaginary, horizontal and vertical magnetic fields at point M are:

$$B_{rx} = \sum_{k=1}^{n} B_{krx} \quad B_{rh} = \sum_{k=1}^{n} B_{krh} \quad B_{ix} = \sum_{k=1}^{n} B_{kix} \quad B_{ih} = \sum_{k=1}^{n} B_{kih} \quad 7.4\text{-}8$$

A magnetic field meter placed at point M with its probe oriented to measure the horizontal component will measure a magnetic field, B_x, given by:

$$B_x = \sqrt{B_{rx}^2 + B_{ix}^2} \quad 7.4\text{-}9$$

Similarly, the vertical component of the magnetic field is given by:

$$B_h = \sqrt{B_{rh}^2 + B_{ih}^2} \quad 7.4\text{-}10$$

The resultant magnetic field is:

$$B = \sqrt{B_x^2 + B_h^2} = \sqrt{B_{rx}^2 + B_{ix}^2 + B_{rh}^2 + B_{ih}^2} \quad 7.4\text{-}11$$

If the currents used are rms values, the resultant field also is an rms value.

The field components B_{rx}, B_{ix}, B_{rh}, and B_{ih} fully characterize the vector field $\vec{B}$. The parameters of the field ellipse can be calculated as shown in Appendix 7.1 or using Applet EMF-1.

The results for a particular application can be obtained by using Applet EMF-6, "Transmission Line Magnetic Field – 2D." The input data required by this applet are the lateral and vertical coordinates of each conductor, the current and phase angle of each conductor, and the lateral and vertical coordinates of the point at which the magnetic field is calculated.

7.4.2 Example Calculation

The magnetic field was calculated for the same example of 525-kV transmission line used for the electric field (see Figure 7.3-4). The line current in this example is 1000 A. The currents are assumed to be balanced and symmetric. The results are shown in Figure 7.4-2. In addition to the resultant magnetic field, both the maximum field component (in the direction of the major axis of the field ellipse) and the minimum field components (in the direction of the minor axis of the field ellipse) are shown. The figure uses a log scale for the magnetic field, because often the magnetic field is of interest at locations outside the right-of-way, where the field levels may be two orders of magnitude lower than the peak level measured inside the right-of-way. The following observations are noteworthy:

- The magnetic field decays with the distance from the line much less than the electric field. As a corollary of this conclusion, conductor height affects both electric and magnetic fields, but the effect is more pronounced for the electric field.
- The magnetic field varies approximately in inverse proportion with the square of the distance from the center of the conductor configuration. This is shown in Figure 7.4-2 by the dashed line: $B = 3.46IP/D^2$, where I is the current, P is the phase spacing, and D is the distance between measuring point and the center phase.
- Conductor diameter affects electric fields but not magnetic fields.
- The minor axis of the ellipse becomes negligible in relation to the major axis as the distance from the line increases. This indicates that the field ellipse collapses into an oscillating vector with constant direction in space. This is a characteristic of lines with flat configurations.
- The magnetic field is proportional to the line current. While the electric field, which is proportional to the line voltage, is relatively stable in time, the magnetic field has temporal variations depending on the fluctuations of the load. There may be a pronounced dependence on the hour of the day, the day of the week, and the season. For this reason, the current for which calculations are made should be well specified. The results may be better presented in a unit of mG/A, or may be given for the maximum expected load.
- Up to a few hundred meters from the line, the earth return currents have a negligible effect compared to the currents in the line conductors, as shown in Table 7.4-1.
- No effect of shield wires was assumed on the results shown in Figure 7.4-2. This is the case when shield wires are either not present or they are sectionalized and do not carry any current. If shield wires are present and grounded at each structure, they carry currents that may have a small but detectable effect on the magnetic field. Shield wire currents are calculated as shown in Section 7.9 or using Applet EMF-8. An example of the shield wire effect on magnetic field is shown in Table 7.4-2. The effect is different on the two sides of the line; the field is slightly increased on one side and slightly decreased on the other.

7.4.3 Calculation of Magnetic Field from Power Lines Using Simple Equations

The customary method of calculation of the magnetic field produced by a power line is to calculate the field caused by each phase separately and then add up the contributions of all the phases. For the purpose of designing low-field lines or reducing the field of existing lines, it is worthwhile to examine the structure of the magnetic field produced by simple arrangements of conductors.

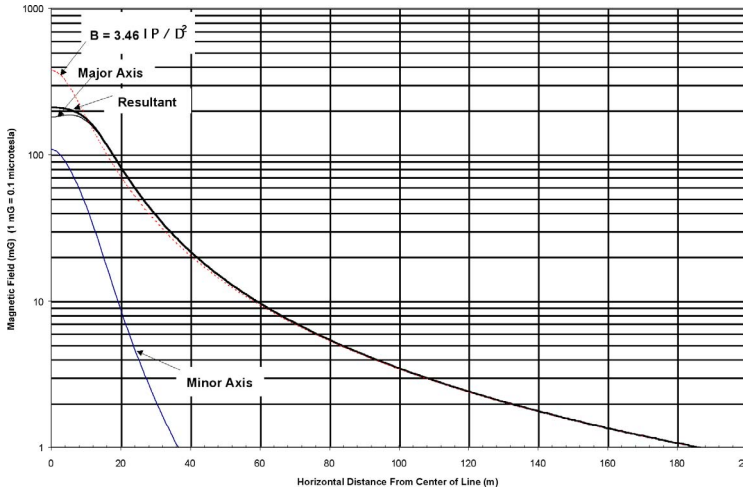

Figure 7.4-2 Magnetic field calculated at 1 m above ground for a three-phase line of flat configuration with 1000 A, phase spacing P = 10 m and height above ground of 10.6 m.

Table 7.4-1 Field Component Due to Earth Currents

Distance from Line Center (m)	Field Due to Conductor Currents (mG)	Field Due to Earth Currents (mG)
0	210	0.08
100	3.5	0.08
200	0.9	0.075
500	0.14	0.05
1000	0.035	0.024
2000	0.009	0.008
5000	0.0014	0.0014

Line: Flat configuration, P = 10 m, H = 10.6 m, I = 1000 A (balanced and symmetric), ground resistivity = 100 Ωm.

Table 7.4-2 Example of Effect of Shield Wires on Magnetic Field of a Three-Phase Line

Distance from Line Center (m)	Field Neglecting Shield Wire Currents (mG)	Field Accounting for Shield Wire Currents (mG)
-200	0.86	0.78
-100	3.47	3.31
0	210.5	210.4
100	3.47	3.65
200	0.86	0.96

Line: Flat configuration, P = 10 m, H = 10.6 m, I = 1000 A (balanced and symmetric); two shield wires at + and – 6.5 m from center, 15.6 m above ground, resistance = 6.7 Ω/mi, reactance = 1.8 Ω/mi @ 1 ft spacing; ground resistivity = 100 Ωm. Shield wires currents are 16.3 A @ 174° (from center phase current) and 15.4 A @ 27°.

The field of a power line can be analyzed efficiently by reducing the set of line currents that form a power line into basic line current elements: monopoles, dipoles, quadrupoles, and higher-order elements. These are described in Appendix 7.2. The equivalent monopole, dipole, and quadrupole of a given set of line currents can be found using Applet EMF-9. Using these elements, the "distant field" of a power line can be predicted accurately using simple equations. Distant field is defined as the field at distances from the center of the power line conductors that are large (e.g., greater than three times) compared to the largest distance between conductors of the power line. Simple equations for the "distant" field of lines with different configurations are shown in Table 7.4-3. The derivation of these equations is in Appendix 7.2.

7.4.4 Calculation of Magnetic Field from Sets of Conductors in Three Dimensions

When currents flow in conductors that can be approximated by straight lines infinitely long and parallel to each other, the magnetic field can be calculated with the method described in Section 7.4.1. Two-dimensional approximations, however, are not practical in many cases. Accurate results require calculations in three dimensions.

For current filaments, one-dimensional paths with zero cross section area, the Biot-Savart law, illustrated in Figure 7.4-3, offers the most convenient calculation tool. Each element, *dl*, of the path of the current *I*, generates a field at the measuring point *P* equal to:

$$d\vec{B} = \frac{\mu}{4\pi r^3} \cdot I \cdot d\vec{l} \times \vec{r} \qquad 7.4\text{-}12$$

$d\vec{l} \times \vec{r}$ is the cross product of the vector $d\vec{l}$ with the vector $\vec{r}$, which is a vector with amplitude $dl \cdot r \cdot \sin(\alpha)$ (α is the angle included by the two vectors) direction orthogonal to both $\vec{r}$ and $d\vec{l}$, and orientation according to the right-hand rule.

The magnetic field caused by a current flowing in a path from point A_1 to point A_2 is obtained by integrating Equation 7.4-12 from A_1 to A_2.

$$\vec{B} = \frac{\mu I}{4\pi} \int_{A_1}^{A_2} \frac{d\vec{l} \times \vec{r}}{r^3} \qquad 7.4\text{-}13$$

The units in 7.4-13 are meter, ampere, and tesla. The field can be expressed in mG by eliminating the term $\frac{\mu}{4\pi}$ (which is the same as multiplying by $\frac{4\pi}{\mu} = 10^7$).

Biot-Savart Law Applied to a Segment

1. If the measuring point is in the plane axis of the segment (Figure 7.4-4)

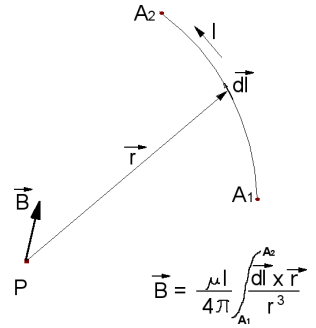
$$B = \frac{2LI}{R\sqrt{L^2 + 4R^2}} \qquad 7.4\text{-}14$$

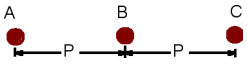
(meter, ampere, milligauss)

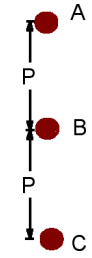
2. If the segment is infinitely long (L = ∞):

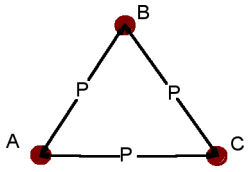
$$B = 2I/R \qquad 7.4\text{-}15$$

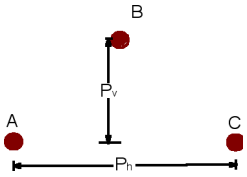
(meter, ampere, milligauss)

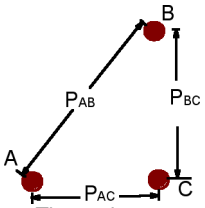


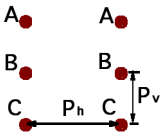


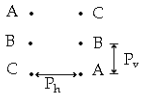


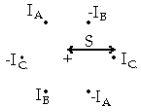


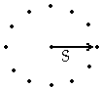


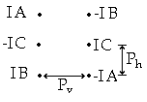


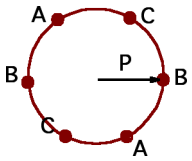


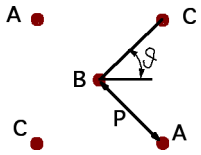












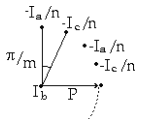


Figure 7.4-3 Illustration of Biot-Savart law.

Table 7.4-3 Distant Field Equations for Different Line Configurations

Configuration	Field[1] at Distance R	Configuration	Field[1] at Distance R
Single Wire	$B = 2I/R$	 Two wires, balanced	$B = 2PI/R^2$
 Two wires, unbalanced	$B_M = 2(I_1 + I_2)/R$ $B_D = P(I_2 - I_1)/R^2$	 Three-phase, flat, balanced	$B = 2\sqrt{3}PI/R^2$ linearly polarized
 I_o, I_1, I_2 Symmetrical components	$B_M = 6I_o/R$ $B_D = 2\sqrt{3}(\tilde{I}_1 - \tilde{I}_2)/R^2$ $B_Q = 2P^2(\tilde{I}_1 + \tilde{I}_2 - 2\tilde{I}_o)/R^3$	 Three-phase, vertical, balanced	$B = 2\sqrt{3}PI/R^2$ linearly polarized
 Three-phase, equilateral delta	$B = \sqrt{6}PI/R^2$ Circularly polarized $B_{MAX} = B_{MIN} = \sqrt{3}PI/R^2$	 Three-phase, non-equilateral delta	$B = \sqrt{3P_h^2 + 4P_v^2} \cdot I/R^2$ Elliptically polarized $B_{MAX} = \sqrt{3}P_h I/R^2$ $B_{MIN} = 2P_v I/R^2$
 Three-phase, general, balanced	$B = \sqrt{6}P_{eq} I/R^2$	 Double circuit, Currents: I_1, I_2 Same phasing	$B = 2\sqrt{3}P_v(I_1 + I_2)/R^2$
 Double circuit, Currents: I_1, I_2 Reverse phasing	$B_d = 2\sqrt{3}P_v(I_1 - I_2)/R^2$ $B_{q\max} = 2P_v^2(I_1 + I_2)/R^3$ $B_{q\min} = 2\sqrt{3}P_v P_h(I_1 + I_2)/R^3$ $B_q = 2P_v\sqrt{P_v^2 + 3P_h^2}(I_1 + I_2)/R^3$	 Six-phase, circular	$B_{\max} = B_{\min} = 6SI/R^2$ $B = 6\sqrt{2}SI/R^2$ Circularly polarized (I is the current in each phase)
 Twelve-phase circular	$B_{\max} = B_{\min} = 12SI/R^2$ $B = 12\sqrt{2}SI/R^2$ (I is the current in each phase)	 Six-phase vertical	$B_{\max} = 4P_h I/R^2$ $B_{\min} = 4\sqrt{3}P_v I/R^2$ $B = 4\sqrt{P_h^2 + 3P_v^2} \cdot I/R^2$ Elliptically polarized (I is the current in each phase)

1. B (mG) is the magnetic field, R (m) is the distance from the center of the set of wires, P (m) is the spacing between wires, and I is the current (A). B_M (mG) is the monopolar component, which varies in inverse proportion to distance, B_D (mG) is the dipolar component, which varies in inverse proportion to the square of the distance, and B_Q (mG) is the quadrupolar component, which varies in inverse proportion to third power of the distance. Bmax is the component along the major axis of the field ellipse and Bmin is the component along the minor axis of the field ellipse.

Table 7.4-3 Distant Field Equations for Different Line Configurations (Continued)

Configuration	Field[1] at Distance R	Configuration	Field[1] at Distance R
A • • C B • • B C • • A Three-phase, split phases, vertical.	$B_{max} = 2\sqrt{3}P_v P_h I/R^3$ $B_{min} = 2P_v^{\,2} I/R^3$ $B = 2P_v\sqrt{3P_h^{\,2} + P_v^{\,2}}\, I/R^3$ Elliptically polarized (I is the current per phase, twice the conductor current)	 Three-phase, split phases, circular.	$B_{max} = B_{min} = 3P^2\, I/R^3$ $B = 3\sqrt{2}P^2 I/R^3$ Circularly polarized (I is the current per phase, twice the conductor current)
 3-Phase, split phases, cruciform.	$B_{max} = 2\sqrt{3}P^2 \cdot \sin(2\vartheta) I/R^3$ $B_{min} = 2P^2 \cdot \cos(2\vartheta) I/R^3$ $B = 2P^2 \cdot (I/R^3) \cdot \sqrt{3\sin^2(2\vartheta) + \cos^2(2\vartheta)}$	 3-Phase, split phases, vertical.	$B = 2\sqrt{13}P^2\, I/R^3$ Linearly polarized (I is the current per phase, twice the conductor current)
A B C B A Three-phase, split phases, horizontal.	$B = 2\sqrt{13}P^2\, I/R^3$ Linearly polarized (I is the current per phase, twice the conductor current)		$B = \dfrac{2\sqrt{3n!}\,P^n \cdot I}{2^{\frac{n(n-1)}{2}} \cdot R^{n+1}}$ Linearly polarized

1. B (mG) is the magnetic field, R (m) is the distance from the center of the set of wires, P (m) is the spacing between wires, and I is the current (A). B_M (mG) is the monopolar component, which varies in inverse proportion to distance, B_D (mG) is the dipolar component, which varies in inverse proportion to the square of the distance, and B_Q (mG) is the quadrupolar component, which varies in inverse proportion to third power of the distance. Bmax is the component along the major axis of the field ellipse and Bmin is the component along the minor axis of the field ellipse.

3. In the general case: measuring point (x_p, y_p, z_p); segments from A_1 (x_1, y_1, z_1) to A_2 (x_2, y_2, z_2)

$$B = B_x\vec{u}_x + B_y\vec{u}_y + B_z\vec{u}_z \qquad 7.4\text{-}16$$

$\vec{u}_x, \vec{u}_y, \vec{u}_z$ are the unit vectors in the x, y, z directions

$$B_x = \frac{2I}{L} K\left[(z_p - z_1)(y_2 - y_1) - (y_p - y_1)(z_2 - z_1)\right] \qquad 7.4\text{-}17$$

$$B_y = \frac{2I}{L} K\left[(x_p - x_1)(z_2 - z_1) - (z_p - z_1)(x_2 - x_1)\right] \qquad 7.4\text{-}18$$

$$B_z = \frac{2I}{L} K\left[(y_p - y_1)(x_2 - x_1) - (x_p - x_1)(y_2 - y_1)\right] \qquad 7.4\text{-}19$$

$$K = \frac{1}{D^2 - D_0^2} \cdot \left[\frac{L + D_0}{\sqrt{L^2 + 2LD_0 + D^2}} - \frac{D_0}{D}\right] \qquad 7.4\text{-}20$$

L is the length of the segment
D is the distance between point P and point A_1
D_0 is the projection of the segment PA on the line A_1A_2.

$$D_0 = \frac{(x_1 - x_p)(x_2 - x_1) + (y_1 - y_p)(y_2 - y_1) + (z_1 - z_p)(z_2 - z_1)}{L}$$

The units in the above equations are m, A, and mG.

The field produced at a point P by a set of current-carrying segments is calculated by adding the contributions of all segments to the field components along each coordinate axis, calculated using Equations 7.4-17 to 7.4-21. These calculations can be performed for a variety of practical geometry by using Applet EMF-7.

Effect of Line Sag

The effect of line sag can be found using the 3-D method of magnetic field calculations (Applet EMF-7). This effect is appreciated by examining the magnetic field contour

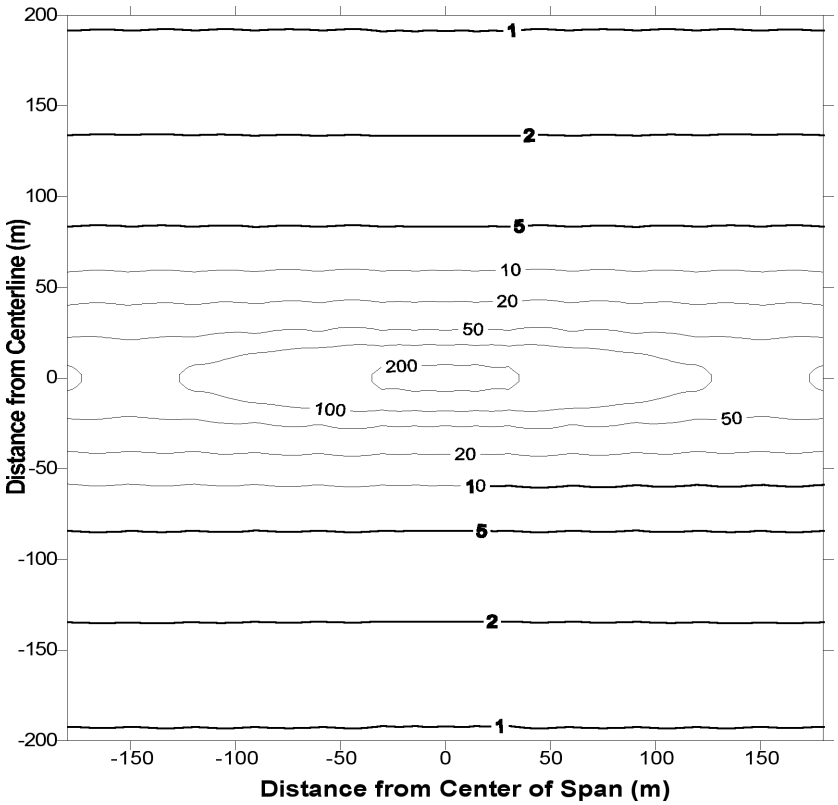

Figure 7.4-5 Example of magnetic field (mG) contour lines at 1 m above ground for one span (300 m) of a line with flat configuration, 10-m phase spacing, 10-m sag and 20 m at the tower attachment points. Line current is 1000 A.

lines calculated at 1 m above ground in an area encompassing one span. An example is shown in Figure 7.4-5.

If a lateral profile is taken at the lowest point of the catenary, the difference in the calculation of the magnetic field at ground level with and without accounting for the sag is negligible. For instance, for the line of Figure 7.4-5, the magnetic field at 1 m above ground under the center phase is 223 mG accounting for the sag and 227 mG if the line is assumed at constant height (same as the minimum height). At a distance of 100 m from centerline, the field at 1 m above ground is 3.55 mG accounting for the sag and 3.53 mG assuming a constant line height.

Magnetic Field in Substations

An application of the 3-D method of calculation is the calculation of magnetic field in substations. Substations for 230 kV and above are largely outdoor, open-air substations. Of interest is the magnetic field inside and outside the substation, particularly at the substation boundary.

The electrical equipment that must be considered for calculating the magnetic field are the overhead high-voltage lines entering or exiting the substation, the substation buses connecting these lines to the transformer bushings, and the underground cables that exit the substation. Each section of line, or bus, or cable must be simulated with a current-carrying segment. The magnetic field from transformers or other substation equipment is frequently negligible compared with the magnetic fields from lines, buses, and cables. It is frequently observed that the largest magnetic fields around the perimeter of a substation are those produced by lines entering or leaving the substation.

The magnetic field is calculated applying the Biot-Savart law (Equations 7.4-12 to 7.4-20). Magnetic field can also be calculated by exercising Applet EMF-7.

7.5 MEASUREMENT OF ELECTRIC FIELDS

7.5.1 Techniques for Measuring the Unperturbed Electric Field

There are different types of meters suitable for the measurement of electric fields from ac power lines. IEEE Standard 644: “Standard Procedures for Measurement of Power Frequency Electric and Magnetic Fields from AC Power Lines” recommends a free-body type meter (IEEE 1994a).

This meter measures the current between two halves of a conductive, isolated body (Deno 1976). The free-body meter is suitable for survey-type measurements because it is self-contained and portable, allows measurements above ground, and does not require a known ground reference.

Other types of electric field meters include ground-reference-type meters, which measure the current to ground of a probe, and electro-optic field meters that measure changes in the transmission of light through a fiber or crystal due to the influence of the electric field. Ground-reference-type meters should be used above grounded conducting surfaces and have found only limited applications. Several electro-optic methods can be used for measuring electric fields, but their application has been limited to laboratory situations.

An electric field meter consists of two parts, the probe and the detector. The probe is the field sensor that produces an electrical signal that is processed by the detector. For free-body meters, the detector is contained in the probe or is an integral part of it and is battery operated. The probe and detector measure the power-frequency-induced current generated by the charge oscillating between the conductive halves (electrodes) of the probe.

Figure 7.5-1 shows the two electrodes of a portable electric field meter. A box containing the detector circuit and the visual display is located between the electrodes. An insulating handle allows the user to hold the meter away from the body at a distance long enough not to affect the measurements (see Figure 7.5-2).

The free-body electric field meter measures the oscillating current flowing between the top electrode and the bottom electrode. This current provides the surface charge to the two electrodes that are at the same potential. A closed-form mathematical expression for the current induced by the electric field is possible when the meter is shaped like a sphere and the two electrodes are hemispheres oriented in the direction of the field to be measured (see Figure 7.5-3).

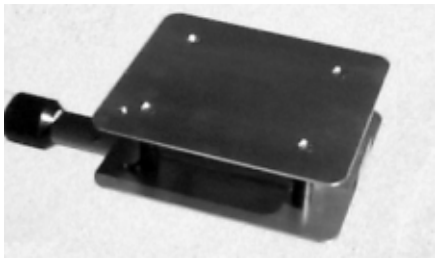

Figure 7.5-1 Free-body ac electric field meter.

Equation 7.5-1 gives the surface charge density, σ, on a conductive sphere in a uniform electric field.

$$\sigma = 3\varepsilon \cdot e \cdot \cos\theta \ \left(\mathrm{C/m^2}\right) \qquad 7.5\text{-}1$$

Where:

- ε is the dielectric constant of air, ($\varepsilon = 8.854 \cdot 10^{-12}$ F/m).
- e is the unperturbed electric field.
- θ is the angle between the direction of the field and the point on the sphere surface where the charge density is calculated.

Integrating the charge density over a hemisphere gives the instantaneous value of the total charge on the hemisphere:

$$q = \int_{\Phi=0}^{2\pi} \int_{\theta=0}^{\pi/2} 3\varepsilon\, e \cos\theta \cdot r \sin\theta \, d\Phi \cdot r \, d\theta \quad = 3\pi\varepsilon \cdot e \cdot r^2 \qquad 7.5\text{-}2$$

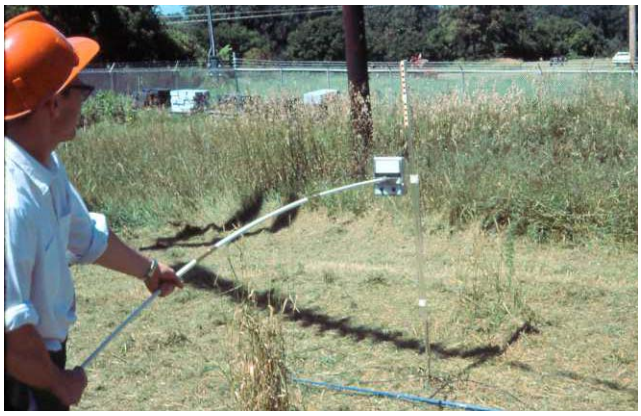

Figure 7.5-2 Measurement of the unperturbed electric field near ground.

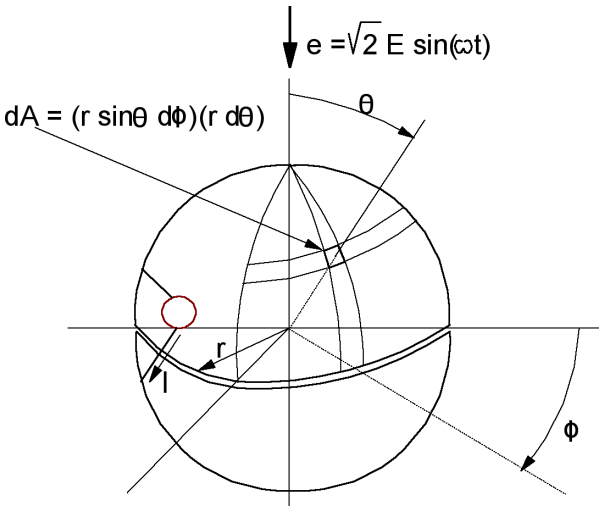

Figure 7.5-3 Current between two hemispheres induced by an electric field.

If the electric field is sinusoidal at a frequency *f*, it can be expressed by Equation 7.5-3, where *E* is the rms value of the field.

$$e = \sqrt{2}E\sin(\omega t)$$
$$\omega = 2\pi f \qquad 7.5\text{-}3$$

The current between the two hemispheres is:

$$i = dq/dt = 3\pi\omega\varepsilon r^2\sqrt{2}E\cos(\omega t) \qquad 7.5\text{-}4$$

The rms value, *I*, of the current is related to the rms value of the field, *E*, by:

$$I = 3\pi\omega\varepsilon r^2 E \qquad 7.5\text{-}5$$

For instance, if E = 1 kV/m and r = 0.1 m, at 60 Hz, the induced current is I = 0.315 μA.

For practical reasons the electrodes are not shaped like a sphere. Therefore, calibration of the meter in a known electric field is necessary. In all cases, however, there is a direct proportionality between induced current and unperturbed electric field. This allows setting the calibration constant independently of the field value.

$$E = \frac{kI}{f} \qquad 7.5\text{-}6$$

Free-body electric field meters are calibrated to read the rms value of the electric field component along the axis of the instrument. The axis of the instrument coincides with the axis of symmetry. If the electrodes are not symmetric, the meter axis must be specified. Equation 7.5-5 applies only to electric fields that are sinusoidal, such as those of most power lines, and at the frequency for which the meter has been calibrated. For these fields, any type of detector (rms, rectified average, etc.) is adequate for accurate measurements. If the electric field contains harmonics, however, the readings of the instrument depend on the type of detector. Some meters may be switched from one type of detector to another and provide a measure of the amount of electric field harmonics.

Equations 7.5-5 and 7.5-6 assume a uniform electric field. However, nonuniform fields also are measured with negligible errors.

The electrodes of the free-body meter cannot be placed in contact with the conductive surface of a body without severely perturbing the field. However, measuring the electric field close to the surface of grounded objects causes very little error. For instance, if the distance between the center of the instrument and the surface of a grounded object is greater than the largest dimension of the meter, the measurement error is less than 5%.

Since the meter measures only one component of the electric field, it is common practice to change the orientation of the meter axis by turning the handle or rotating it in the vertical plane until a maximum electric field value is read. This is the maximum field component, and it lies along the major axis of the field ellipse. In power line situations, measurements are often made near the ground (for instance, at a height of about 1 m). In these cases, the field meter may be held to measure the vertical component of the electric field. The vertical component practically coincides with the maximum field, while the horizontal component is negligible in comparison.

Measurement standards provide guidance for the measurement of power-frequency electric fields from ac power lines (IEEE 1994a). Calibration of the meter may be performed in a parallel plate system that generates a known electric field (Shih et al. 1977; Takuma et al. 1985). The recommended geometry consists of parallel plates 1.5 m x 1.5 m, with 0.75 m spacing between plates. The electric field strength at the center of this system is within 1% of the uniform field given by the voltage between plates divided by the plate spacing. This small error is predicated on the condition that the electric field meter has no diagonal dimension greater than 0.23 m. Once an electric field meter has been calibrated in a parallel plate system, its calibration can be more conveniently checked by injecting a known current between the electrodes.

Another calibration method is to measure the current flowing between a conductive plate of known area and a flat ground (EPRI 1982). Although this method is less accurate than the parallel plate method, it is convenient for transmission-line work because it employs the ac field generated by the line itself. The current induced in a 1×1-m plate by an electric field at a frequency, *f*, has a magnitude given by:

$$I = 2\pi f\varepsilon E \qquad 7.5\text{-}7$$

In a 60-Hz field of 1 kV/m, the current collected by the plate is 3.34 μ A; in a 50-Hz field, the current is 2.78 μ A. Conversely, if the measured induced current is *I* (ampere), the electric field is:

$$E = \frac{I}{2\pi f\varepsilon} = 3\cdot 10^8 I \ (\textit{for } 60\ \textit{Hz}),$$
$$= 3.6\cdot 10^8 \ (\textit{for } 50\ \textit{Hz}) \ \left(\mathrm{V/m}\right) \qquad 7.5\text{-}8$$

To obtain accurate results, an insulating sheet must be placed between the plate and the ground, and a guard ring must be placed around the plate and grounded through a

separate connection, other than that between plate and ground through the measuring ammeter (see Figure 7.5-4). For best accuracy, the plate should be a little less than 1 m^2. The air gap that separates the plate from the guard ring must have the edges perfectly aligned on a flat plane so that the dielectric flux is divided equally between plates and guard ring. The effective area of the plate is equal to the area of the center panel plus one half the area of the gap. The width of the guard ring should be at least five times the height of the plate above the virtual ground. The virtual ground may be a few centimeters below the surface of dry gravel, macadam, or the like. To minimize field distortion, the meter and the operator should be away from the plate and the operator must kneel.

The procedure recommended by the IEEE for measuring the lateral profile of the electric field of transmission lines consists of holding the meter at the height of 1 m above ground, at a distance of at least 2.5 m from the operator (see Figure 7.5-2) (IEEE 1994a). Usually, however, only small errors are encountered when the meter is kept at 1 m height even when the meter is kept at 1.5 m from the operator (DiPlacido et al. 1978). The measured field would be greater than the unperturbed field if the meter were kept at a height greater than 1 m, because the body of the operator would enhance the field at those heights. At heights lower than 1 m, the operator would partially shield the meter and the measured field would be lower than the unperturbed field.

The typical accuracy of practical outdoor electric field measurements is near 10%, but in controlled conditions it is easily better than 5%. The accuracy is limited by a number of factors that include:

- distortion of the field caused by the body of the person holding the meter,
- conductivity of the handle (measurements in the presence of moisture may give erroneous results),
- error in reading a display at a distance,
- error in calibrating the meter,
- difficulty in positioning the meter at the desired point and with its axis in the desired direction,
- an error dependent on the detector type, particularly if the field has a significant harmonic content.

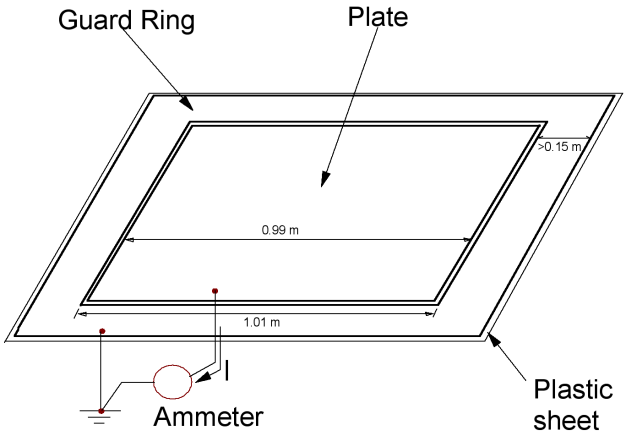

Figure 7.5-4 Conductive plate arrangement for field meter calibration near a power line.

When comparing measured and calculated values of the electric field, it must be noted that errors may occur both in the measurements and in the calculations. Calculation errors may occur because the geometry may not be well known or is not well simulated, the terrain may not be flat, and objects that cannot be well simulated in the calculations may perturb the field. If the terrain is not flat, the field close to ground will be enhanced by hills and reduced by valleys. If the ground is irregular or if there is tall grass, a virtual average ground that accounts for these irregularities should be assumed for the calculations and the measurements should be made away from any protuberance. The presence of bushes or trees will reduce the field at ground, often by a significant amount (see Section 7.16).

7.5.2 Measurement of the Electric Field on a Boundary Surface

The electric field, E, on a boundary surface may be determined by measuring the current, I, induced in a known area, S, and using Equation 7.5-9.

$$I = 2\pi f \varepsilon E S \qquad 7.5\text{-}9$$

An example of an application is the measurement of the electric field at ground by means of a flat plate, as shown in the previous section. The technique used for more complex surfaces is shown in Figure 7.5-5. In this example, the current is measured from a sensor consisting of a small square of copper foil surrounded by more copper foil that acts as a guard ring. A coaxial cable, with its shield connected to the

Figure 7.5-5 Measurement of electric field on a boundary surface.

guard ring and grounded, is used to connect the sensor to the ammeter.

7.5.3 Measurement of the Space Potential

The space potential is a very useful parameter to characterize the induction by electric fields in tall vertical objects in a transmission-line environment or in objects in a nonuniform electric field such as in a substation. In fact, the currents induced in objects in a nonuniform field are a function of the unperturbed space potential and not of the unperturbed electric field.

A technique suitable for the measurement of space potential is shown in Figure 7.5-6. The probe consists of a conductive object of small dimensions, placed at the measuring point and grounded through a shielded wire. An ammeter is placed in series with the wire between the probe and the ground. The shield of the wire is connected to the case of the meter and to ground. The current collected by the shield should flow to ground bypassing the meter. The measuring system is shown schematically in Figure 7.5-7.

The current induced in the probe is given by:

$$I_{probe} = k\,[(V_{sp} - V_{probe}) + L \cdot E] \qquad 7.5\text{-}10$$

Where:

- k is a coefficient of proportionality, which depends on the shape of the probe.
- V_{sp} is the space potential before insertion of the probe (unperturbed space potential). V_{probe} is the voltage of the probe.
- E is the unperturbed electric field at the probe location.
- L is a dimension function of the geometry of the probe.

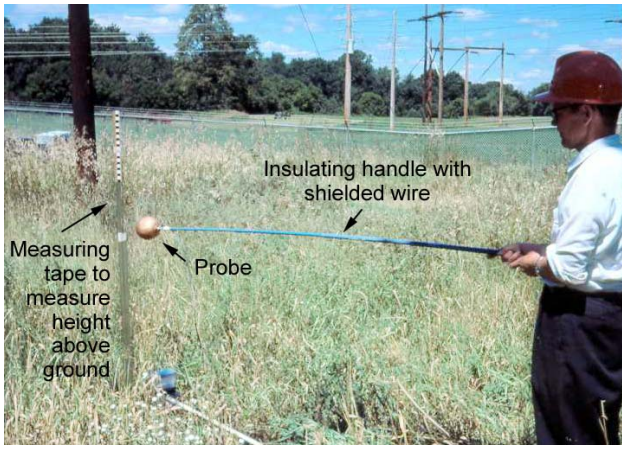

Figure 7.5-6 Measurements of the unperturbed space potential.

If the probe consists of a sphere of radius R, then $L = 3R$. For probes of small dimensions with respect to the distance to ground, the term $L \cdot E$ is very small in comparison to V_{sp} and can be neglected. If the probe is grounded, $V_{probe} = 0$, Equation 7.5-10 becomes:

$$I_{probe} \approx kV_{sp} \qquad 7.5\text{-}11$$

Equation 7.5-11 indicates that the current induced in the probe is directly proportional to the space potential. The probe calibration constant k is determined through a calibration procedure. The probe is placed in the center of the parallel plate setup used to calibrate the field meter (see Section 7.5.1), as shown in Figure 7.5-8. A known voltage, V (e.g., 100 V), is applied to the entire measuring system (probe, shielded cable, and ammeter all connected together), while the two plates are connected together and kept at ground potential. If the ammeter measures a current I, the probe calibration constant is I/V.

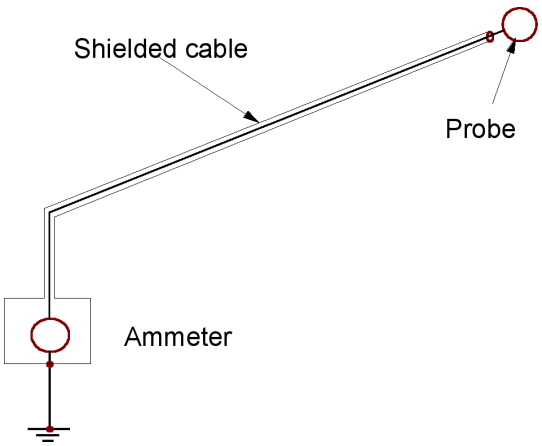

Figure 7.5-7 Schematic diagram of the space potential measuring system.

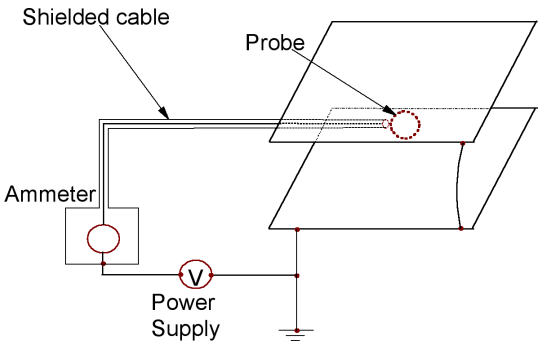

Figure 7.5-8 Schematic diagram of the calibration of a space potential probe.

7.6 MEASUREMENT OF MAGNETIC FIELDS

7.6.1 Magnetic Field Meters

A vast array of magnetic field meters is available. The IEEE has provided specifications to characterize instrumentation for measuring magnetic fields with sinusoidal frequency content in the range of 10 Hz to 3 kHz (IEEE 1994b).

Magnetic field meters consist of two parts: the sensor (or sensors) and the detector. The sensor can be made of wire coils from several inches to a fraction of an inch in diameter. For use near power lines, the coils must be electrically shielded in order to be immune from interference caused by the electric field. Small coils are sometimes wound around ferromagnetic cores. This arrangement has the same effect as increasing the area of the coil. The sensor coil is connected to a detector that measures the voltage across the coil. If the coil has N turns and an equivalent area A (see Figure 7.6-1), the voltage induced by a magnetic field is given by:

$$V = NA\frac{db_z}{dt} \qquad 7.6\text{-}1$$

Where:

b_z is the component of the magnetic field perpendicular to the area of the loop.

The measured quantity depends on the circuitry of the detector. In some cases, the voltage is integrated, and the rms value of the integrated quantity is measured. In this way, the rms value of the field is obtained. Some meters have a detector circuit that filters all frequencies but one—for instance, 60 Hz. Other meters operate in a wide frequency range. For example, some magnetic field meters measure the rms value of the magnetic field in the frequency range from 40 to 800 Hz. Filtering out the low frequencies is important if the meters are used for surveys requiring movements in the magnetic field of the earth. In fact, even though the magnetic field of the earth is constant (dc), movements may cause changes in the magnetic flux in the coil and therefore (see Equation 7.6-1) may induce a voltage. In this respect, body movements are relatively slow, and filtering out frequencies up to 10 Hz is usually sufficient to avoid interference even when measuring the lowest power-frequency fields.

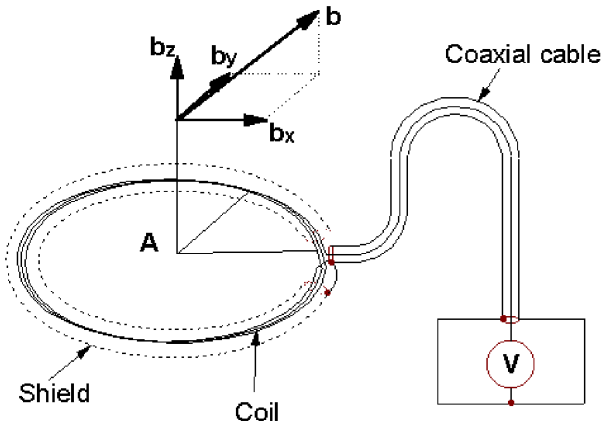

Figure 7.6-1 Magnetic field meter with sensor coil and voltmeter detector.

The recommended procedure for calibrating magnetic field meters is to introduce the meter (or the probe only, if separate from the meter) into a uniform magnetic field of known magnitude and direction (IEEE 1994a; Frix et al. 1994). Helmholtz coils are frequently employed for this task. A single square loop of many turns, N, of wires can also be used. In this case, the uniformity is reduced, but sufficient accuracy can still be obtained. The magnetic field in milligauss, B, in the center of the loop is perpendicular to the plane of the loop and is given by:

$$B = \frac{8\sqrt{2}NI}{L} \qquad 7.6\text{-}2$$

Where:

I is the current in a wire.

N is the number of turns.

L is the length of the side of the square loop.

Magnetic field meters with only one sensor coil are called single-axis meters. They measure the component of the field along the axis of the coil. For completeness, the field components along three orthogonal directions should be measured by orienting the sensor coil along these directions. If the measured field components, B_x, B_y, and B_z are rms values, the rms value of the resultant magnetic field, B, is given by:

$$B = \sqrt{B_x^2 + B_y^2 + B_z^2} \qquad 7.6\text{-}3$$

If the field is at the power frequency with no significant harmonics, the vector field rotates in space describing an ellipse. The component along the major axis of this ellipse, B_{max}, is measured by changing the orientation of the probe until the maximum reading is obtained.

Single-axis meters are useful for finding the location of field sources consisting of hidden conductors (e.g., underground water pipes) carrying a net current. In proximity of these sources, the maximum reading is obtained when the coil (see Figure 7.6-1) lies in the plane containing the field-producing conductor. The location of the wire may be estimated by making measurements at two different points.

Modern digital magnetic field meters have three sensor coils that measure simultaneously three orthogonal compo-

nents. The value of the three components is processed internally by the meter according to Equation 7.6-3. The meter directly provides the resultant field B. The rms resultant field read by a three-axis meter does not change with the orientation of the meter, because the value of B is independent of the choice of the three orthogonal axes. Magnetic field meters of this type usually do not provide information about the phase angle of the measured field. The value of B_{max} cannot be derived from three orthogonal component magnitude measurements.

Three-axis digital meters can be of two types: survey meters and digital recorders. Survey meters display the value of the field. As the field changes, the display is refreshed and the new value is displayed. The time between two successive measurements should be short (e.g., 0.5 s or less) to allow for rapid search of sources of field. Digital recorders not only display the value of the field but also store it in memory. The field may be measured at a fixed time interval and the values may be stored in memory. These meters have a provision for downloading the data into a PC at the end of the measurement period. Meters of this type may have additional features that allow measurements of the field versus time, field versus distance, and area mapping of the field. The last two features are made easy by the use of a calibrated wheel that sends to the meter information about the distance traveled.

7.6.2 Measurement of Magnetic Field from Power Lines

According to the IEEE, the magnetic field should be measured at a height of about 1 m above ground level (IEEE 1994-2). The value of the field is not very sensitive to variations of height. However, if another height is used, it should be explicitly indicated. If a single-axis meter is used, the probe should be oriented alternatively in three orthogonal directions in order to measure the vertical field (B_z), the horizontal field perpendicular to the power line (B_x), and the horizontal field parallel to the power line (B_y). The maximum value (magnitude of the field ellipse major axis) can also be measured if desired to obtain a measure of the field polarization. The component of the field parallel to the line, in the case of a long line without changes in direction, is negligible. Most conveniently, however, measurements are made with a three-axis digital recorder. B_x, B_y, and B_z are measured simultaneously and their resultant $B = \sqrt{B_x^2 + B_y^2 + B_z^2}$ is displayed. Orthogonal components and resultant are stored in memory.

The body of the operator does not affect the magnetic field. Therefore, the operator may stay close to the meter. Most objects are nonmagnetic and do not affect the measurements. Objects containing magnetic materials (e.g., cars and trucks) should be kept away (at least three times the largest dimension of the object).

The magnetic field of a power line is described by the magnetic field "lateral profile." This is a plot of the magnetic field versus distance in a direction perpendicular to the power line. A lateral profile can be obtained by carrying the meter. At known locations, the operator may stop and record the information. The lateral profile can be easily obtained using the special wheel mentioned earlier. The operator must walk slowly in the direction perpendicular to the line. It is a good practice to measure the height of the line at the location of the profile. Line height can change with current and weather conditions. These changes affect the field under the conductors and to a much lesser extent the field at the edge of the right-of-way and beyond.

The magnetic field depends on the current of the line, which may vary in time. Therefore, the date and time of the lateral profile must be recorded. If the line current at the time of the measurements is known, the lateral profile may be expressed in mG/A, and the magnetic field can be estimated for other current values, such as those corresponding to future loads.

A magnetic field recorder placed at a fixed location may be used to record temporal variations of magnetic field. Variations of magnetic field may be significant, although not as large as those caused by many other common field sources. Figure 7.6-2 shows two 24-hour plots of the magnetic field measured in two different residences—one in which the field was caused predominantly by a transmission line, and the other in which the field was caused by currents in the residence's grounding system, which is the most common source of residential magnetic field in North America (Zaffanella 1993). Both plots show a dependence of the field on the hour of the day. Short-term variability of the transmission-line field, however, is comparatively small. Daily and seasonal variations may be significant. Magnetic fields that are calculated on the basis of line current rating are worst-case scenarios because transmission lines are typically operated well below rating. Utilities and power pools variously define the rating of a transmission line: peak load, emergency load, design load, winter normal continuous capacity of the circuit, winter normal continuous capacity of the conductors, winter short-time emergency rating of the conductors, etc. The relation between actual magnetic field and calculated magnetic field at line rating is a function of the type of line. For instance, New York State utilities in 1990 estimated that the yearly average magnetic field at the edge of the right-of-way of their EHV transmission lines was only about 10% of the magnetic field calculated using winter short-time emergency rating. However,

the values calculated in these emergency conditions may be reached or approached for short periods of time.

Magnetic field measurements, in general, compare well with computer modeling calculations (Olsen et al. 1988). The uncertainty of magnetic field measurements results from the combination of calibration errors, temperature effects, and influence of extraneous fields. For carefully made measurements, the error should be well within ± 10%. The uncertainty of the results of calculations may be larger because of errors in measuring conductor heights, uncertainty in the values of the current at the time of the measurements, errors in the calculation of shield wire currents, and lack of knowledge about buried conductors that may carry induced currents. At large distances from the transmission line, magnetic field from earth currents may become important, and magnetic field from line current unbalance may dominate the measurements.

7.6.3 Waveform Capture Instrumentation

Instruments that capture and digitize the waveshape of the magnetic field are available. The field is measured along three orthogonal axes. The instantaneous values of the field components along each axis are sampled at a high rate in order to correctly measure harmonics of the field. For instance, a sampling rate greater than 2000 Hz is needed to measure harmonics up to 720 Hz (11th harmonic of 60 Hz). Some instruments also measure the dc field along three orthogonal axes. One cycle of the power frequency is sufficient to characterize the waveshape of transmission-line fields.

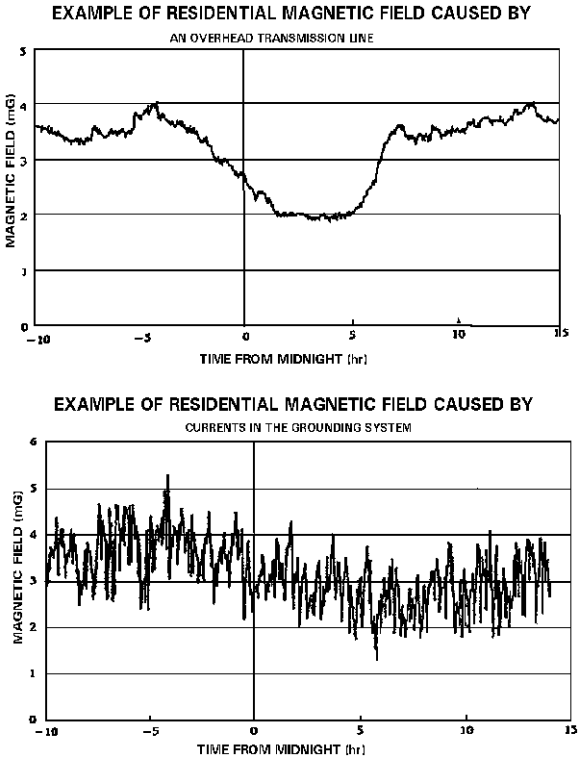

Figure 7.6-2 24-h magnetic field recordings. Top: field from a transmission line. Bottom: field from currents in a residential grounding system.

Waveshape capture instruments store the digitized waveshape in their internal memory. The data are downloaded to a PC and analyzed after the measurements. Some instruments display the waveshapes of the three orthogonal components. The parameters of the wave can be calculated after downloading the data into a PC or may be displayed directly by the instrument. These parameters include the coefficients of the Fourier series of each space component, the rms value of each frequency component, and the degree of polarization at the fundamental frequency and at each harmonic frequency.

The magnetic field of an ac transmission line is, in general, characterized by a relatively pure sinusoidal wave with little harmonic content. Within the right-of-way, the harmonic content is similar, but not equal, to the harmonic content of the line current. Typically, the third and fifth harmonics are of the order of 0-1% of the fundamental. Higher harmonics are, in general, less than 0.1%. The third harmonic field is monopolar. It decays at a slower rate than the field at the fundamental frequency and of the fifth harmonic, which are generally dipolar. Therefore, the magnetic field third harmonic percentage increases with the distance from the line.

Waveform capture instrumentation also provides the phase angle of each field component and, therefore, makes it possible to measure the polarization of the field.

7.7 COMPARISON BETWEEN HV TRANSMISSION-LINE AND COMMON ENVIRONMENT ELECTRIC AND MAGNETIC FIELDS

The power-frequency electric fields that exist near ground within the right-of-way of EHV transmission lines are practically the highest to which people may be exposed. The power-frequency magnetic fields are also significantly higher than ambient fields, but there are many other common environments with comparable or higher magnetic field values. Table 7.7-1 shows typical values of the electric and magnetic field for 230-kV and 500-kV transmission lines. Electric and magnetic fields that are encountered in other common environments are shown in Table 7.7-2.

Table 7.7-1 Typical Transmission Line Electric and Magnetic Field Levels

Line Voltage (kV)	Electric Field				Magnetic Field[1]			
	Max (kV/m)	Edge of Right-of-Way (kV/m)	At 30 m (kV/m)	At 60 m (kV/m)	Max (mG)	Edge of Right-of-Way (mG)	At 30 m (mG)	At 60 m (mG)
230	2	1.5	0.3	0.05	60	20	7	1.8
500	7	3	1	0.3	100	30	13	3.2
1. 1 mG = 0.1 μT								

Table 7.7-2 Electric and Magnetic Field Levels in Common Environments (Data from the U.S.)

Electric Field		Magnetic Field[1]	
Largest field at ground level near overhead distribution lines [2]	For 50% of the lines: > 8 V/m For 5% of lines: > 60 V/m	**Residential field at center of rooms [3]**	
Sofa/chair near lamp [4]	4 – 15 V/m	50% of houses, average for all rooms	0.6 mG
Under fluorescent light [4]	4 – 7 V/m	50% of houses, room with highest field	1.1 mG
Middle of rooms with lights and appliances [4]	0.5 – 8 V/m	5% of houses, average for all rooms	2.6 mG
Workshop with electric tools [4]	8 – 55 V/m	5% of houses, room with highest field	5.6 mG
Under electric blanket [4]	10 – 50 V/m [5]	1% of houses, average for all rooms	5.8 mG
Shopping mall [4]	4 – 7 V/m	1% of houses, room with highest field	12.2 mG
Classrooms w/o fluorescent lights [2]	< 0.5 V/m	Average field in 50% of classrooms [2]	0.4 mG
Classrooms with fluorescent lights [2]	2 – 15 V/m	Average field in 5% of classrooms [2]	1.3 mG
Magnetic Field near Appliances		Average for grocery stores [7]	1.9 mG
Electric range, 27 cm away [3]	2 – 28 mG [6]	5% of the area of grocery stores [7]	7.5 mG
Television, 27 cm away [3]	3 – 12 mG [6]	Average for hospitals [7]	1.3 mG
Air conditioner, window unit, 27 cm away [3]	0.5 – 9 mG [6]	5% of the area of hospitals [7]	3.7 mG
Microwave oven, 27 cm away [3]	17 – 67 mG [6]	Average for office buildings [7]	0.7 mG
Analog clock/radio, 27 cm away [3]	2.5 – 25 mG [6]	5% of the area of office buildings [7]	2.5 mG
Fluorescent light, 27 cm away [3]	1 – 23 mG[6]	Average for machine shops [7]	3.9 mG
Aquarium pumps, 27 cm away [3]	1.2 – 63 mG [6]	Time distribution for welders in machine shops [7]	50%: 5.2 mG 5%: 25 mG
Toaster oven, at 27 cm [3]	1 - 20 mG [6]		
Electric heater, at 27 cm [3]	1.6 - 41 mG [6]		
Dishwasher, at 27 cm [3]	5 - 15 mG [6]		
Can opener, at 27 cm [3]	12 - 325 mG

7.8 ELECTRIC FIELD INDUCTION IN OBJECTS

7.8.1 Introduction

The electrical quantities that define the effects of transmission-line electric field on an object are:

- The current, I_{sc}, that would flow in a short circuit from the object to ground or to another grounded object.
- The voltage, V_{og}, induced between object and ground or another grounded object.
- The energy, J, that is discharged in a spark occurring when a contact is made between the object and ground or another grounded object. If the spark occurs at the peak of the voltage wave, J represents the maximum energy stored (excluding trapped charge effects).

The electrical parameters of the object are:

- The equivalent surface area, S, of the object. This quantity is defined as the area of a flat plate that would collect the same short-circuit current, I_{sc}, as that collected by the object. The plate is placed at ground level in a uniform field of the same value as the average unperturbed field to which the object is exposed (Deno 1975).
- The power-frequency impedance, Z_{og}, of the object to ground. This impedance is measured at the power frequency (50 or 60 Hz). For some objects, it can be represented with a Norton equivalent impedance consisting of a resistance in parallel with a capacitance. For certain other objects, such as vehicles on rubber tires, the impedance to ground consists of a complex network of resistances and capacitances (see Figure 7.8-1) that cannot be represented by a simple resistance in parallel with a capacitance.
- The spark-discharge capacitance, C_s. This is the capacitance of the object to ground that is discharged with a short time constant, not affected by the resistances to ground of the object, when the object contacts the ground (Maruvada and Hylten-Cavallius 1975). If the object is well insulated from ground, the impedance to ground is due only to this capacitance: $Z_{og} = 1/(2\pi f C_s)$.

The unperturbed average electric field, E, at the location of the object represents the source of induction. It allows the evaluation of the induction on an object without considering the actual geometry and electrical parameters of the conductors that generate the electric field. Without this simplification, the calculation would be very complicated. This simplification is justified because the presence of the object has a negligible effect on the electrical charges on the conductors that generate the electric field at the object. If the unperturbed field is nonuniform over the volume occupied by the object, the average unperturbed field should be considered. For tall objects, the average unperturbed field can be substituted by the space potential divided by the height of the object. For long objects, over whose length the electric field is not constant either in magnitude or in phase, an equivalent uniform electric field must be calculated (see Section 7.8.4). The current induced in an object in a uniform field can be calculated using scale models of the object (EPRI 1982) or analytical techniques (Tranen and Wilson 1971; Appendix 7.6).

Given the unperturbed average electric field, E, and the electrical parameters of the object, S, Z_{og}, and C_s, the induction quantities are calculated as follows:

$$\tilde{I}_{sc} = j2\pi f \varepsilon \tilde{E} S \qquad 7.8\text{-}1$$

The phase angle of the current is 90° greater than that of the field.

For 60 Hz, $I_{sc} = ES/(3 \cdot 10^8)$.
For 50 Hz, $I_{sc} = ES/(3.6 \cdot 10^8)$.

$$V_{og} = I_{sc} \cdot Z_{og} \qquad 7.8\text{-}2$$

$$J = \frac{1}{2} C_s \left(\sqrt{2} V_{og}\right)^2 = C_s \cdot V_{og}^2 \qquad 7.8\text{-}3$$

Where:

J is the energy that is discharged when the object-to-ground voltage is at its peak, which is $\sqrt{2}$ times greater than the rms value.

The capacitance C_s is used because other capacitances (e.g., the tire capacitance to ground C_g) would be discharged with a longer time constant (see Figure 7.8-1). Spark discharges take place with time constants of 1μs or less. The series resistance R_s is sufficiently large to make the spark-discharge contribution of C_g negligible. The impedances to ground in the equivalent circuit are subject to a large degree of uncertainty, and the open-circuit volt-

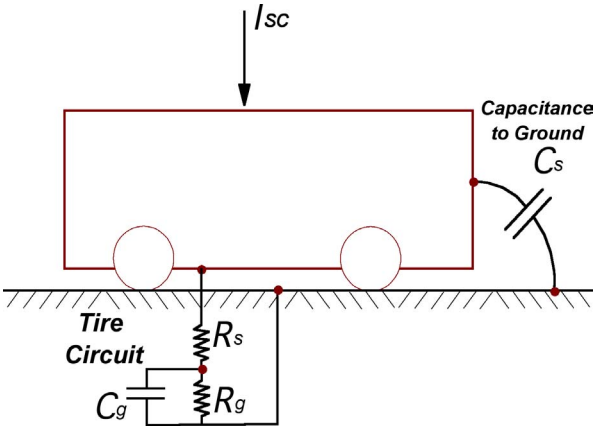

Figure 7.8-1 Equivalent circuit of a vehicle for power-frequency electric field induction.

age to ground is extremely variable (Reilly 1982). The most reliable measurement is that of the short-circuit current, which is the basic quantity that defines the electric field induction.

7.8.2 Electrical Parameters of Objects with Different Shapes

Sphere above Ground

A sphere of radius r at a height h above ground has an equivalent charge-collecting area given by Equation 7.8-4

$$S = \frac{4\pi h}{\frac{1}{r} - \frac{1}{2h}} \quad \text{for} \quad h >> r \quad \text{s} = 4\pi hr \qquad 7.8\text{-}4$$

When this equation is considered in combination with Equation 7.8-1 and with the concept that in a uniform electric field, the space potential at the sphere is $V_{sp} = Eh$, the result is:

$$I_{sc} = j\omega\varepsilon V_{sp} \frac{4\pi}{\frac{1}{r} - \frac{1}{2h}} \quad \text{for} \quad h >> r$$
$$I_{sc} = j\omega\varepsilon V_{sp} 4\pi r \qquad 7.8\text{-}5$$

Equation 7.8-5 is applicable also when the electric field is nonuniform.

The capacitance of a sphere is:

$$C_s = 4\pi\varepsilon r \qquad 7.8\text{-}6$$

Hemisphere on a Ground Plane

The equivalent charge-collecting area is:

$$S = 3\pi r^2 \qquad 7.8\text{-}7$$

This area is three times larger than the projected area. The shape factor, defined as the ratio between equivalent charge-collecting area and the projected area, is 3.

Half-Ellipsoid on a Ground Plane

The equivalent charge-collecting area of a hemisphere given in Equation 7.8-7 may be extended to a half-ellipsoid with semi-axes equal to a and b on the ground plane as follows:

$$S = 3\pi ab \qquad 7.8\text{-}8$$

Cylinder above Ground

The equivalent charge-collecting area of a long cylinder above ground must be referred to the unit of length, L, of the cylinder and is:

$$S/L = \frac{2\pi h}{\ln(2h/r)} \qquad 7.8\text{-}9$$

The short-circuit current, expressed as a function of the space potential, is:

$$I_{sc} = j\omega\varepsilon V_{sp} \frac{2\pi}{\ln(2h/r)} \qquad 7.8\text{-}10$$

If the cylinder is not very long in relation to its height above ground, the end effects will significantly affect the value of S. The end effects may be estimated equivalent to the addition of the equivalent charge-collecting area of a sphere with radius and height above ground equal to those of the cylinder.

$$S = \frac{2\pi h}{\ln(2h/r)} \cdot L + \frac{4\pi h}{\frac{1}{r} - \frac{1}{2h}} \qquad 7.8\text{-}11$$

Half-Cylinder on a Ground Plane

The equivalent charge-collecting area per unit of length, L, of a long half-cylinder on a ground plane is:

$$S = 4rL \qquad 7.8\text{-}12$$

This area is two times larger than the projected area. The shape factor, previously defined for a hemisphere, is 2.

If the half-cylinder is not very long in relation to its height above ground, the end effects will significantly affect the value of S. The end effects may be estimated equivalent to increasing the length of the cylinder by an amount equal to the radius of the cylinder.

$$S = 4r(L + r) \qquad 7.8\text{-}13$$

Vertical Cylinder

The equivalent charge-collecting area of a vertical cylinder (see Figure 7.8-2) is given by Equation 7.8-14 (Reilly 1978).

$$S = \frac{\pi L^2}{\ln\left[\frac{L}{r}\sqrt{\frac{4h + L}{4h + 3L}}\right]} \qquad 7.8\text{-}14$$

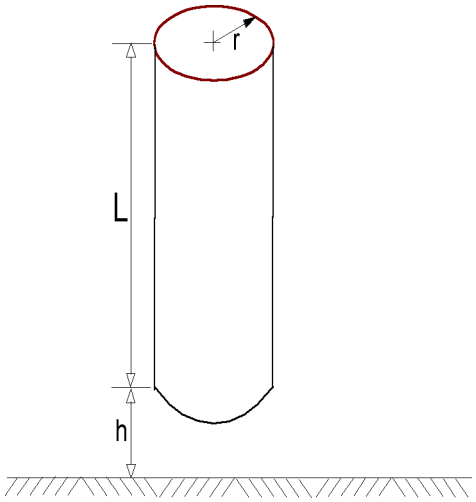

Figure 7.8-2 Vertical cylinder above ground.

Box

The equivalent charge-collecting area of a box may be obtained from the curves of Figure 7.8-3, which give the shape factor (*S/AB*) of a box with length *A*, width *B*, and height *H* of the top surface above the ground plane. The curves are given for the box placed on the ground plane (*C = 0*, see Figure 7.8-3). However, the curves may also be used with an error less than 10% for *0 < C < B/2*. These curves were obtained from experimental data using boxes formed with metallic wire mesh placed on a flat ground in a known electric field.

The use of Figure 7.8-3 is indicated in the following example. Assume that *A* = 1.22 m, *B* = 0.61 m, and *H* = 0.71 m. Then *A/B* = 2 and *H/B* = 1.16. The shape factor is obtained by interpolation of the data obtained in correspondence of *A/B* = 2 from the curves in Figure 7.8-3 for *H/B* = 1 and *H/B* = 2. A shape factor *S/AB* = 6.2 is obtained. Thus the equivalent charge-collecting area of the box is *S* = 4.62 m².

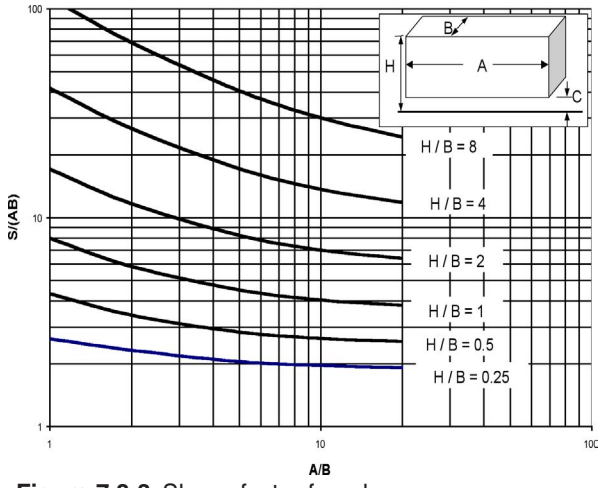

Figure 7.8-3 Shape factor for a box.

Horizontal Rectangular Plate

The equivalent charge-collecting area of a horizontal rectangular plate may be obtained from the curves of Figure 7.8-4, which give the shape factor (*S/AB*) of a plate with length *A*, width *B*, and height *H* of the plate above the ground plane. These curves also were obtained from experimental data.

The use of Figure 7.8-4 is indicated in the following example. Assume that *A* = 1.22 m, *B* = 0.61 m, and *H* = 0.71 m. These are the same parameters of the example for the box. The shape factor obtained from the data of Figure 7.8-4 is *S/AB* = 5. Thus the equivalent charge-collecting area of the plate is *S* = 3.72 m².

Objects with Any Shape Close to Ground—The 45° Shield Angle Approximation

When an object has a complex shape, its equivalent area may be estimated by projecting the top edges of the object on the ground using 45-degree cones. The total area of the projections obtained in this way is taken as the equivalent charge-collecting area. An example of an application of this method is shown in Figure 7.8-5. In this case. the equivalent charge-collecting area is: $S = AB + 2H(A+B) + \pi H^2 = 4.9$ m².

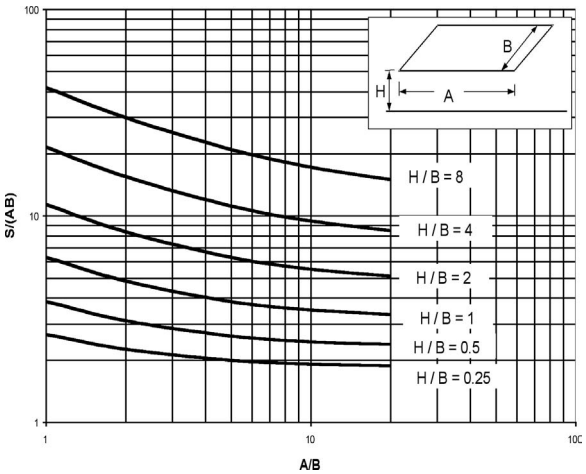

Figure 7.8-4 Shape factor for a horizontal plate.

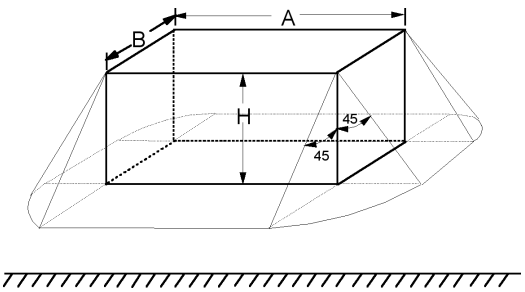

Figure 7.8-5 Equivalent area calculated using the 45° shield angle approximation.

Silos

The shape factor for a silo with diameter D and height H is given by the curves of Figure 7.8-6. The equivalent charge-collecting area, S, is obtained multiplying the silo area projected on the ground, $\frac{\pi D^2}{4}$, by the shape factor.

Houses

The shape factor for buildings with a rectangular cross plan (A x B) is given by the curves of Figures 7.8-7 to 7.8-9. The equivalent charge-collecting area, S, is obtained by multiplying the building area projected on the ground, $A \cdot B$, by the shape factor.

Antennas

The short-circuit current of antennas mounted on buildings in proximity of transmission lines may flow in the body of a person during installation or maintenance. The short-circuit

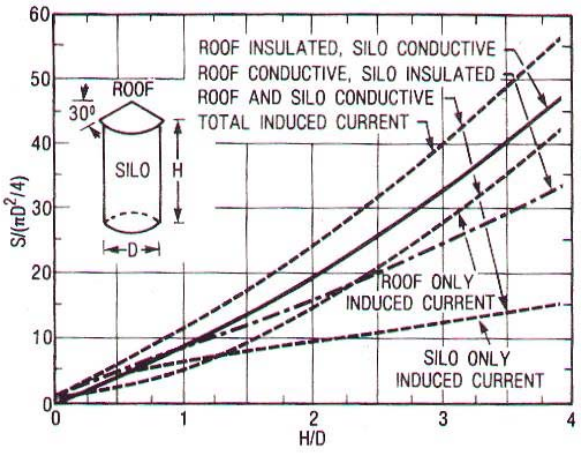

Figure 7.8-6 Shape factor for silos.

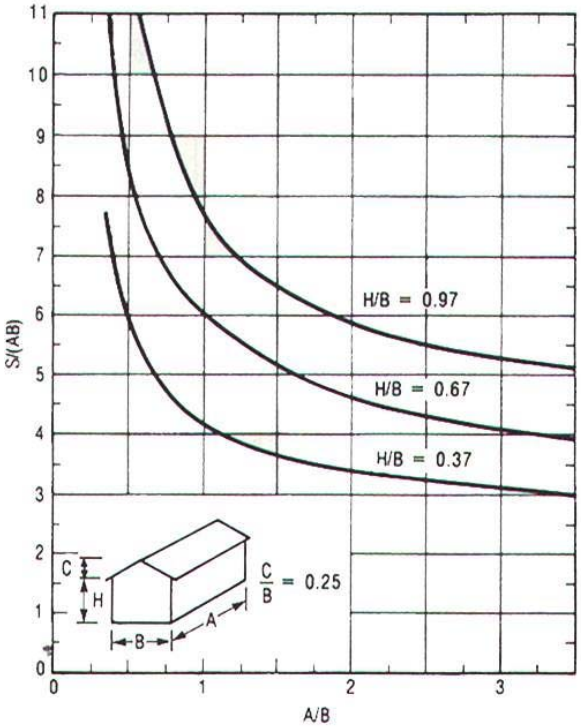

Figure 7.8-7 Shape factor for conductive gable roofs with insulating buildings.

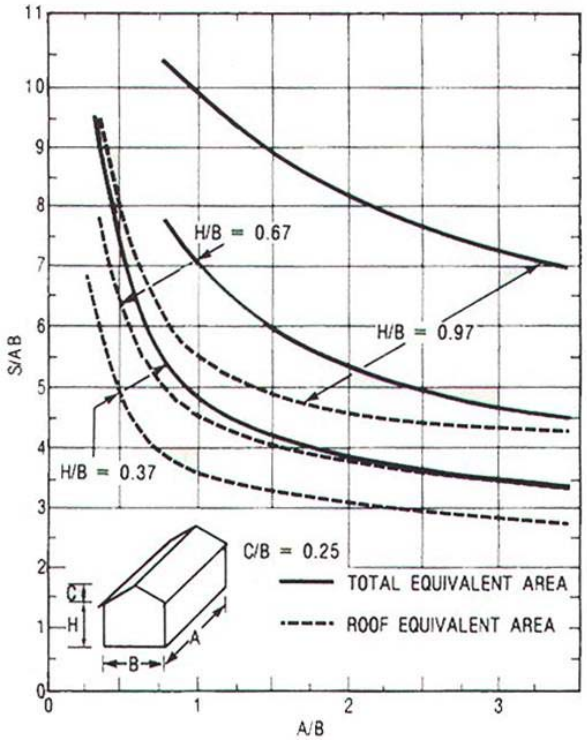

Figure 7.8-8 Shape factor for conductive buildings with conductive gable roofs.

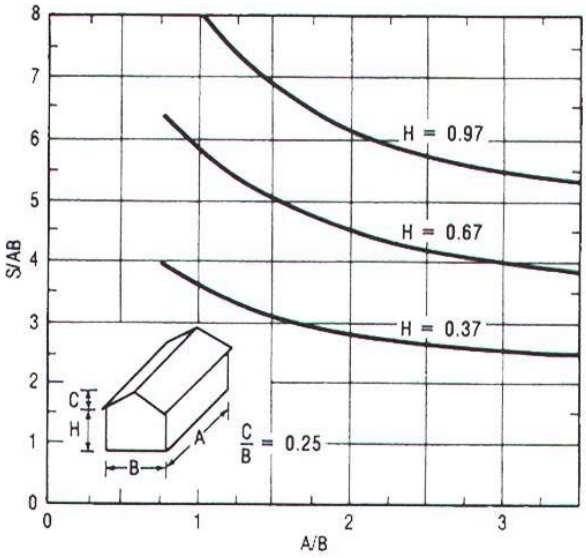

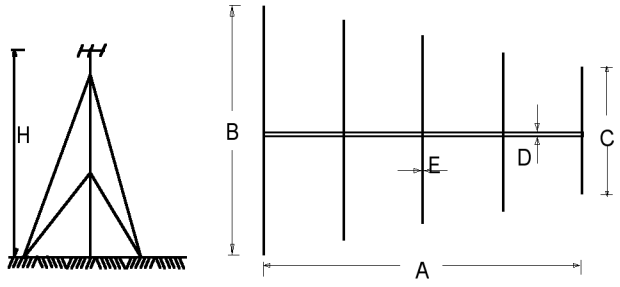

Figure 7.8-9 Shape factor for conductive buildings with insulating gable roofs.

current is given by Equation 7.8-1, in which E represents the average electric field over the antenna height perturbed by the presence of the building, and S is the equivalent charge-collecting area of the antenna. The field perturbation caused by the building, assumed conductive, is shown in the example of Figure 7.8-12. An accurate calculation of the perturbed field can be made using 3-D electric field computer programs. The equivalent charge-collecting areas of three different antennas (shown in Figure 7.8-10) are given by the curves of Figure 7.8-11. The spark-discharge capacitance, C_s, of an antenna depends on its dimensions. The value of C_s is indicated in Figure 7.8-10 for heights above ground of 10 m or greater. The capacitance increases when the height above ground is decreased and becomes 20–50% higher when the height is 1 m.

Figure 7.8-10 Dimensions of antennas whose equivalent charge-collecting area is given in Figure 7.8-11.

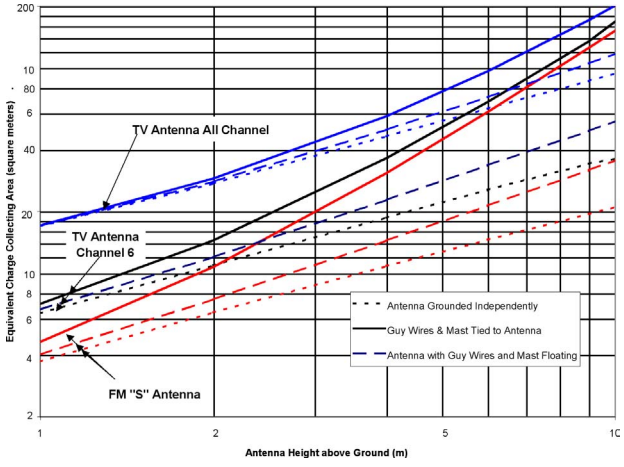

Figure 7.8-11 Equivalent charge-collecting area for three different antennas (see Dimensions in Figure 7.8-10).

Rain Gutters (Reilly and Cwiklewski 1981; EPRI 1982)
The current flowing in a conductive connection between a gutter and a building is given by Equation 7.8-1. The equivalent charge-collecting area is given by Equation 7.8-15.

$$S = \frac{2\pi h_{eq}}{\ln(2h_{eq}/r_{eq})} L \qquad 7.8\text{-}15$$

This is the same equation as Equation 7.8-9 for a cylinder above ground. However, an equivalent radius, r_{eq}, is used instead of r, and an equivalent height above ground, h_{eq}, instead of the real height above ground. The equivalent radius of a gutter is about equal to its largest dimension divided by two. The equivalent height is equal to the unperturbed space potential at the gutter with the building present, divided by unperturbed electric field at the gutter without the building. For one- or two-story buildings, the equivalent height of the gutter can be estimated as one fifth of the height of the gutter above ground.

The capacitance of the gutter to ground is given by:

$$C_s = \frac{2\pi\varepsilon}{\ln(2h_{eq}/r_{eq})} L \qquad 7.8\text{-}16$$

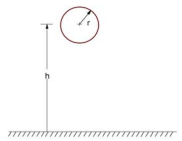
For a gutter well insulated from the roof, the impedance to ground coincides with its capacitive impedance.

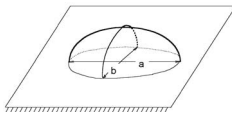
$$Z_{og} = \frac{1}{j\omega C_s} \qquad 7.8\text{-}17$$

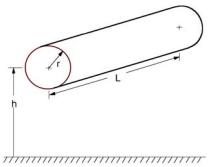
For example, assume h = 3 m, E = 2000 V/m at 60 Hz, a rain gutter length L = 20 m, and a rain gutter equivalent radius r = 0.65 m. Then h_{eq} = 0.6 m, S = 123 m² (The large charge-collecting area of the gutter results from its height above ground. See Figure 7.8-5.), Isc = 0.82 mA, C_s = 1810 pF, and, for a well-insulated gutter, Z_{og} = 1.47 MΩ and V_{og} = 1200 V.

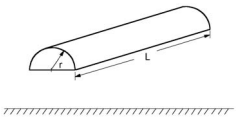
Summary Tables
The equations and the methods for calculating the induction quantities (equivalent charge-collecting area, spark-discharge capacitance) of different objects are summarized in Table 7.8-1. These quantities can also be calculated for a variety of objects in practical transmission-line situations using Applet EMF-10. The equivalent charge-collecting area of an object is used to calculate the short-circuit current in a uniform electric field. If the electric field is nonuniform along the height of the object, the average electric field should be used, or the space potential at the top of the object divided by the object's height. If the electric field is nonuniform along the length of the object, the average electric field calculated as shown later in this section should be used.

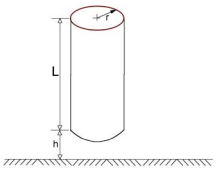
Table 7.8-1 Equivalent Charge-Collecting Area and Spark-Discharge Capacitance of Objects in a Uniform Electric Field

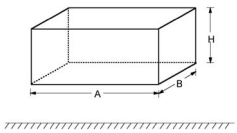


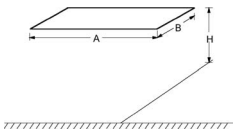


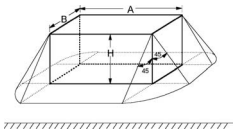


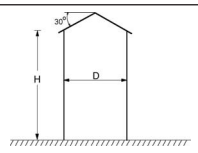


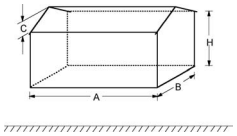


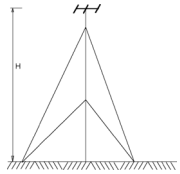


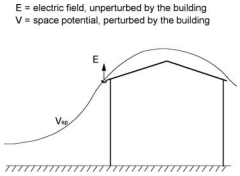












Object		Equivalent Charge-Collecting Area	Spark-Discharge Capacitance
Sphere above ground		$S = \dfrac{4\pi h}{\dfrac{1}{r} - \dfrac{1}{2h}}$ for $h >> r \quad S = 4\pi hr$	$C_s = 4\pi\varepsilon r$
Hemisphere on the ground		$S = 3\pi r^2$	
Half-ellipsoid on the ground		$S = 3\pi ab$	
Cylinder above ground		$S = \dfrac{2\pi h}{\ln(2h/r)} \cdot L + \dfrac{4\pi h}{\dfrac{1}{r} - \dfrac{1}{2h}}$	$C_s = \dfrac{2\pi\varepsilon}{\ln(2h/r)} L$
Half-cylinder on the ground		$S = 4r(L + r)$	
Vertical cylinder		$S = \dfrac{\pi L^2}{\ln\left[\dfrac{L}{r}\sqrt{\dfrac{4h+L}{4h+3L}}\right]}$	
Box		See Figure 7.8-3	
Flat plate		See Figure 7.8-4	
45° shield angle approximation		Top area with 45° cones projection on the ground	
Silos		See Figure 7.8-6	
Houses with gable roofs		Conductive roof, insulating house: see Figure 7.8-7 Conductive roof, conductive house: see Figure 7.8-8 Insulating roof, conductive house: see Figure 7.8-9

Table 7.8-2 shows experimental data for the ratio between short-circuit current and electric field and for the spark-discharge capacitance of different objects.

7.8.3 Accuracy Expected in Calculating Short-Circuit Currents

The accuracy of the results of calculations of short-circuit currents depends on the assumptions about their shape. Practical engineering problems do not involve perfect spheres or cylinders but objects of complicated shapes. Tables 7.8-1 and 7.8-2 contain data for many different objects. The accuracy of these data is of the order of ±5% for uniform electric fields. If approximations are used, accuracy depends on the subjective judgment in approximating the actual shape with one with known solution. Experienced engineers may achieve accuracy of the order of 10–20% even for complicated shapes. If better accuracy is desired, the user may exercise Applet EMF-10 "Equivalent Area of Objects in an Electric Field," based on the algorithms illustrated in Appendix 7.6.

Table 7.8-2 Induced Current Coefficient and Spark Discharge Capacitance of Different Objects

Object	Induced Current Coefficient I_{sc}/E (mA per kV/m)	Spark-Discharge Capacitance (pF)
Large tractor - trailer Total length 15.75 m Trailer: L=12.2 m, W=2.4 m, H=3.7 m	0.64	2000 ~ 3000
Tractor – Milk tanker Total length: L=13.8 m Tanker: L=10.3 m, W=2 m, H=2.6 m	0.40	
Large school bus L=10.4 m, H=2.8 m, W=2.44 m	0.39	1800
Small farm tractor L=3.7 m, W=1.95 m, H=1.5 m	0.06	
Combine L=9.15 m, W=2.3 m, H=3.5 m	0.38	
Wagon L=4.6 m, W=1.8 m, H=1.7 m	0.11	1000
Pickup truck L=5.2 m, W=2 m, H=1.7 m	0.10	
Car L=5.7 m, W=1.9 m, H=1.5 m	0.11	
Car L=4.6 m, W=1.78 m, H=1.37 m	0.088	800
Person: height = 1.75 m	0.016	100
Horse L=2 m, shoulder H=1.26 m, 385 kg	0.027	180
Cow L=2 m, shoulder H=1.17 m, 318 kg	0.024	200

Example: Electric Field Induction for an Automobile

Consider the automobile shown in Figure 7.8-13. The calculation of short-circuit current and open-circuit voltage may be made according to the following steps.

- The automobile may be approximated by a box with length A = 4.6 m and width B = 1.78 m.
- The height of the equivalent box is a weighted average of the heights of the different sections:
  $H = (0.86 \cdot 1.73 + 1.37 \cdot 1.83 + 0.94 \cdot 1.04)/4.6 = 1.08$ m

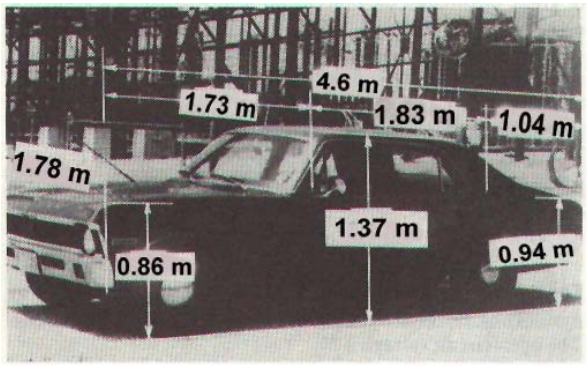

Figure 7.8-13 Automobile dimensions for short-circuit current evaluation.

- The shape factor, *S/(AB)*, is found from Figure 7.8-3, in correspondence to $A/B = 4.6/1.78 = 2.6$ and $H/B = 1.08 / 1.78 = 0.61$.
  $S/(A \cdot B) = 3.25$
- The equivalent charge-collecting area is:
  $S = 3.25\ A \cdot B = 26.5\ m^2$
- The short-circuit current is given by Equation 7.8-1. For an electric field of 1 V/m at the frequency of 60 Hz:
  $I_{sc} = 2\pi f \cdot 8.854 \cdot 10^{-12} \cdot 26.5 = 8.84 \cdot 10^{-8}$ A, i.e., $I_{sc} = 0.084$ mA/(kV/m)
- This result is close to that indicated in Table 7.8-2 for the same car.
- The capacitance to ground of an automobile depends on the type of pavement. The value of 800 pF listed in Table 7.8-2 is a typical value. If the tires and pavement provide a perfect insulation from the electrical ground, the impedance to ground is due only to the capacitance and is:
  $Z_{og} = 1/(2\pi f \cdot 800 \cdot 10^{-12}) = 3.32\ M\Omega$
- The open-circuit voltage is:
  $V_{og} = 3.32 \cdot 10^{6} \cdot 8.84 \cdot 10^{-8} = 0.29$ V/(V/m).

In an electric field of 9 kV/m, the short-circuit current for the automobile of this example would be $0.084 \cdot 9 = 0.76$ mA, and the open-circuit voltage would be $0.29 \cdot 9000 = 2610$ V.

The open-circuit voltage (2610 V) and the spark-discharge capacitance (800 pF) characterize the intensity of the discharge occurring when a person touches the automobile (see Section 7.10). For this example, Figure 7.10-7 indicates that the discharge will be above the annoyance level for most people.

7.8.4 Electric Field Induction in Long Objects in a Nonuniform Electric Field

There are two sources of errors in applying single-phase, uniform-field data to three-phase fields. First, the magnitude of the field and, second, the phase angle of the electric field may vary significantly over the dimensions of the object (Reilly 1979). Therefore, a different procedure should be used as illustrated by the following two examples.

Vehicle Perpendicular to the Transmission Line

Assume that a 10.4-m-long school bus is centered under the maximum electric field and is perpendicular to a three-phase line. The average electric field over the equivalent bus length should be considered, rather than the field at the peak of the lateral profile. The equivalent length is the actual bus length plus an extra length (~ 3.5 m) to account for end effects. The real and imaginary components of the uniform electric field that causes the same induction are the real and imaginary components of the field calculated over the equivalent length, L, of the bus, from x_1 to x_2:

$$\tilde{E}_{eq} = \frac{\int_{x_1}^{x_2} \tilde{E}(x) \cdot dx}{L} \qquad 7.8\text{-}18$$

Equation 7.8-18 applied to the data of Table 7.8-3 shows that the equivalent uniform electric field is 86% of the maximum field. Therefore, the induced short-circuit current for the bus perpendicular to the line is 86% of the current induced in a bus parallel to the line at the point of maximum field.

Table 7.8-3 Example Calculation of Equivalent Electric Field for a Vehicle Perpendicular to a Three-Phase Line

Distance from Centerline (m)	Electric Field Magnitude (kV/m)	Electric Field Phase Angle (degree)	Real Component (kV/m)	Imaginary Component (kV/m)
6 (end effect)	4.78	70.5	1.59	4.48
7 (end effect)	5.14	79.3	0.96	5.05
8	5.54	86.5	0.34	5.53
9	6.05	93.9	-0.41	6.04
10	6.36	98.1	-0.90	6.30
11	6.63	102.2	-1.40	6.48
12	6.71	104.5	-1.68	6.50
13	6.68	106.3	-1.87	6.41
14	6.55	107.6	-1.98	6.24
15	6.26	109.0	-2.04	5.92
16	5.97	110.0	-2.04	5.61
17	5.64	110.0	-1.93	5.30
18 (end effect)	5.29	111.0	-1.90	4.94
19 (end effect)	4.88	11.0	-1.75	4.56
Total			-15.02	79.36
Total (magnitude)			80.77	
Average Magnitude			80.77/14 = 5.8 kV/m	

For large vehicles, including tractor-trailers, the mitigation effect of the field nonuniformity and of the phase change are significant, and they should be included in the calculations because these vehicles are critical for the application of the National Electric Safety Code (NESC) 5-mA criteria.

Fence Near a Transmission Line

If a fence has different sections in different electric fields, or if it is not parallel to the line, computations should be made using an equivalent electric field calculated with Equation 7.8-18, or by adding the currents induced in different sections, as shown in this example. Consider a 120-m fence (60 m on each side of the centerline), 1-m above ground, with wire diameter of 0.64 cm. Assume that the fence is perpendicular to the double-circuit line of Figure 7.3-15, with phase sequence C, A, B, C′, B′, A′ (from left to right). The fence is sectioned into eight 15-m-long sections. The field magnitude and phase angle are calculated for each section, as shown in Table 7.8-4. The short-circuit currents of the different sections are added accounting for magnitude and phase angle. The total current is 0.268 mA. The capacitance to ground does not depend on the fence location and is C = 1070 pF. The open-circuit voltage for a well-insulated fence is 690 V.

Table 7.8-4 Induced Current in a Fence not Parallel to a Transmission Line

Fence Section	Average Electric Field (kV/m)	Average Phase Angle (degree)	Induced Short-Circuit Current (mA)
1	0.4	140	0.017
2	0.8	125	0.035
3	2.7	100	0.120
4	2.8	-20	0.124
5	3.7	-75	0.164
6	2.4	-20	0.107
7	0.5	0	0.022
8	0.15	30	0.007

7.8.5 Impedance of Vehicles to Ground

Short-circuit currents and spark-discharge voltages are a function of vehicle-to-ground and person-to-ground impedances. The largest currents and voltages occur when the vehicle is perfectly insulated from ground and the person well grounded. This is seldom the case.

Impedances depend on a number of variables. To overcome the difficulty of defining the effect of each variable, a series of statistical measurements were made for different types of vehicles, in different weather conditions, and for different types of ground surfaces (EPRI 1982). The experiments were conducted under a three-phase test line. Three different types of ground surfaces were prepared: dirt, macadam (the American term “black top” is used in the figures), and gravel. The test vehicles were a school bus (10.4 m long, 2.44 m wide, 2.8 m high), a farm tractor (3.76 m long, 1.95 m wide, 1.46 m high), and a small truck (4.6 m long, 1.9 m wide, 1.65 m high). The measurements were performed twice each month for an entire year. The dates were selected in advance to cover all types of weather without bias. The following quantities were measured:

- Unperturbed electric field, E_g, at the height of one meter above ground
- Vehicle short-circuit current, I_{sc}
- Vehicle open-circuit voltage
- Person-to-vehicle open-circuit voltage
- Person-to-vehicle short-circuit current
- Person-to-ground open-circuit voltage
- Person-to-ground short-circuit current

The results confirmed that the short-circuit current, I_{sc}, is proportional to the unperturbed electric field near ground, E_g. The measured values were:

- For the school bus: I_{sc} / E_g = 0.39 mA/(kV/m)
- For the farm tractor: I_{sc} / E_g = 0.06 mA/(kV/m)
- For the small truck: I_{sc} / E_g = 0.11 mA/(kV/m)

The data for the farm tractor showed some dispersion because of changes in the position of the driver.

The major statistical parameters of interest are the impedance vehicle-to-ground, the current person-to-vehicle, and the voltage person-to-vehicle. These parameters are shown in terms of probability of occurrence in Figures 7.8-14 to 7.8-22.

The impedance vehicle-to-ground was calculated as the ratio between the open-circuit voltage and the short-circuit current: $Z_g = V_{oc} / I_{sc}$.

The current person-to-vehicle was referred to the short-circuit current, I_{sc}. The median value of the person-to-vehicle current was between I_{sc} /100 and I_{sc} /25 for the school bus and less for the other two vehicles.

The induced voltage between a person and a vehicle is a useful parameter to assess the severity of spark discharges. For all the vehicles tested, the maximum induced voltage was $V_{pv} \approx 0.3\ E_g$, whereas the median values were between 0.008 E_g and 0.07 E_g. These voltages were lower than those between vehicle and ground, indicating that a person assumes a potential intermediate between that of the vehicle and ground. Although the worst-case condition was never experienced during the test program, it may conceivably occur under unusual circumstances. The U.S. National

Electric Safety Code prescribes that the induced current should be less than 5 mA in the worst case (NESC 1997). For the school bus tested, this translates into an electric field of 12.8 kV/m. In this field, the median values of the current bus-to-person would be between 0.02 and 0.05 mA, and the median values of the induced voltages would be between 100 and 900 V. Therefore, if a line is designed according to code, short-circuit currents vehicle-to-person would generally not be perceptible (see Section 7.10), Spark discharges, however, may exceed perception level and occasionally annoyance levels (see Section 7.10). In none of the conditions experienced during the test program would the spark discharge voltage have been sufficient to cause gasoline ignition during refueling operations (see Section 7.14).

7.9 MAGNETIC FIELD INDUCTION IN OBJECTS

7.9.1 Short-Circuit Currents and Open-Circuit Voltages of Sets of Conductors Parallel to Transmission Lines

A power transmission line may induce significant voltages in conductive objects that have a considerable length parallel to the line, such as fences, pipes, rails, and wires. If these conductors are a part of a loop or a network, currents may flow in these objects or in the connections between these objects and people, giving rise to important safety issues. Induced currents and voltages in parallel wires are important considerations for the safety of personnel who work on de-energized lines parallel to energized lines. The inductive coordination problem has been studied since the start of the power industry and a rich literature on the subject is available, covering subjects such as pipes (Dabkowski and Taflove 1979; Taflove and Dabkowski 1979a; Taflove and Dabkowski 1979b; Taflove et al. 1979; Jaffa and Stewart 1981; EPRI 1985; Frazier et al. 1986), railroads (EPRI 1985; Frazier et al. 1986), fences (Jaffa 1981), and the general issues of inductive coordination (Dabkowski 1981; Olsen and Jaffa 1984).

Magnetic induction is responsible for currents in shield wires used for lightning protection when these wires are bonded to more than one transmission structure. When the shield wires are sectionalized, grounded only at one structure, and insulated at other structures in order to reduce losses, the magnetic induction generates a voltage between

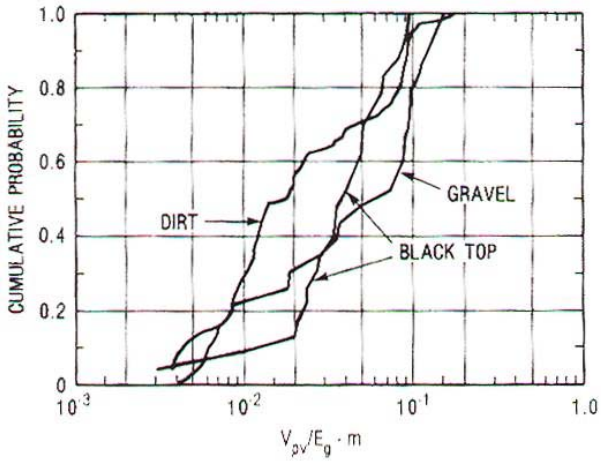

Figure 7.8-22 Probability that a given value of vehicle-to-person voltage, V_{pv} / E_g, will not be exceeded. Data for a small truck.

shield wires and these structures. Magnetic induction generates currents and voltages in conductor networks located near the transmission lines: distribution line neutrals and their ground connections, water pipe systems, and building steel columns and beams. In some cases, the induction in these networks reduces the magnetic field at locations where a reduced magnetic field is desired. Indeed, a special passive conductor network can be designed for that purpose (see Section 7.17).

The voltage, $V_{a,b}$, induced in a loop formed by two conductors, *a* and *b*, parallel to a transmission line and connected to each other at the ends of a long section of length *L*, is given by:

$$\tilde{V}_{a,b} = L \cdot \sum_i \frac{j\omega\mu \tilde{I}_i}{2\pi} \ln \frac{D_{ib}}{D_{ia}} \qquad 7.9\text{-}1$$

The distances D_{ia} and D_{ib} are from conductor *i* of the transmission line. The summation is extended to all the conductors. In most practical situations, the earth return currents may be neglected.

The voltage $V_{a,b}$ may be regarded as the difference of two voltages assigned to each individual conductor. For instance, the voltage assigned to conductor *a* is:

$$\tilde{V}_a = L \cdot \sum_i \frac{j\omega\mu \tilde{I}_i}{2\pi} \left(\ln \frac{2L}{D_{ia}} - 1 \right) \qquad 7.9\text{-}2$$

It can be verified that:

$$\tilde{V}_{a,b} = \tilde{V}_a - \tilde{V}_b \qquad 7.9\text{-}3$$

Equation 7.9-2 may be written:

$$\tilde{V}_a = \sum_i Z_{ia} \tilde{I}_i \qquad 7.9\text{-}4$$

Z_{ia} is the mutual impedance between conductor *a* and conductor *i*.

$$Z_{ia} = L \cdot \frac{j\omega\mu}{2\pi} \left(\ln \frac{2L}{D_{ia}} - 1 \right) \qquad 7.9\text{-}5$$

If there are two or more conductors parallel to the transmission line, voltages and currents are related through matrix Equation 7.9-6.

$$[V] = [Z][I] \qquad 7.9\text{-}6$$

The matrices contain variables that refer to all conductors, those of the transmission line and those where voltages are induced by the transmission lines. [*V*] is the array of voltages per unit of length of the conductors (the longitudinal electromotive force (LEF), also called the longitudinal electric field), [*I*] is the array of conductor currents, and [*Z*] is an impedance matrix containing self and mutual impedances. All variables are complex numbers. The mutual impedance between two conductors is given by Equation 7.9-5. The self-impedance of a conductor, for instance conductor *a*, is given by:

$$Z_a = L\left[R_a + \frac{j\omega\mu}{2\pi} \left(\ln \frac{2L}{GMR} - 1 \right) \right] \qquad 7.9\text{-}7$$

Where:

R_a is the resistance (ac resistance at the power frequency of 50 or 60 Hz).

GMR is the Geometric Mean Radius.

For a conductor of radius *r* and with uniform current distribution:

$$GMR = 0.779\, r \qquad 7.9\text{-}8$$

For transmission-line conductors, the value of *GMR* (in meters) may be derived from tables giving the conductor self-reactance, X_a, in ohm per mile for 1-ft spacing at the frequency $f = 60$ *Hz*, using Equation 7.9-9:

$$GMR = 0.305 \cdot e^{-(2\pi X_a/(1610 j 2\pi 60\mu)} \qquad 7.9\text{-}9$$

If the reactance were given in ohm per kilometer for 1-m spacing at the frequency of 50 Hz, Equation (8.9-10) should be used:

$$GMR = e^{-(2\pi X_a/(1000 j 2\pi 50\mu)} \qquad 7.9\text{-}10$$

It is useful to partition matrix Equation 7.9-6 as shown in Equation 7.9-11.

$$\left[\begin{array}{c|c} Z_{tt} & Z_{tp} \\ \hline Z_{pt} & Z_{pp} \end{array} \right] \left[\begin{array}{c} I_t \\ \hline I_p \end{array} \right] = \left[\begin{array}{c} V_t \\ \hline V_p \end{array} \right] \qquad 7.9\text{-}11$$

Where:

t indicates the transmission-line conductors,

p denotes the conductors parallel to the transmission line where induction takes place.

Assume, for instance, that the parallel conductors are connected to each other at their ends. In this case, all the voltages induced on the parallel conductors are equal, and the sum of the parallel conductor currents is zero. The currents and the voltage drop along the parallel conductors can be calculated solving the system (7.9.12) consisting of *2p+1* equations with *2p+1* unknowns (V_p, V, I_p).

$$\begin{aligned} &[V_p] = V[1] \quad \text{All the voltages are equal to V} \\ &\sum_p I_p = 0 \quad \text{Kirchoff law} \\ &[Z_{pt}][I_t] + [Z_{pp}][I_p] = [V_p] \quad \text{Derived from (7.9 - 11)} \end{aligned} \qquad 7.9\text{-}12$$

Assume, instead, that the parallel conductors are not connected to each other or to the ground (except at one point). In this case, the currents are all zero. The induced voltages can be calculated, from Equation 7.9-13, which is derived from 7.9-11.

$$[V_p] = [Z_{pt}][I_t] \qquad 7.9\text{-}13$$

Calculations of induced voltages and currents for simple geometry can be made using Applet EMF-8.

Effect of Conductive Ground

If the ground were perfectly conductive, then the image of each conductor should be considered—i.e., a conductor carrying an opposite current and placed below the ground in a mirror location. Since the earth is not perfectly conductive, the earth currents move deeper into the earth and a phase delay occurs. In most practical cases and for the power frequency, the earth may be considered nonconductive in comparison to the line conductors, and the earth return current, if any, may be placed at an infinitely large distance from the conductors. The detailed analysis of how to account for earth return current is shown in Appendix 7.5. The main results of the analysis are reported here. The depth of the return current is given by Equation 7.9-14:

$$return\ depth = 1.31\delta = 1.31\sqrt{\frac{\rho}{\pi f \mu}} \qquad 7.9\text{-}14$$

Where:
ρ is the soil resistivity.
μ is the soil permeability.
f is the frequency.
δ is the skin depth.

In most cases the permeability of the soil is the same as that of air. Assuming a soil resistivity of 100 Ωm, the earth return depth at 60 Hz is approximately 850 m. Therefore, in most practical cases, the earth return currents may be neglected. This is especially true for transmission-line currents that are balanced, because all the conductor return currents are placed at nearly the same location inside the earth. If there is an unbalance, the return current may affect the induction of parallel conductors that are at distances from the power lines comparable to the return depth. Accounting for earth return current, the mutual impedance per unit of length between two conductors *a* and *i*, at a distance d_{ia} from each other, is given by Equation 7.9-15.

$$Z_{ia} = \frac{\omega\mu}{8} + \frac{j\omega\mu}{2\pi} \ln \frac{1.31\sqrt{\frac{\rho}{\pi f \mu}}}{D_{ia}} \qquad 7.9\text{-}15$$

7.9.2 Shield Wire Currents

The phase currents induce shield wire currents. The shield wire currents are calculated assuming that no current flows from the shield wires to ground through the towers. This assumption is valid only for the middle span of a long line with uniform earth resistivity and tower-to-earth impedance. Transposition of the line, discontinuity of the ground wires, and line terminations also invalidate this assumption.

Shield wire currents are calculated solving the matrix Equations (7.9-16).

$$\begin{bmatrix} Z_{aa} & Z_{ab} \\ Z_{ba} & Z_{bb} \end{bmatrix} \cdot \begin{bmatrix} I_a \\ I_b \end{bmatrix} = \begin{bmatrix} V_a \\ V_b \end{bmatrix} \qquad 7.9\text{-}16$$

Where:
I_a is the array of line currents.
I_b is the array of shield wire currents.
V_a and V_b represent line and shield wire voltages, respectively.
Z_{aa}, Z_{ab}, Z_{ba}, and Z_{bb} are impedance matrices.

The shield wire currents are calculated by requiring that the shield wire longitudinal voltages (*V/m*) be zero. This means no voltage drop from one tower to the next because both towers are at earth potential, since no current flows from shield wire to ground along the towers. If $V_b = 0$, the system (7.9.16) can be solved for the shield wire currents, I_b.

$$[I_b] = -[Z_{bb}]^{-1} \cdot [Z_{ba}] \cdot [I_a] \qquad 7.9\text{-}17$$

Shield wire currents should be treated as line currents in the calculation of magnetic field induction on wires parallel to the transmission line. The presence of shield wires slightly reduces the magnetic field and the magnetic field induction in objects.

Shield wire currents can be calculated using Applet EMF-8.

7.10 RESPONSE OF PEOPLE TO TRANSMISSION-LINE FIELDS

This section is useful for analysis, design, and mitigation of situations of short-term exposure to electric fields that may result in complaints. It reports the values of currents and spark-discharge energies that cause different levels of sensations. Also reported are the levels of electric field that cause various degrees of sensations caused by hair stimulation. This section also reports some data on electric currents inside the human body but does not discuss their biological importance.

7.10.1 Induced Currents and Their Distribution

Power-frequency currents are induced in the body of people who are in an electric field produced by high-voltage transmission lines. Knowledge of these currents and of how they are distributed inside the body is useful to relate results of biological studies conducted in the laboratory to the electric field produced by transmission lines. Simplistic models are able to estimate the current distribution in the human body with very little accuracy (Spiegel 1977). Determining the distribution of the currents in the internal organs requires the knowledge of the relative resistance of the various tissues of the body (Dawson et al. 1998). In contrast, it is relatively easy to determine experimentally the amount of currents that enters the various surfaces of the body and the total current that flows in a cross section of the body. These experiments were conducted with a special manikin used as the power-frequency electric equivalent of a human body (Deno 1977b; EPRI 1982). The manikin was made of insulating material, and its surface was covered with copper foil. The foil covering a section of the body was separated from the foils of adjacent sections by small gaps bridged by wire connections. This arrangement allowed measuring the current flowing between sections. Measurements were made for various body postures, for body either grounded or insulated from ground, and for uniform and nonuniform electric fields. When the body was at ground potential, the total current to ground was measured in a low-impedance connection to ground.

Total Body Current Induced in a Person Erect and Grounded

The short-circuit current, I_{sc}, for a person in the erect position over a flat ground and away from other objects is given by:

$$I_{sc} \approx 9 \cdot 10^{-11} f \cdot h^2 \cdot E \qquad 7.10\text{-}1$$

The current is proportional to the power frequency, f, the unperturbed uniform electric field, E, and the square of the height of the person h. For instance, a person 1.75 m tall standing erect and grounded in a 1-kV/m 60-Hz electric field would have a short-circuit current equal to about 0.017 mA. The equivalent charge-collecting area of a person is obtained combining Equations 7.8-1 and 7.10-1:

$$S \approx 1.62 \cdot h^2 \qquad 7.10\text{-}2$$

A person 1.75 m tall has an equivalent charge-collecting area equal to about 5 m^2. If the person is grounded through the feet, the current I_{sc} is flowing through the feet. Grounding may occur when a person is barefoot, has conductive or wet shoes, or is in tall grass that makes contact with the legs.

Current Induced in a Person Insulated from Ground

If the person is insulated from ground, as occurs when the person is standing or walking with insulated shoes on dry ground, the body acquires a voltage to ground, V_{og}, which is a function of the capacitance, C, of the person to ground.

$$V_{og} = \frac{I_{sc}}{2\pi f C} \qquad 7.10\text{-}3$$

The short-circuit current flows through the capacitance C. Part of this capacitance is between feet and ground. The current flowing through the feet to ground is:

$$I_{sc} \approx 9 \cdot 10^{-11} f \cdot h^2 \cdot E \cdot \left(1 - 2.9 \cdot 10^{-11} \frac{h}{C}\right) \qquad 7.10\text{-}4$$

The value of the capacitance between a person and ground is a function of the height of the top of the sole of the shoes above a conductive ground, as shown in Figure 7.10-1. For a 1.75-m tall person and a typical capacitance value of 150 pF, the current flowing through the feet, calculated with Equation 7.10-4 is 0.011 mA, or about two-thirds of the current that flows through the feet when the person is grounded through the feet.

Current Induced in a Person for Different Body Postures

Person erect, grounded, hands by sides, and with feet at a height, L, above ground:

$$I_{sc} \approx 9 \cdot 10^{-11} f \cdot h^2 \cdot E \cdot (1 + 2L/h) \cdot (1 - 0.2L/h) \quad \text{for } L < h$$
$$I_{sc} \approx 9 \cdot 10^{-11} f \cdot h^2 \cdot E \cdot (1 + 2L/h) \cdot 0.8 \quad \text{for } L > h \qquad 7.10\text{-}5$$

Person erect, grounded, with one outstretched hand, and with feet at a height, L, above ground:

$$I_{sc} \approx 1.07 \cdot \left(9 \cdot 10^{-11} f \cdot h^2 \cdot E \cdot (1 + 2L/h) \cdot (1 - 0.2L/h) \right) \quad \text{for } L < h$$
$$I_{sc} \approx 1.07 \cdot \left(9 \cdot 10^{-11} f \cdot h^2 \cdot E \cdot (1 + 2L/h) \cdot 0.8 \right) \text{for } L < h \qquad 7.10\text{-}6$$

Person erect, grounded, on the ground with one hand overhead:

$$I_{sc} \approx 1.12 \cdot \left(9 \cdot 10^{-11} f \cdot h^2 \cdot E \right) \qquad 7.10\text{-}7$$

Current Induced in a Person Who Is Not Erect or Is in a Nonuniform Electric Field

The space potential approach is particularly useful when the electric field is not uniform or the person is not erect. Nonuniform fields occur close to nonflat boundaries, such as near vehicles, substation equipment, towers, trees, and bushes. The most practical approach for determining the current induced in the body of the person is to determine the unperturbed space potential, V_{sp}, at the location of the chest of the person and calculate an equivalent electric field, E_{eq}, which is equal to the unperturbed uniform electric field that would induce the same current in the body of the person standing erect in a uniform field.

$$E_{eq} = V_{sp} / h_c \qquad 7.10\text{-}8$$

Where:

h_c s the height of the chest above ground when the person is erect.

The induced current may be calculated using Equation 7.10-1, but with E_{eq} instead of E.

For example, consider a person standing near a grounded fence that perturbs the field in such a way that, at the position of the chest, the electric field is 12 kV/m and the space potential is 10.4 kV/m. If the height of the chest above ground is 1.3 m, the equivalent electric field is 8 kV/m. The current flowing into a contact with ground is 0.13 mA. Using the actual electric field of 12 kV/m would have yielded results 50% higher. A grounded fence does indeed shield a person, even though the local electric field may be enhanced.

7.10.2 Field Enhancement on the Surface of the Body

The electric field on the surface of the body, E_s, does not coincide with the unperturbed field, E, because the field is changed by the presence of the body:

$$E_s = kE \qquad 7.10\text{-}9$$

Where:

k is the field enhancement.

The field enhancement may be calculated for simple geometry. For a complicated geometry, it may be more accurate to measure the surface field using the technique illustrated in Figure 7.5-5. Results of measurements are shown in Table 7.10-1 (EPRI 1982).

Surface irregularities such as body hair and clothing produce an ill-defined surface field.

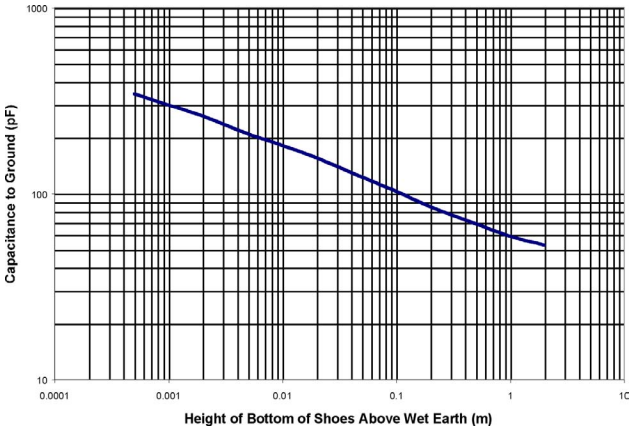

Figure 7.10-1 Person-to-ground capacitance measured with dry thin-soled shoes.

Table 7.10-1 Field Enhancement on the Surface of the Body (Person Grounded)

Position	Subject	Field Enhancement
Forehead	Manikin (h = 1.84 m) Person (h = 1.75 m)	23.3 20.0
Top of head	Manikin Person	16.6 18.3
Back of head	Manikin Person	18.3 15.2
Arm by side	Person	7.7
Arm outstretched	Person	9.3

Field enhancement is a function of the body posture and of the nonuniformity of the field. The surface field depends to a larger degree on the unperturbed space potential than on the unperturbed local electric field.

The current density on the surface of the upper portion of the body is the best parameter to characterize electrical quantities such as the total induced current, the electric field on the skin or hair, and the open-circuit voltage to ground. For this reason, personal electric field exposure monitors are based on the principle of measuring the induced current in a portion of the upper body surface. Such monitors are worn on arms, shoulders, and safety hats. The most accurate electric field exposure monitors are based on measuring the current induced in a conductive vest worn over insulating clothing and connected to an electrode in contact with the body.

7.10.3 Currents Induced by Spark Discharges

During a vehicle refueling operation, if there is a critical mixture of fuel and air in the gap and in the surrounding volume and if the spark discharge voltage is sufficiently high, fuel may ignite, although the probability that it happens is so low that in practice ignition will never occur (see Section 7.14).

A spark discharge is self-extinguishing, but may be repetitive because the voltage between the two bodies may be restored under the action of the ac electric field. After the contact between the two bodies is made, the discharges will cease, but a steady-state current at the power frequency will flow. The combination of transient and steady-state currents may be below the level of perception or may cause various sensations from perception without annoyance to a severe startle that may cause uncontrolled reactions.

The effects of spark discharges in an ac electric field depend on the peak value of the transient currents, their waveshape, and their repetition rate. These parameters, in turn, are a function of the type of contact and of the resistance of the discharge circuit. For the same type of contact and the same value of resistance, the transient currents depend on the voltage existing across the contact just before the spark and on the capacitance discharged by the spark. The value of the instantaneous voltage at the moment of the spark is difficult to determine. Therefore, it is preferable to define as the spark-discharge voltage the rms value of the voltage between the objects across which the discharge occurs.

The equivalent circuit for a spark discharge between a charged person and a grounded object is shown in Figure 7.10-2. This circuit shows lumped parameters to simulate the nonlinear distributed parameters of actual situations.

The spark-discharge voltage is:

$$V_{oc} = V\frac{C_2}{C_1 + C_2} \qquad 7.10\text{-}10$$

Where:

C_2 is the person-to-line capacitance and is negligible in comparison to C_1, which is the person-to-ground capacitance.

The capacitance of the person being discharged is:

$$C = C_1 + C_2 \approx C_1 \qquad 7.10\text{-}11$$

The person-to-ground capacitance is a function of the height of the bottom of the shoes above a conductive earth, as shown in Figure 7.10-1. Practical values of C are between 120 and 200 pF.

The terms R_B and R_S in Figure 7.10-2 represent the body-discharge resistance and the discharge resistance through the skin at the point of spark, respectively. The body resistance is the resistance from the charged surfaces of the body to the point of the spark. It is concentrated in the area of the body close to the spark. When the contact is made with a firmly held metal object, the total resistance is equal to the body resistance and has a minimum value of 250-400 Ω. When the spark occurs at a point on the skin, the spark-discharge resistance through the skin, R_S, becomes predominant. This resistance is nonlinear with voltage and is time varying. The equivalent initial resistance assumes values between 2,000 and 40,000 Ω.

The person-to-ground voltage, V_{oc}, is a function of the electric field, of the person's position, and of the impedance to ground. Measurements have shown that, for a person standing on insulating ground, or on an insulating platform, or in a switchyard with crushed stones, $V_{oc}/E = 0.18 – 0.42$ m, with an average value of 0.275 m (EPRI 1982). In the case of perfect insulation, the voltage to ground is

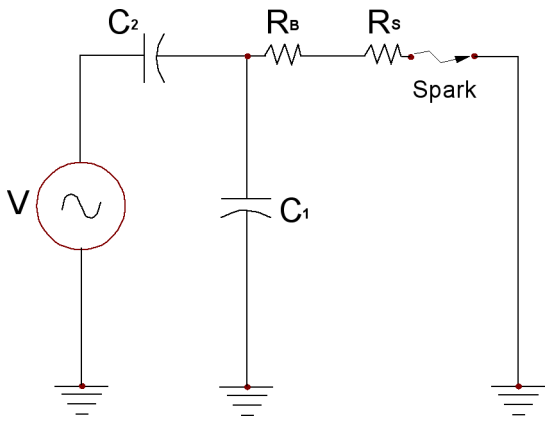

Figure 7.10-2 Equivalent circuit for a person-to-ground spark discharge.

$V_{oc} = I_{sc}/(\omega C)$, where C is derived from Figure 7.10-1 and I_{sc} is calculated according to Equation 7.10-4. For a person wearing shoes and walking on conductive ground (wet ground or grass), $V_{oc}/E = 0 – 0.3$ m, depending on the insulation of the shoes.

For a person standing on macadam, or "black top," beside a vehicle (thus partially shielded by it):

	Median Value	Maximum Value
School Bus	$V_{oc}/E = 0.06$ m	0.16 m
Farm Tractor, or Small Truck	$V_{oc}/E = 0.13$ m	0.22 m

The equivalent circuit for a spark discharge between a charged object and a person is shown in Figure 7.10-3. The resistance R_C in this circuit represents the contact resistance at the point where the person is grounded, such as a hand contact with a conductive object or a contact through conductive shoes on conductive ground.

The transient currents caused by spark discharges have a shape described in Figure 7.10-4, which shows a sequence of current pulses followed by a steady state current after the contact is fully established. Figure 7.10-5 shows an example of waveshape for one current pulse. The waveshape is not a simple exponential, such as that occurring in a linear R-C circuit, because the contact resistance varies in time. Two equivalent resistances are defined in the example of Figure 7.10-5: the initial resistance equal to the voltage before the contact divided by the initial current, and the resistance during the main part of the discharge, calculated through the average time constant.

The transient current propagation through the body is dominated by resistances and not by inductances. In fact, the skin depth for the propagation of these transient currents is

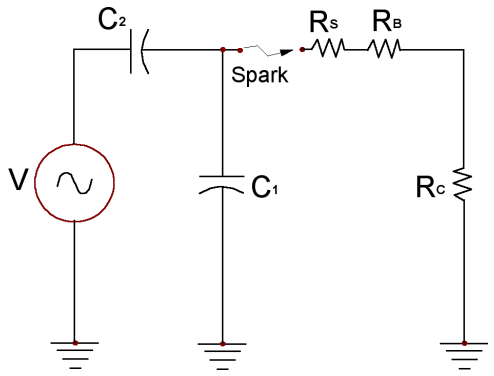

Figure 7.10-3 Equivalent circuit for a spark-discharge object-to-person.

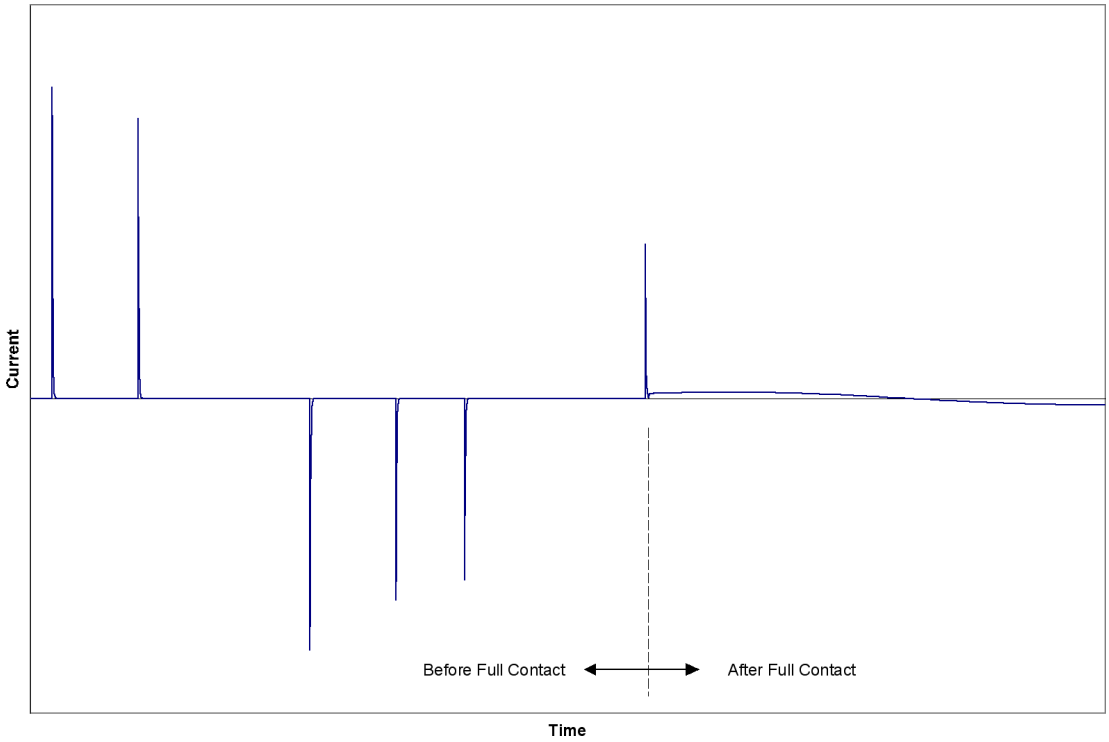

Figure 7.10-4 Sequence of current pulses in a spark discharge and current after contact.

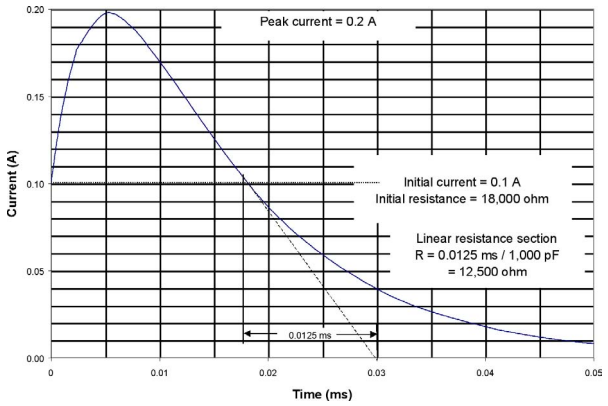

Figure 7.10-5 Waveshape of a current pulse in a spark discharge at a wet index finger. Peak voltage of 1800 V, capacitance = 1,000 pF.

sufficiently large for the hand and arm current distribution to be independent of inductances, even for the shortest time constants. The spark resistance is concentrated at the point of spark. Consequently, the current wave through the body has the same shape. The distribution of the transient currents inside the body depends on the point of contact and on the relative resistance of the different organs.

Comparison with Carpet-Induced Spark Discharges

Spark discharges occurring in proximity to high-voltage transmission lines are similar to those occasionally experienced by people walking on carpets in very dry rooms and touching a metallic object. People walking on carpets in very dry rooms may charge themselves with negative dc voltages with values depending on the insulating characteristics of the shoes and carpet and the type and degree of shuffling the shoes over the carpet. Voltages around 4 kV are a common occurrence, and voltages up to 8 kV may be generated indoors in dry winter climates. The capacitance of a person on a carpet is about 200 pF.

Comparison with the spark-discharge parameters in the case of person-to-ground spark discharges induced by high-voltage transmission line electric field shows that crest voltages and capacitance values are of the same order. In fact, for V_{oc}/E = 0.275 m, a crest voltage of 4 kV may be reached in an electric field of 10 kV/m. A notable difference, however, is the spark repetition that occurs in an alternating electric field when the contact is slow or brushing.

7.10.4 Transient Currents Induced by Switching Surges

Usually switching surges have peak voltages less than twice the peak value of the phase-to-ground voltage and times-to-crest exceeding 100 μs. If a person is in contact with an insulated object near the line at the time of the surge, a transient current will flow through the person's body.

The transient current caused by a switching surge is a single pulse. The crest value of this pulse is much lower than the crest value of a spark discharge. Assume a single-phase source, with a power frequency voltage, V, causing a short-circuit current, I_{sc}, in a conductive object. The source-to-object capacitance is $C_1 = I_{sc}/(2\pi fV)$. If the source voltage is an exponential transient with peak value $V_c = k\sqrt{2}V$ and time constant τ, a person touching the object would be subject to a transient current with the same time constant and crest value, I_c, equal to:

$$I_c = V_c \frac{C_1}{(RC_1 + \tau)} \approx V_c \frac{C_1}{\tau} = I_{sc} \frac{k\sqrt{2}}{2\pi f\tau} \qquad 7.10\text{-}12$$

If k = 1.8, τ = 400 μs, and f = 60 Hz, the crest voltage of the transient current is 17 times greater than the rms value of the short-circuit current. For I_{sc} = 2 mA, I_c = 34 mA. This value is much lower than the crest value of spark-discharge currents that may be of the order of hundreds of milliampere.

There has been no report of people sensing the electrical effect of switching surges. Switching surge exposure is infrequent compared to exposure to spark discharges, which, furthermore, have much higher peak currents and may occur repeatedly while making or breaking a contact.

7.10.5 People Response to Short-Term Exposure to Electric Field

Short-term exposure to electric field produced by ac transmission lines, substations, and overhead high-voltage apparatus may be classified according to the type of effect causing a sensation in people.

- Spark discharges, which cause transient currents in the body of a person when the electrical breakdown of an air gap occurs between the person's body and a conductive object, or ground
- Electric fields on the surface of the body, which exert forces on hair with consequent hair stimulation
- Steady-state ac currents, which enter a person contacting an object

The effects were listed in order of practical frequency of occurrence above perception levels. Spark discharges, causing a startled reaction or aversion to ac field exposure, are of major importance in establishing threshold of annoyance or uncomfortable sensations. The effects of electric field on hair are of minor importance and are present only in very high electric fields. Responses to steady-state currents are used to establish safety limits with respect to the possible largest charged object that a person might contact in conditions of good insulation of the object and good grounding of the person. Such situations are infrequent and

in almost all cases are preceded by spark discharges of considerable values.

The intensity of stimulation is classified according to the type of human response. Four categories of stimuli may be identified (EPRI 1982):

- Primary shock
- Secondary shock
- Perception
- Below perception

Primary shocks may produce direct physiological harm, such as heart fibrillation, respiratory tetanus, and inability to voluntarily control muscles.

Secondary shocks cannot produce such harm but are annoying and may produce involuntary muscle reactions. Secondary shocks are of subjective interpretation and may be defined in various ways: annoyance, startle, and aversion. Annoyance occurs when a person would consider the sensation to be mildly irritant if it occurred repeatedly. A startle would occur unexpectedly and would be likely to produce an unintentional muscular effect that may be hazardous under a defined set of circumstances. Aversion occurs when the person is motivated to avoid situations that would lead to a similar experience.

Perception occurs without shock when a person consciously detects the presence of a stimulus. The sensation is gentle and not necessarily unpleasant.

The following levels separate the preceding four categories:

- Minimum primary shock level
- Minimum secondary shock level
- Threshold of perception

Each of these levels is definable only in conjunction with a probability of occurrence in a well-defined set of circumstances. This probability is expressed as the percentage of people who have reactions above a particular level.

Response to Spark Discharges

Spark discharges induced by transmission-line electric fields do not have enough energy to cause primary shocks. They may, however, cause perceptible and annoying sensations to a person touching an insulated object or to an insulated person touching a grounded object. Sensitivity to spark discharges depends on the point of contact. The most sensitive points of contacts are the back of fingers or hands and the ankles. The electric field must be increased by a factor of about 1.5 to reach the same sensitivity with the tips of fingers, and by another factor of about 1.5 for contact with the palm (EPRI 1982). There is little difference in the response to spark discharges between men and women, with the exception of sparks to the tips of index fingers, in which case, women's perception is generally greater, probably due to more sensitive skin corresponding to a lower resistance (EPRI 1982). Temperature and humidity have a significant effect on the sensitivity to spark discharges. Weather conditions may cause variations in perception and annoyance levels by a factor of 2 or greater (EPRI 1982). The skin is most insensitive in dry and cold weather, which causes high values of skin resistance.

Discharges between a Person and Ground or between a Person and an Umbrella

Figure 7.10-6 shows the percentage of people who may experience sensations above the threshold of perception and above the minimum annoyance level for different spark-discharge situations (IEEE 1978; EPRI 1982). Different curves correspond to different situations.

Group 4 curves correspond to spark discharges between the thumb and the metallic shaft of an umbrella. The umbrella is held at the insulating handle, and the thumb is moved slowly until it touches the metallic shaft, and then it is removed. Different curves were obtained for rainy and fair-weather days. During rainy days, the umbrella's material becomes wet, and the equivalent surface area of the umbrella increases. Also during rainy days, finger sensitivity is higher because of higher humidity. In this situation the discharge capacitance is that of the umbrella (about 60 pF when dry and about 70 pF when wet).

Group 5 curves correspond to spark discharges between a small, grounded wire, simulating a blade of grass and the ankle. The person is erect and slowly touches the wire with the ankle and then moves the ankle away from the wire.

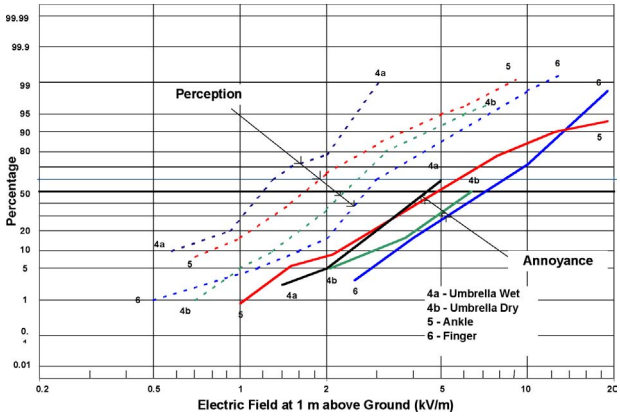

Figure 7.10-6 Percentage of people experiencing perceptible or annoying spark discharges in different situations in different electric fields. Data for 136 adults (EPRI 1982).

The discharge capacitance is that of a person to ground (see Figure 7.10-1).

Group 6 curves correspond to spark discharges between the tip of the index finger and a grounded object. The approach is made slowly, and then the contact is broken by withdrawing the finger. The discharge capacitance is that of a person to ground (see Figure 7.10-1). Considering a median value of 170 pF and a median value of the person-to-ground open circuit voltage equal to 0.275 kV / (kV/m), curves 6 of Figure 7.10-6 indicate the following median values for perception and annoyance thresholds:

- Perception threshold
  E = 2.7 kV/m V_{oc} = 740 V C = 170 pF
- Annoyance threshold
  E = 7 kV/m V_{oc} = 1900 V C = 170 pF

Straight lines reasonably match the data in Figure 7.10-6 when the field is plotted using a log scale and the probabilities of perception and annoyance are plotted using a normal probability scale. The data indicate a wide variability in human response. The ratio between fields corresponding to 84% and 16% probability is between 2.5 and 4.3. The curves for annoyance have about the same slope as the curves for perception. The ratio between annoyance and perception fields ranges between 2.6 and 3.8. At fields corresponding to 50% probability of perception, the probability of annoyance is 2~3%— i.e., when 50% of the people do not perceive any sensation there are a few people who judge the sensation annoying.

The data presented in Figure 7.10-6 correspond to repeated contacts. If the contact is casual, the voltage at the moment of the spark is likely to be less than the crest voltage of the open-circuit voltage. In fact, it is possible to make contact at $V = 0$ if the speed of approach is sufficiently high (greater than 15 cm/s). With repeated contacts, the chance that the voltage at the moment of the spark equals the crest voltage is high. In addition, with a slow approach and rapid withdrawal after the spark, the instantaneous spark voltage may be up to twice the crest of the open-circuit voltage.

Discharges between a Person and an Insulated Object

The severity of spark discharges between a person and an insulated object depends on the following parameters:

- V_{oc}: the open-circuit voltage of the object to ground
- C_s: the capacitance of the object to ground
- I_{sc}: the short-circuit current when the object is connected to ground through a low impedance.

If a person at ground potential touches an insulated object, the capacitance C_s will be discharged through the contact. The discharge may be flowing directly through the skin or, if the instantaneous voltage between person and object at the moment of the spark is sufficiently high, through a spark. If the contact is not made firmly, there could be a series of sparks. The current in the contact may be described as in Figure 7.10-4. After the contact is established, a current at the power frequency will flow. If the object is insulated and the person is electrically grounded, this current will approach the value of the short-circuit current, I_{sc}. The person can be considered effectively grounded not only when touching a grounded metallic object, but also when standing barefoot or wearing wet or conductive shoes on grassy or wet ground.

A person contacting a metallic object in an electric field may sense the capacitive discharge occurring when a contact is made or broken, or the short-circuit current occurring after a contact is made, or both.

Data regarding the values of V_{oc}, C_s, and I_{sc} that correspond to the threshold of perception and annoyance are few and based on people's subjective interpretation (especially in what constitutes annoyance). A summary of the data (EPRI 1982; IEEE 1978, Reilly 1992) that are relevant to spark discharges between a person and an insulated conductive object near a high-voltage transmission line is shown in Figure 7.10-7. The data from the Red Book (EPRI 1982) are for a well-insulated object. The perception threshold data from Reilly are given for different values of the parameter k, which is given by Equation 7.10-13.

$$k = \frac{V_{oc}}{V_{highest}} \qquad 7.10\text{-}13$$

$V_{highest}$ is the largest possible object-to-ground voltage. $V_{highest}$ occurs for a perfectly insulated object ($R = \infty$), when all the current I_{sc} flows in the capacitance C_s.

$$V_{highest} = \frac{I_{sc}}{\omega C_s} \qquad 7.10\text{-}14$$

When the leakage resistance becomes of the same order or smaller than the capacitive impedance, $1/C_s$, the voltage is less than the highest possible by the factor k.

If the leakage resistance is known, the value of k may be derived from Equation 7.10-15.

$$k = \frac{R}{\sqrt{R^2 + (1/\omega C_s)^2}} \qquad 7.10\text{-}15$$

The response of a person to the electrical stimulus occurring when touching an object varies with the value of k. For the same values of C_s and V_{oc}, a low value of k means a higher value of I_{sc}. Therefore, while the discharges occurring when

the contact is made or broken produce the same sensations, there is a stronger sensation during the contact.

The following example illustrates the concepts presented in this section. Assume an object, for instance a gutter system, with C_s = 400 pF and I_{sc} = 0.2 mA. The capacitive impedance of the gutter to ground is $1/\omega C$ = 6.6 MΩ. If the leakage resistance of the gutter is much greater than this value, the voltage between the gutter system and ground, given by Equation 7.10-14, is $V_{highest}$ = 1320 V. According to Figure 7.10-7, in correspondence to C_s = 400 pF, V_{oc} = 1320 V, and k = 1, the situation may produce sensations well above perception and corresponding to the annoyance levels for 50% of the people. Assume now that the gutter system has a leakage resistance to ground of 2 MΩ. According to Equation 7.10-15, k = 0.29; according to Equation 7.10-13, V_{oc} = 385 V. According to Figure 7.10-7, in correspondence to C_s = 400 pF, V_{oc} = 385 V, and k = 0.25, the situation may produce sensations just about at the level of perception for 50% of the people.

Effect of Frequency

The frequency of the electric field has an effect on sensation because it causes a different spark repetition rate during the approach, and it affects the short circuit current after the contact is established. Test data obtained with dc voltages are not applicable to the ac case and could be quite misleading, resulting in much higher open-circuit voltages. Results of tests (EPRI 1982) performed with electric fields at different frequencies are shown in Figure 7.10-8. The data indicate that people are more sensitive to spark discharges in electric fields with higher frequency. However, the difference between the effects of 50 Hz and of 60 Hz electric fields is very small and insignificant when compared with the large dispersion of human response data.

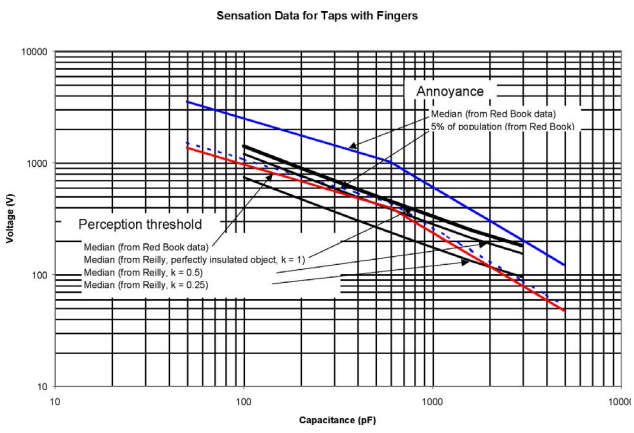

Figure 7.10-7 Perception and annoyance data for taps with fingers. Median values correspond to 50% of people.

Response to Steady-State Currents

Of practical interest for transmission-line design and operation applications are the ac currents flowing into the body of a person from hand to hand or from hand to feet when touching a large object, which collects current induced by the ac electric field. Only a few data are available for this case. Most data refer to laboratory tests in which people held the electrodes firmly in their hands.

Experimental results are shown in Figure 7.10-9 for perception of direct current and in Figure 7.10-10 for perception of alternating current (Dalziel 1954, 1972). The data follow a normal distribution with a large dispersion (the 99% values are four times larger than the 1% values). Average values for men equal 5.2 mA for dc current and 1.1 mA for currents alternating at 60 Hz. The first sensation for direct current is that of heat, whereas the first sensation for alternating current is a stinging sensation. Insufficient data are available for women, although the comparison of average values indicates a 2:3 ratio in the threshold of perception levels (Thompson 1933).

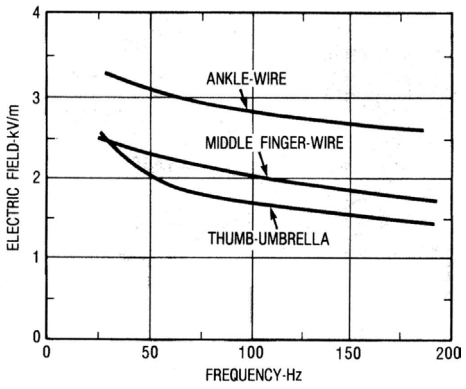

Figure 7.10-8 Median values of threshold of perception of spark discharges as a function of the frequency of the electric field.

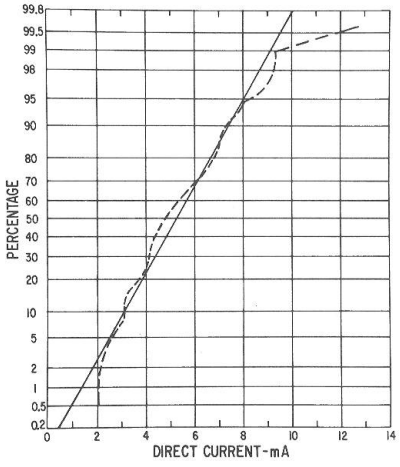

Figure 7.10-9 Distribution of minimum direct currents perceptible by men. Data for 115 men.

As the intensity of the current increases, control of the muscles in which the current flows becomes increasingly difficult. Above a certain value of current, it is not possible to release the grip on an object. The current for which this situation first occurs is called the "let-go current." Figure 7.10-11 shows the distribution of let-go values of direct currents. Figure 7.10-12 shows the distribution of let-go values of currents alternating at 60 Hz (Dalziel and Massoglia 1956; Dalziel 1972). The minimum let-go 60-Hz current values, arbitrarily defined as those corresponding to a probability of 0.5%, are 9 mA for men and 6 mA for women. A more conservative value of 5 mA might be applied for children. The National Electric Safety Code has specified that transmission-line clearances shall be consistent with a maximum induced current of 5 mA, to be calculated for the largest expected sag and for the largest vehicle anticipated under or near the transmission line (Banks and Vinh 1984; NESC 1997).

The effect of frequency on let-go current is shown in Figure 7.10-13 (Dalziel et al. 1943). There is practically no difference between 50 Hz and 60 Hz.

Increasing the value of the current above let-go may produce ventricular fibrillation (Dalziel 1960). Fibrillating current values are available for some animals. The fibrillating current is proportional to the body weight as shown in Figure 7.10-14. In addition to body weight and current

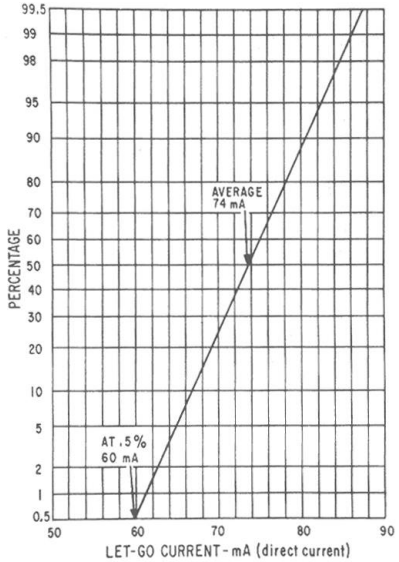

Figure 7.10-11 Distribution of let-go direct current values for men. Data for 28 men.

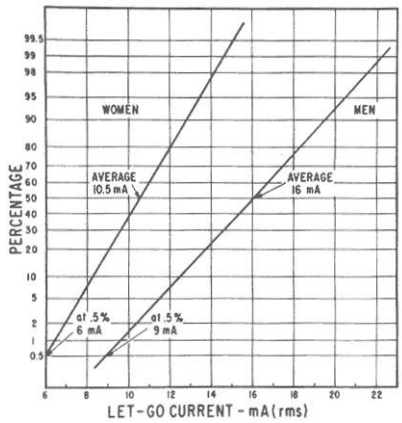

Figure 7.10-12 Distribution of let-go 60-Hz currents value. Data for 28 women and 134 men.

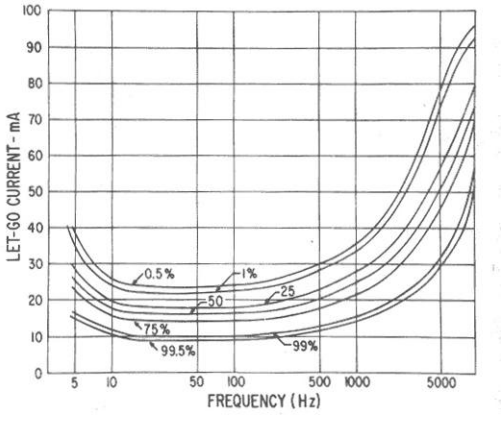

Figure 7.10-13 Effect of frequency on let-go current for men. The curves refer to different percentages of the population.

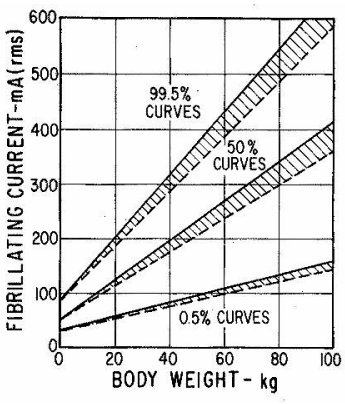

Figure 7.10-14 Fibrillating current versus body weight for six species of animals (calves, dogs, sheep, cats, rabbit, and guinea pigs). Continuous curves: All animals considered. Dashed curves: Guinea pig omitted.

magnitude, fibrillation is a function of the shock duration, according to the classic electrocution Equation 7.10-16 (Dalziel 1968, 1972; Dalziel and Lee 1969).

$$I = \frac{k}{\sqrt{t}} \quad (I \text{ in mA and } t \text{ in seconds}) \qquad 7.10\text{-}16$$

Dalziel gives a value of k = 116 for "normal adult worker" (Dalziel 1972), while in previous work had indicated a range of 116 to 185 (Dalziel and Lee 1969).

A summary of the response of adult men to steady-state ac electric currents is shown in Figure 7.10-15 (EPRI 1982).

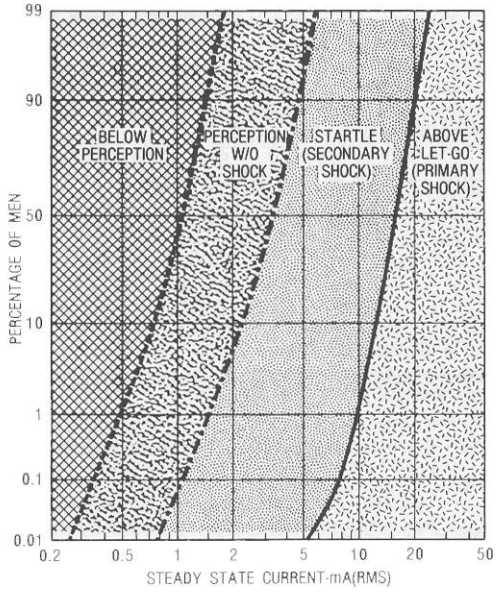

Figure 7.10-15 Statistical distribution of responses of adult men to steady-state ac currents through a gripped contact.

The few data available for women indicate levels approximately two-thirds those for men. Data for children are not existent.

Response to Hair Stimulation

In high electric fields, sensation is also caused by stimulation of hair nerves. Such stimulation occurs when skin with hair is exposed directly to the electric field or when currents pass from clothes to body through hair. Figure 7.10-16 presents the percentage of people who experience sensations above the threshold of perception and above the minimum annoyance level.

The curves marked with 1 correspond to stimulation of the hair of the hand when a person extends the arm over the head searching for the position where the sensation is strongest. Curves 2 correspond to stimulation of the hair of the head (forehead, eyebrows, sideburns), with the arms on the side of the body. Curves 3 correspond to a tingling sensation in parts of the body covered with clothes (elbow, shoulder, sides). Straight lines match reasonably well the data when the field is plotted in a log scale and the probability in a normal probability scale. The dispersion is much larger than for spark discharges (see Figure 7.10-6). There is a 7~9 ratio between 84% and 16% probability levels. The ratio between annoyance and perception fields is 6 ~10. The median values of the threshold of perception levels are:

Hand hair: 7 kV/m
Head hair: 23 kV/m
Between body and clothes: 20 kV/m

Median annoyance levels are much higher and are never reached in practical conditions.

Women, probably because of less hair, appear to be much less sensitive than men to this type of electric field effect. For a group of 8 women, the 50% value of perception for hand hair was 17.5 kV/m, as opposed to 6.7 kV/m for a group of 60 men tested the same day (EPRI 1982). Low

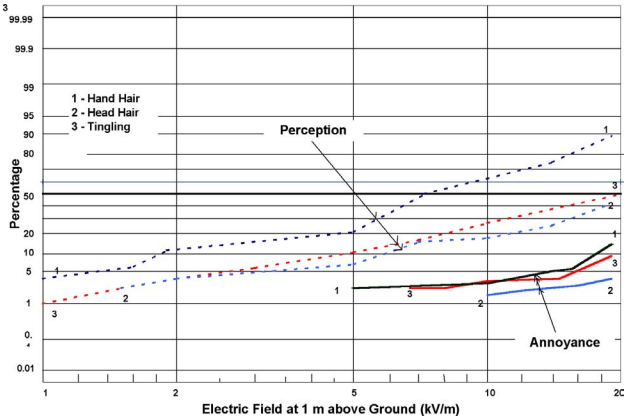

Figure 7.10-16 Hair stimulation and tingling (136 persons).

humidity and low temperature lower sensitivity, although the effect of individual parameters is not clear.

The frequency of the electric field affects the sensation, as shown by the curves of Figure 7.10-17. Greater sensitivity occurs at lower frequencies. The difference between 50 Hz and 60 Hz is small and insignificant when compared with the large dispersion of these data.

The basic mechanism of hair stimulation is not fully understood. It is assumed that hair collects charges that give origin to a force acting on the hair, thus causing vibration. Hair vibration has been observed at the power frequency and at twice the power frequency. These observations produce different interpretations of the nature and polarity of the charges on the hair. Conductive hair, such as wet hair, has a charge of the same polarity as that on the skin. Thus, the mechanical force on the hair has a frequency double that of the power frequency. However, if hair is insulating, a net charge of fixed polarity could remain on the hair, thus justifying a force at the power frequency.

7.11 BIOLOGICAL EFFECTS OF ELECTRIC FIELDS

Electric fields from electrical facilities have been studied for a variety of reasons and for many purposes. Much of the investigation of electric field from transmission lines and stations has included health concerns, particularly since the advent of EHV transmission in the 1960s and the subsequent great expansion of EHV systems. This Reference Book does not discuss the research performed on health effects of the electric field. The body of literature on possible biological and health effects of electric fields on people, animals, and plants has been reviewed and commented upon by many organizations (Bridges 1978; AMA 1994; NIEHS 1998; NRPB 2001).

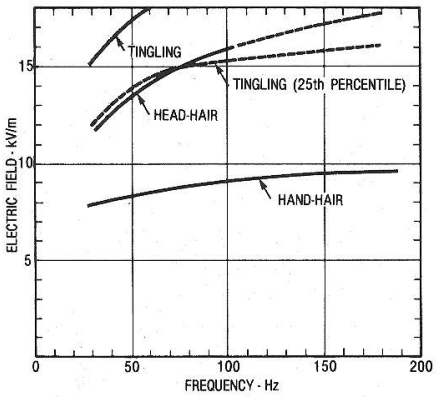

Figure 7.10-17 Median value of the threshold of perception of hair stimulation versus the frequency of the electric field.

To date, no health effect of ac electric fields of the type and value as those existing in transmission-line and station environments has been conclusively found nor accepted by the scientific community. Although health complaints by substation workers in the former Soviet Union were reported (Korobkova et al. 1972), medical examinations of transmission-line workers in the U.S. (Kouwenhoven et al. 1967), in Sweden (Knave 1980), and in Canada (Roberge 1976) failed to find health problems attributable to the electric field.

Even after considerable research, it is not possible to draw definitive conclusions. It is often necessary, nevertheless, for system planners, line designers, and state and federal regulatory agencies to take decisions on the values of electric field for which electrical facilities can be designed and operated. No rules for electric field intensity inside and outside the transmission corridor have been widely accepted. International Commission on Non-Ionizing Radiation Protection (ICNIRP) guideline document regards a current density of 100 mA/m^2 as the threshold for changes in the nervous system and recommends not exceeding one-tenth of this value—i.e., 10 mA/m^2 (ICNIRP 1998). For a person, 10 mA/m^2 may be reached in an unperturbed electric field of 25 kV/m. Recommendations and guidelines for electric field are presented in Appendix 7.3. Most of these rules are not based on accepted scientific findings. Some rules have been established with the purpose of allowing construction of new facilities while offering a guarantee that these new facilities would not exceed field values normally found in facilities that already exist in the same region.

7.12 CURRENTS INDUCED IN THE HUMAN BODY BY TRANSMISSION LINE MAGNETIC FIELDS AND A COMPARISON WITH THOSE INDUCED BY ELECTRIC FIELDS

The currents induced inside the body of a person exposed to ac electric and magnetic fields depend on the electrical characteristics of the different organs, tissues, and membranes of the body. A detailed electrical representation of the body has been developed and used to calculate current distributions in various parts of the body caused by electric (see Section 7.10.1 and Dawson et al. 1998) and magnetic fields (Stuchly and Zhao 1996). A discussion about this rigorous treatment and the presentation of the results of calculations is beyond the scope of this Reference Book. However, a simplified model is presented that provides an approximate comparison between electric-field and magnetic-field induced currents resulting from exposure to transmission-line fields.

The magnetic-field induced currents in the human body may be calculated by approximating the body cross section with a circle of radius *r*. Consider the rms value, *B*, of the component of the magnetic field normal to this cross section. The current density, *j*, at a distance *x* from the center of the cross section is calculated with Equation 7.12-1.

$$j = v / (2\pi x \rho) \qquad 7.12\text{-}1$$

Where:

ρ is body resistivity.

v is the voltage induced in a circular area of radius x.

The induced voltage is given by:

$$\begin{aligned} v &= -\frac{d\Phi}{dt} \\ &= -\frac{d}{dt}\left(\pi x^2 \sqrt{2} B \sin(2\pi f t)\right) \\ &= 2\pi f \sqrt{2} \cos(2\pi f t) \cdot \pi x^2 \end{aligned} \qquad 7.12\text{-}2$$

In the steady state:

$$V = -j 2\pi f \sqrt{2} B \cdot \pi x^2$$

The rms value of the current density is:

$$J = \frac{V}{2\pi x \rho} = \frac{\pi f B x}{\rho} \qquad 7.12\text{-}3$$

The highest current density occurs on the periphery of the cross section ($x = r$).

The comparison between currents induced by a 1000 V/m electric field in a person erect and grounded and the currents induced in a 100 mG (10 μT) vertical magnetic field is shown in Table 7.12-1. These field values were chosen because they are representative of electric and magnetic field in outdoor situations near the right-of-way. The highest electric-field induced current is in the ankle. Magnetic-field induced currents are lower. The highest magnetic-field induced current is in the chest. Even at that location, the magnetic-field induced currents are significantly lower than the current induced by the electric field.

Electric-field induced currents may be significantly greater when a person touches a conductive object. In this situation, part or all of the object's short-circuit current will flow to ground through the body of the person. In this respect, it should be mentioned that electric-field induced currents resulting from touching a conductive body in an electric field are the same as touching an appliance or any other object that may have a small amount of conductive current leakage. Electric field induction often causes transient spark-discharge currents, with peak values that may be 1000 times greater than the steady-state current peak. The current density at the point of entrance in the body may be 10^6 times greater. No similar phenomena are caused by magnetic-field induction.

Table 7.12-1 Comparison of Currents Induced in the Body of a Person by Electric and Magnetic Fields Typical of Situations near the Right-of-Way

Electric Field	Person 1.75 m high, standing in a 1000 V/m (See Section 7.10)		
Position	**Current**	**Circumference**	**Current Density**
Neck	48 μA	38 cm	0.42 mA/m²
Waist	126 μA	91 cm	0.19 mA/m²
Ankle	164 μA	23 cm	4.0 mA/m²
Magnetic Field	**Person standing in a 100 mG (10 μT) vertical magnetic field. Body resistivity ρ = 10 Ωm**		
Position		**Radius**	**Current Density**
Chest		17 cm	0.032 mA/m²
Head		9 cm	0.017 mA/m²

7.13 BIOLOGICAL EFFECTS OF MAGNETIC FIELDS

Magnetic fields from electrical facilities have been studied for a variety of reasons and for many purposes. This chapter discusses the currents and voltages that are induced in long conductors parallel to transmission lines and that may generate safety issues for fences, pipelines, de-energized parallel lines, and shield wires. Appendix 7.4 discusses the possible monitor jitter caused by power line magnetic fields. This chapter covers engineering issues that may also be applicable for the consideration of possible health effects of long-term exposure to power-frequency magnetic fields such as calculations, measurements, design rules, and methods for field reductions.

Much of the investigation of magnetic fields from transmission lines and stations has included health concerns, particularly since the publication of the results of epidemiological studies starting in 1979 and continuing in different countries for the following 20 years (Wertheimer and Leeper 1979; Tomenius 1986; Savitz et al. 1988; London et al. 1991; Feychting and Ahlbom 1993; Verkasalo et al. 1993; Olsen et al. 1993; Linet et al. 1997; Tynes and Haldorsen 1997; Michaelis et al. 1998; McBride et al. 1999; UK Childhood Cancer Study Investigators 1999; Ahlbom et al. 2000; Greenland et al. 2000). This Reference Book does not discuss the research performed on health effects of the magnetic field. The body of literature on possible biological and health effects of magnetic fields on people, animals, and plants has been reviewed and commented

upon by many organizations (AMA 1994; NIESH 1998; NRPB 2001).

In their information booklet on EMF, the National Institute of Environmental Health Sciences and the National Institute of Health report the following conclusion (NIEHS-NIH 2002): "Electricity is a beneficial part of our daily lives, but whenever electricity is generated, transmitted, or used, electric and magnetic fields are created. Over the past 25 years, research has addressed the question of whether exposure to power frequency EMF might adversely affect human health. For most health outcomes, there is no evidence that EMF exposures have adverse effects. There is some evidence from epidemiological studies that exposure to power-frequency magnetic field is associated with an increased risk of childhood leukemia. This association is difficult to interpret in the absence of reproducible laboratory evidence or a scientific explanation that links magnetic fields with childhood leukemia. EMF exposures are complex and come from multiple sources in the home and workplace in addition to power lines. Although scientists are debating whether EMF is a hazard to health, the NIEHS recommends continuing education on ways of reducing exposure."

Several countries and state regulatory agencies have developed recommendations and guidelines for magnetic fields. No U.S. federal recommendations for occupational or residential exposure to 60-Hz magnetic fields currently exist. Various recommendations and guidelines are presented in Appendix 7.3.

Magnetic field levels are frequently an issue when a line is sited, when developments are planned near transmission lines and substations, and when health effects are attributed to the proximity of electrical facilities. Because of the importance of this issue, considerable effort has been spent in researching practical cost-effective ways to reduce magnetic fields (see Section 7.17).

7.14 FUEL IGNITION

This section discusses electric-field induced fuel ignition during refueling and fuel ignition induced by corona at the conductor surface. There is no apparent real problem in these situations, yet the power industry's deep concern for public safety has led to research whose results are presented here. There has been no report of accidental ignition of fuel caused by spark discharges induced by transmission-line electric fields. Corona discharges do not have sufficient energy to create fuel ignition except in special cases.

7.14.1 Fuel Ignition Caused by Spark Discharges

Lewis and von Elbe determined the minimum discharge energy required in ideal conditions for ignition of flammable mixtures of hydrocarbon vapor and air (Lewis and von Elbe 1951). Their work covered different fuels and different types of discharges. An excellent summary of the subject was prepared by McKinney (McKinney 1962).

The minimum energy required to cause ignition of a specific mixture varies with the test setup. For example, a minimum ignition energy spark requires such high voltage that corona at the electrodes may partially discharge the circuit before the spark occurs. The energy dissipated in the spark goes in different proportions to heat the mixture and the electrodes. The dissipation of energy in heating the electrodes causes the quenching of the flame, and plays a dominant role in the process of ignition causing significant differences between different electrode arrangements. For example, electrodes with round edges and minimum corona will be massive thermal sinks that tend to quench an ignited flame. Most of the investigations reported in the literature were aimed at finding the arrangements corresponding to the minimum discharge energy, whereas EPRI research focused on the discharge energy required for fuel ignition in realistic conditions associated with refueling near a high-voltage transmission line (EPRI 1982).

Three methods of causing ignition were considered by McKinney:

- Ignition by discharge of capacitive circuits between fixed or closing electrodes
- Ignition by interruption of inductive circuits between opening contacts
- Ignition by hot wires

In proximity to overhead ac transmission lines, the main concern is with capacitive discharges from large objects caused by electric field induction.

The discharges induced by the power-frequency electric field may be repetitive, and, owing to the effect of trapped charges, more voltage (and energy) may be available after the first spark if the electrodes are moved apart (withdrawing electrodes). Sequences of sparks to ground from an insulated object modify the object potential, as shown in Figure 7.14-1. When the spark gap is kept constant and the voltage is raised, the voltage at the moment of the spark is equal to or less than the peak voltage existing without a spark. The same situation occurs if the voltage is kept constant and the gap distance is decreased by closing the electrodes. However, if the gap distance is increased by withdrawing one of the electrodes from the other, the spark voltage may reach values higher than the open-circuit voltage with no spark, as shown in Figure 7.14-2. The maximum spark voltage could conceivably be twice the open-circuit voltage. This phenomenon is influenced by the leakage resistance to ground and by corona appearing on the

electrodes (in the case of small objects when higher voltages are required). The voltage-doubling effect may be reached with high parallel leakage resistance for objects of large capacitance to ground.

The energy required for ignition is a function of the fuel-to-air ratio of the mixture. In most cases, the minimum ignition energy corresponds to the stoichiometric mixture. For a single capacitive discharge, the minimum ignition energy of hydrogen is about 0.02 mJ. The minimum ignition energy for the majority of hydrocarbons that make up the most commonly used fuels is much higher, being equal to about 0.25 mJ.

The dielectric loss of the capacitor used in the discharge circuit, the ignition quenching characteristics of the electrodes, and the electrode wetting by the fuel are important parameters (EPRI 1982). For these reasons, fuel ignition tests are difficult to reproduce. Tests simulating realistic situations were performed using electrodes shaped like gasoline cans and open containers filled with gasoline connected to objects having different capacitances to ground

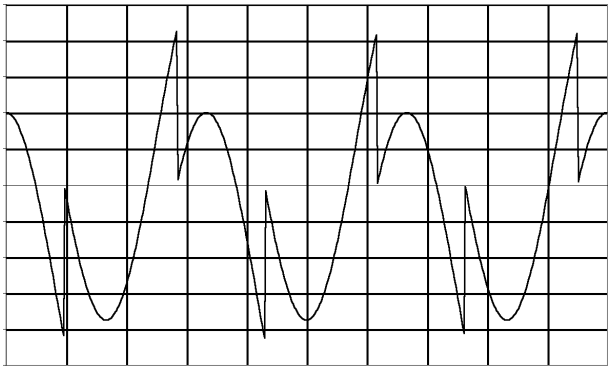

Figure 7.14-1 One spark per cycle. Large object.

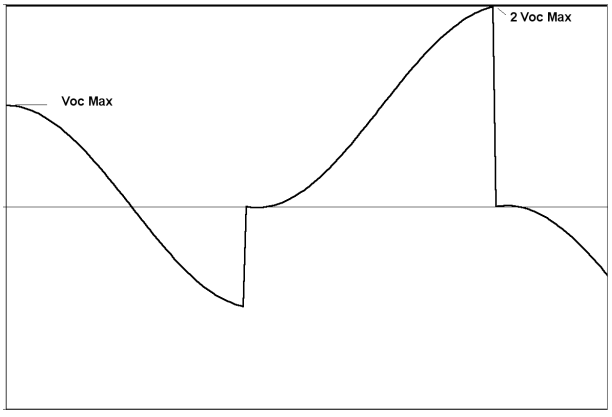

Figure 7.14-2 Voltage-doubling effect.

in an electric field produced by a 60-Hz high-voltage test line (EPRI 1982). The results were plotted as shown in Figure 7.14-3. A straight line was drawn through the points representing the minimum ignition voltage obtained. The equation for minimum ignition voltage is:

$$V_{oc} = 4.6 \cdot C^{-0.3} \quad (V_{oc} \text{ in volt rms and } C \text{ in farad}) \qquad 7.14\text{-}1$$

The actual ignition voltages obtained during several experiments ranged from 1 to 2 times the minimum values. Sparks originating from a sharp point, such as a pin, lowered the minimum ignition voltage obtained with a spout by a factor of 1.5.

The curve in Figure 7.14-3 that gives the minimum ignition voltage is not a constant energy curve; therefore, it is not possible to refer to the energy as the only parameter that characterizes the potential for ignition. The minimum ignition energy is 2.1 mJ with a 100 pF capacitor and 13 mJ with 10,000 pF. For a large vehicle with a typical capacitance value of 1,500 pF, the minimum ignition voltage is 2,000 V rms, and the energy stored at the peak of the voltage is 6 mJ.

In order to characterize the potential for ignition, it is necessary to provide both the value of the rms voltage existing prior to the discharge and the value of the capacitance. The actual voltage at the instant of ignition may be greater than the crest value of the open-circuit voltage prior to the discharge owing to the voltage-doubling effect previously illustrated. In fact, the minimum ignition voltages were obtained by withdrawing the spout from the gasoline container.

Figure 7.14-3 also contains a curve from McKinney (McKinney 1962) obtained by rearranging the Lewis and

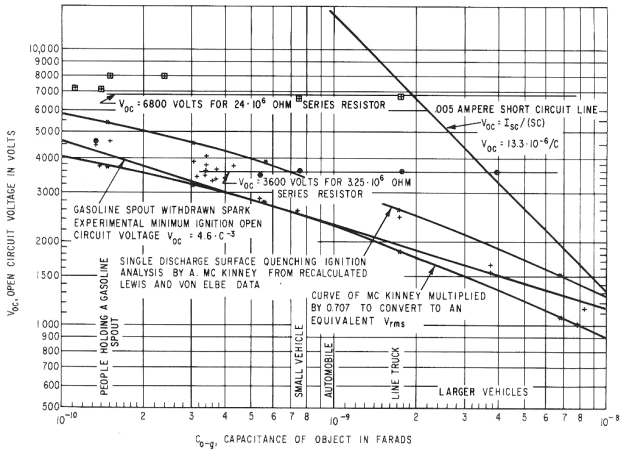

Figure 7.14-3 Minimum open-circuit voltage for ignition of gasoline caused by spark discharges between a can spout and a vehicle tank.

von Elbe data on ignition of mixtures of natural gas and air with single capacitor discharges with plain electrodes (Lewis and von Elbe 1951). Translating McKinney's curve to ac rms voltages produces a relatively close agreement with Equation 7.14-1. It is, therefore, suggested that this equation be used for situations that might occur near overhead ac transmission lines. Also in Figure 7.14-1, the curve of V_{oc} and C corresponding to a short-circuit current of 5 mA is drawn. According to the U.S. National Electric Safety Code, 5 mA is the maximum short-circuit current allowed from a vehicle located under a transmission line. It can be seen that spark discharges that have the potential of igniting gasoline correspond to situations in which the short-circuit current is much less than 5 mA. However, spark discharges at the level of potential gasoline ignition cause a painful sensation, a strong warning sign that fueling operations in such conditions may result in fuel ignition.

It must be noted that in realistic conditions, even when the open-circuit voltage and the capacitance values are above the minimum required, gasoline ignition is very improbable because several conditions must occur simultaneously in order to obtain ignition:

- The vehicle must have high impedance to ground, such as well-insulated tires on a very dry pavement.
- The gasoline must be fresh and easily ignitable.
- Warm dry sunny day. When the temperature is less than 10 ºC, the minimum ignition voltage may be as much as twice the minimum given by Equation 7.14-1.
- The gasoline container must be grounded—for instance, through the body of a person standing on wet ground or vegetation.
- The spark must occur in an area where the fuel and air are close to the stoichiometric proportion.
- There must be a sequence of sparks with the gasoline-pouring spout being slowly withdrawn from the tank.
- The operator ignores spark discharges above the perception level that are likely to occur in a situation where there is a potential for gasoline ignition. In a practical scenario, a person will experience perceptible and annoying spark discharges and is likely to consider them as a warning against proceeding with fueling operations without suitable precautions.

Section 7.8 describes the statistical nature of the voltage that exists between a person and a vehicle. This voltage is always lower than that needed for fuel ignitions. It can be concluded that the probability of an ignition occurring is so low that in practice it will never occur. The fact that no fuel ignition due to sparks caused by transmission-line electric field has been reported substantiates this conclusion (Deno and Silva 1985). Furthermore, the potential consequence of fuel ignition is not catastrophic. Analysis indicates that an ignition would cause only a "puff" at the filler neck, similar to the effect produced by lighting a gasoline stove (EPRI 1982). In fact, the gasoline partial pressure inside the tank at a temperature greater than –18 ºC results in a fuel-air mixture too rich to support combustion. For extremely low temperatures, at which combustion becomes possible, the spark energy required for ignition is much greater.

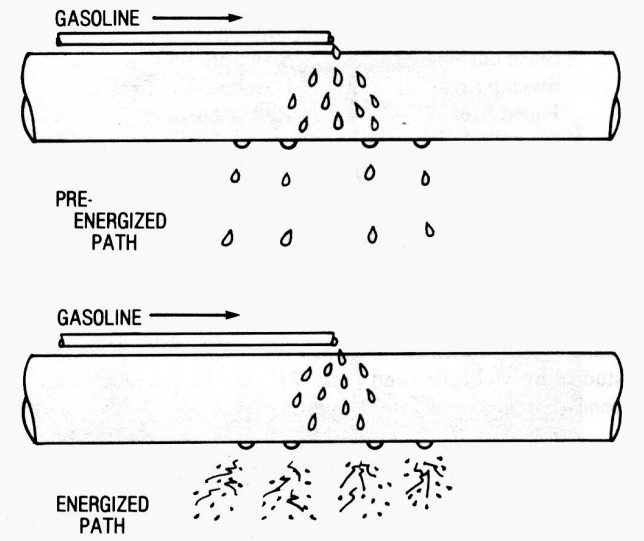

Figure 7.14-4 Effect of electric field on dripping of fuel droplets from a conductor.

7.14.2 Corona-Induced Fuel Ignition

In some situations, such as with gas line blow off on a shared right-of-way, combustible hydrocarbon gases may approach transmission-line conductors where there is corona. Ignition by hydrocarbon vapors by transmission-line corona was investigated by EPRI (EPRI 1982).

The high electric field at and near the surface of a conductor in corona greatly affects the shape of the droplets of fuel and the dripping from the conductor surface, as shown in Figure 7.14-4. In the presence of a high electric field, the dripping fuel is pulled off the dripping path.

Ignition occurs only in calm wind conditions (wind velocity less than 5 km/hr). Humidity and temperature have little effect on ignition. The surface electric field necessary for ignition is dependent on the conductor diameter: 15.3 kV/cm for a 5.5-cm diameter conductor, 17.4 kV/cm for a 3.3-cm diameter conductor, and more than 30 kV/cm for a 1.6-cm diameter conductor.

7.15 EFFECTS OF HIGH-INTENSITY ELECTRIC FIELDS

High-intensity electric fields may cause burning of transmission-line wood poles with grounded hardware and also of poles without any hardware, burning of dead trees or dead tree branches, damage to tree tips, corona from grounded objects, and damaging currents on the surface of fiber optic cables strung near the high-voltage conductors (Karady and Devarajan 2001). The phenomena discussed in this section occur only at high-intensity electric fields, such as those that exist near the conductor support structures of EHV transmission lines. Some of the effects were a common experience in proximity of UHV test lines (EPRI 1982), but are rarely experienced at EHV voltages. The phenomena described in this section are of little or no concern at 220/230 kV or lower voltage levels.

7.15.1 Wood Pole Burning

The grounding and bonding of the hardware of wood structures have been used to prevent the insulator leakage current from flowing on the wood surface. However, the current induced by the electric field on wood surfaces when they are wet or moist flows to the nearest hardware. If the current density at the hardware is high enough, the wood surface near the hardware may form a dry band, the voltage builds up across the dry band, arcing starts, and the wood gets slowly carbonized and eventually burns. A photograph of the initial burning of a wood pole near hardware is shown in Figure 7.15-1.

Wood poles are used for lines with voltages up to 345 kV. They are seldom used for 500-kV lines. Most wood structure burning reports are for 345-kV lines (Lusk 1975; Lusk and Mak 1976).

The phenomenon of wood pole burning near hardware is affected by many parameters, such as the conductivity of the wood surface, the dryness of the wood below the surface, the shape of the hardware, and the highest space potential to which the surface of the pole is exposed. Experience has suggested that a condition for the occurrence of wood burning near hardware is that the surface of the pole at some point exceeds a space potential of 100 kV (EPRI 1982). The space potential is that which exists without the object present—i.e., the unperturbed space potential. Burning occurred at the first moisture after a long period of dry weather or in the winter in cold and dry weather but with snow covering the surface of the pole (EPRI 1982).

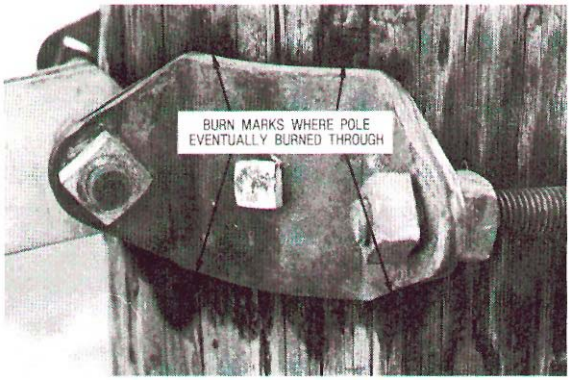

Figure 7.15-1 Initial burning around a collar holding guy wires of a wood pole installed in a high electric field region.

Pole fires may also occur on poles without hardware. These poles may be installed near transmission lines for various reasons—for instance, for the purpose of supporting instrumentation of some kind. The current flowing on a moist surface may encounter discontinuities, and may form dry bands and arcing along the pole. This phenomenon is similar to that occurring on contaminated insulators in humid weather and to that causing damage to fiber optic cables strung near the conductors of high-voltage lines (Karady and Devarajan 2001). Experience has suggested that, for poles without hardware, just as for those with hardware, a condition for the occurrence of wood burning is that the surface of the pole at some point exceeds an unperturbed (without the pole) space potential of 100 kV (EPRI 1982). This rule of thumb may be applied in the analysis of wood pole-burning situations.

The possibility of wood pole burning may be analyzed by calculating the space potential at various points along the pole and determining whether any of these exceeds the 100 kV limit. Space potential contour lines can be obtained using Applet EMF-2 (2-D geometry) or Applet EMF-4 (3-D geometry). Figure 7.15-2 shows the space potential contour lines around a 550-kV transmission line. Any dead tree or wood pole that protrudes inside the 100-kV contour line may be subject to burning caused by the transmission-line electric field.

7.15.2 Dead Tree Burning

Unlike live trees, dead trees have a very high resistance in dry weather because they have no sap. In dry weather, therefore, dead trees cause very little perturbation of the electric field produced by a transmission line. In wet weather or when the surface is covered with melting frost or snow, however, the surfaces of the branches form conductive sheaths that collect electrical charges and discharge them to the ground. There will be no current inside the tree but only on the surface. The phenomenon is the same as previously illustrated for wood poles. Figure 7.15-3 shows branches of a dead tree broken because of burning. Details of a stump show clear signs of burning.

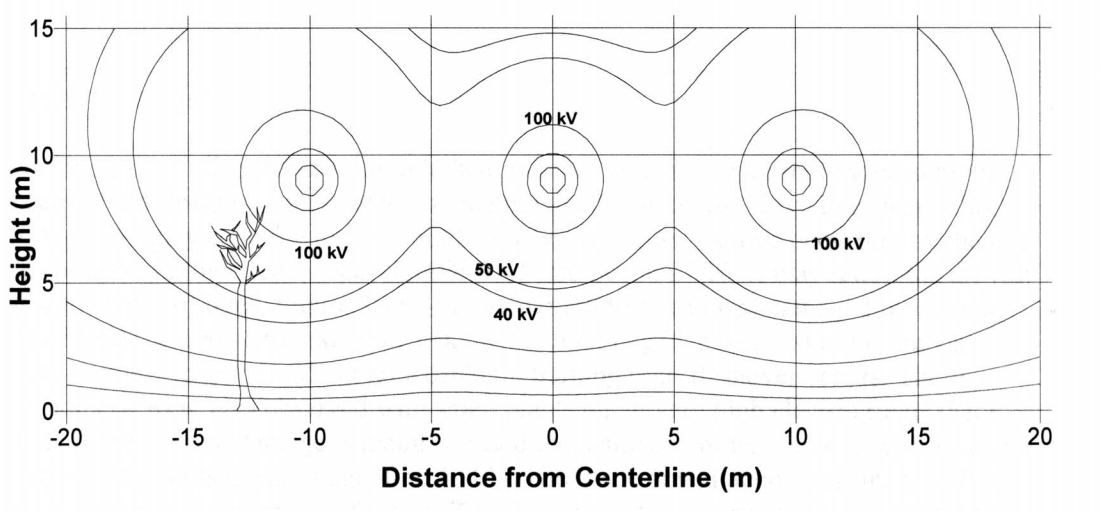

Figure 7.15-2 Space potential lines for a 525-kV transmission line (bundles of 3 x 3.3 cm, 46-cm spacing, 10-m phase spacing, 9-m height at midspan).

The 100-kV space potential rule also applies to dead trees. Experience indicates that burning occurs only at space potentials greater than 100 kV (EPRI 1982). Figure 7.15-2 shows space potential contour lines for a 500-kV line. The portion of dead trees that intrude inside the space delimited by the 100-kV contour line may experience burning.

7.15.3 Tree Tip Damage

Live trees are well grounded through their conductive sap. The current induced by the electric field flows to ground without creating much power loss. Live trees near a high-voltage line may continue to grow until a flashover occurs. Corona occurring on the tree tips because of the intense local electric field (see Section 7.15.4) may retard the growth of some types of trees. Figure 7.15-5 shows a birch tree with tips damaged by corona. Other types of trees—for example, oaks with round-edged leaves and blunt branch buds—appear to grow without noticeable tip burning until flashover occurs. These phenomena were also observed with small plants but at very high electric fields (McKee et al. 1978) Corona damage is mainly caused by positive corona, whose inception occurs at space potentials greater than 30 to 40 kV. The space potential contour lines, such as those shown in the example of Figure 7.15-2 are useful to determine the potential impact of this phenomenon.

Figure 7.15-3 Dead tree in a high electric field region. Branches that have burnt through and a stump detail.

7.15.4 Corona on Grounded Objects

A common experience near single UHV test lines, especially if single-phase, was the observation at night of corona on wood poles, bushes, and trees in the immediate proximity of the line (EPRI 1982). If a sharp metallic object, such as a key, is held high toward the line, audible and visual corona may be experienced. These phenomena may be experienced near some EHV transmission lines. An example is shown in Figure 7.15-4, which shows corona from needles of a tall pine tree near a 500 kV line.

Corona occurs on grounded objects when the electric field at their surface exceeds the breakdown electric field of air

Figure 7.15-4 Corona from needles in the top part of a tall pine tree near a 500 kV transmission line, photographed with a DayCor camera. Courtesy of the Bonneville Power Administration.

(~30 kV/cm). Such high levels may be reached when the height of the object is large and the tip of the object is sharp. At sharp points, corona appears first during the negative polarity half-cycle (negative corona). Corona onset is a function of the shape of the tip of the object and of the space potential. At larger space potential, corona also appears on the positive half-cycle (positive corona). While negative corona onset is critically dependent on the shape of the tip of the object, positive corona onset depends little on the shape. The space potential at positive corona varies from 30 kV for small objects to 40 kV for objects resembling plates 2.5 cm thick and 25 cm in diameter (EPRI 1982).

Negative corona produces very little visible light and audible noise. Positive corona, on the other hand, is clearly visible at night and audible if the ambient is quiet. The audible noise of a corona source is detected by the human ear but not by an instrument above ambient levels of 40 – 45 dBA. Each positive corona point generates radio noise currents between 1.5 and 5 mA. Negative corona radio noise is about 15 dB lower. Radio noise currents of such magnitude would be of concern if the line radiated them. In all cases, however, the radio noise current circulates in a very small circuit from the corona point to ground and is not propagated by the line. The radio noise decays very fast with distance from the source, and falls below ambient at a distance twice the height of the object.

Ozone is generated in measurable, but very minute, quantities only by positive corona. To detect ozone, the ozone sensor must be placed closer than a few centimeters from the source. Ozone is generally not detectable away from the transmission line. Since, in practical conditions, positive corona onset is not reached on the tips of most crops, no crop damage by corona is expected. Positive corona may occur on the tips of the branches of tall trees near 500-kV or higher voltage lines, depending on the type of tree, and damage can be observed (see Figure 7.15-5).

Figure 7.15-5 Black birch with electric-field-damaged branches photographed from the ground.

7.16 METHODS FOR REDUCING TRANSMISSION-LINE ELECTRIC FIELDS

7.16.1 Introduction—Passive and Active Shielding

A method often used to minimize the effects of the electric field is to shield the area of interest from the high-voltage conductors by placing conductive objects above or around that area. Shielding reduces the electric field and consequently its effects. Because most field effects occur close to ground, and are a function of the magnitude of the unperturbed electric field, the reduction of the field at 1 m above ground is the primary objective of the shielding methods discussed in this section. It should be pointed out, however, that there are other methods to reduce electric field effects such as the grounding of structures, the use of conductive straps on vehicles, and the use of conductive suits to reduce currents induced on line workers.

Different shielding methods represent alternative means of reaching specific objectives. The choice of the method depends on subjective considerations that are often a function of local conditions and on the selection of the admissible field in the area to be shielded.

Methods of shielding may be classified as "passive," if shielding is provided by grounded conductive objects, or as "active," if shielding is provided by conductors energized at appropriate voltages and phases. Each shielding method changes the value of the electric-field intensity and of the space potential from the value without the shield. A useful parameter to categorize the degree of shielding is the shielding factor, *S*, defined in Equation 7.16-1 as:

$$E_s = E_u \cdot S \qquad 7.16\text{-}1$$

Where:

E_s is the electric field at ground with the shield present.

E_u is the unperturbed electric field without shield.

Also, a shielding efficiency, *SE*, may be defined, as shown in Equation 7.16-2.

$$SE = 1 - S = \frac{E_u - E_s}{E_u} \qquad 7.16\text{-}2$$

Also used is the "field reduction factor," *F*, which is the inverse of the shielding factor, as shown by Equation 7.16-3:

$$F = 1/S = E_u / E_s \qquad 7.16\text{-}3$$

The concepts of shielding factor, shielding efficiency, and field reduction factor may be applied to objects in nonuniform fields or to objects not close to ground. In these cases,

however, it is preferable to use the space potential of a point, as shown by Equation 7.16-4 for the shielding factor, *S*.

$$V_{sp,s} = V_{sp,u} \cdot S \qquad 7.16\text{-}4$$

Where:

$V_{sp,s}$ is the space potential with the shield present.

$V_{sp,u}$ is the unperturbed space potential without the shield.

7.16.2 Shielding by a Horizontal Grid of Grounded Wires

A horizontal grid of wires at ground potential placed at height, *H*, above ground provides an effective shield of the electric field caused by transmission lines either above the grid or at a distance from the grid, as shown in Figure 7.16-1 (Deno 1977a).

Infinite Grid

The width of the grid, *W*, is shown in Figure 7.16-1. If the grid can be considered infinitely large ($W = \infty$), and the unperturbed field is uniform over the extent of the field, the average field under the grid can be calculated in a straightforward manner.

The shielding efficiency of an infinite grid, SE_∞ (defined by Equation 7.16-2 is given by Equation 7.16-5).

$$SE_\infty = \frac{2\pi\, H/S}{\ln\frac{2H}{R} + \ln\left[\frac{e^{2\pi H/S} - e^{-2\pi H/S}}{4\pi H/S}\right]} \qquad 7.16\text{-}5$$

Where:

H is the height of the grid also ground.

S is the spacing between wires (assumed uniform).

R is the radius of the wires.

For instance, a grid of 0.0048-m wires, spaced 3.43 m apart, and at a height above ground of 6.85 m provides a shielding efficiency of 0.73 (73%). The field under the grid is reduced to 27% of its unperturbed value (shielding factor = 0.27).

Even if the unperturbed field is not uniform over the grid, Equation 7.16-5 can still be used to calculate the shielding efficiency, which is independent of the unperturbed field.

Finite Grid

The shielding efficiency is the product of two factors: the shielding efficiency of an infinite grid, SE_∞, and the edge factor, which is a function of the ratio between the distance, *x*, from the edge of the grid and the height, *H*, of the grid.

$$SE(x) = SE_\infty \cdot f(x/H) \qquad 7.16\text{-}6$$

The values of the function *f(x/H)* are given in Figure 7.16-2.

The edge effect is negligible below the grid at distances greater than *2 H* (*H* is the height of the grid's wires) from the closest grid's edge. At the edge of the grid, the edge factor is about 0.73. The edge factor applies only to the closer of the two grid terminations.

This method of calculating the shielding efficiency of a horizontal grid is sufficiently accurate for closely spaced wires.

When the ratio of grid-wire spacing, *S*, to grid height, *H*, exceeds 1.8, the shielding efficiency varies significantly from point to point even under the grid. For widely spaced wires, the shielding efficiency at any point may be calculated by adding the shielding efficiency of each wire, using wires that are no further than *3H* from the calculation point. For this purpose, the shielding efficiency of each wire is individually calculated by multiplying SE_∞, calculated for $S/H = 1.8$, by the edge factor for a single wire (dashed curve in Figure 7.16-2). For instance, assume that $S = 2H$, $R = 0.0002\ H$, and that the calculations are performed directly under a grid wire. The shielding efficiency

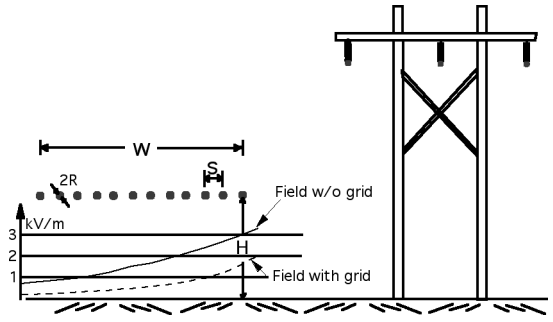

Figure 7.16-1 Horizontal grid of grounded wires as an electric field shield.

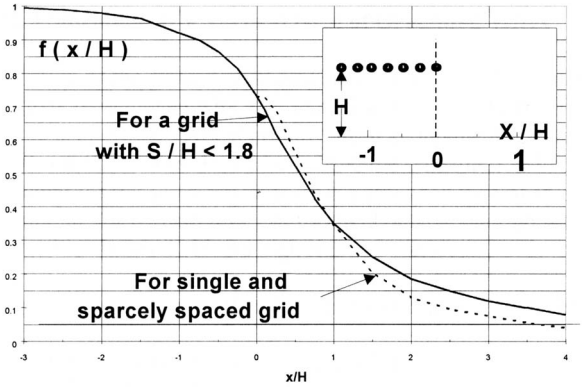

Figure 7.16-2 Edge factor for a horizontal grid of shield wires.

is contributed by three wires, one directly above, and two at a distance *2H*. The shielding efficiency due to the grid is $SE = SE_\infty \cdot (f(0) + 2 \cdot f(2))$ For this example: $SE_\infty = 0.33$, f(0) = 0.73, f(2) = 0.12, and, *SE* = 0.32.

If the calculation point were at the midpoint of two grid wires, $SE = SE_\infty \cdot (2f(1) + 2f(3)) = 0.28$. Note that the shielding efficiency for an infinite grid calculated with Equation 7.16-5 would have resulted in *SE* = 0.30.

An accurate solution of transmission-line electric field shielding by a horizontal grid of wires parallel to the transmission-line wires can be obtained by accounting for all shield wires and transmission-line wires and using the algorithms described in Section 7.3. The electric field in the presence of a grid of shield wires can be calculated using Applet EMF-5.

7.16.3 Shielding By a Vertical Grid of Grounded Wires

Reduction of the ground-level electric field off the edge of a transmission-line right-of-way may be achieved with a vertical, fencelike set of parallel wires. Wood poles may be used to support the vertical grid in a most economical manner. The position of these "electrostatic" fences should be outside the transmission-line outer phases at a distance sufficient for flashover clearance. This grounded type of shielding is particularly appropriate for reducing the electric field outside the right-of-way in areas of low admissible electric field and high right-of-way cost.

The geometry of a vertical grid is shown in Figure 7.16-3. The design parameters are:

H_{max} = height above ground of the top wire
H_{min} = height above ground of the bottom wire
n = number of wires
d = diameter of wires
S_i = spacing between the wire i and the wire $i+1$

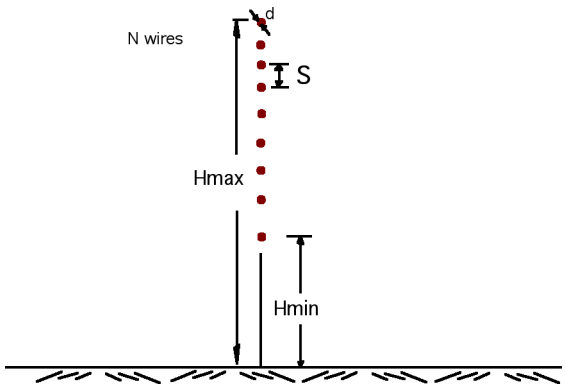

Figure 7.16-3 Geometry of a vertical grid.

$R = \frac{S_{n-1}}{S_1}$, with the condition that $\frac{S_{i+1}}{S_i} = \frac{S_i}{S_{i-1}}$, i.e., consecutive spacings are in the same geometric ratio. When $R = 1$, the wires are equally spaced.

The bottom wire of the grid should be at a height sufficient to allow the movement of vehicles. The distance between shield and phase conductors should be greater than the minimum clearances prescribed by the National Electrical Safety Code. This should not constitute a limitation to the use of this type of shield, because the grid may be positioned effectively away from the wires. The other parameters should be chosen to achieve the desired reduction of the electric field outside the right-of-way.

Both E_u and E_s vary with the distance from the vertical grid, and the shielding efficiency is a function of that distance. The functions $E_u(x)$ and $E_s(x)$ depend in a complicated way on the characteristics of the line (flat, delta, vertical, double circuit). This renders a generalized characterization of the shielding efficiency as a function of the distance, *x*, from the grid, *SE(x)*, impossible.

A modified concept of shielding efficiency, the "shielding function," *f*, is of more practical application.

$$f = \frac{\tilde{E}_u - \tilde{E}_s}{\tilde{E}'_u} = \frac{-\tilde{E}_G}{\tilde{E}'_u} \qquad 7.16\text{-}7$$

Where:
$\tilde{E}_u$ and $\tilde{E}_s$ are calculated at the point where the shielding is calculated.
E_G is the magnitude of the field induced by the grid charges.
$\tilde{E}'_u$ is the unperturbed field at the grid location.

$$\tilde{E}_s = \tilde{E}_u + \tilde{E}_G = \tilde{E}_u - f \cdot \tilde{E}'_u \qquad 7.16\text{-}8$$

The shielding factor is:

$$\tilde{SF} = \frac{\tilde{E}_s}{\tilde{E}_u} = 1 - f \cdot \frac{\tilde{E}'_u}{\tilde{E}_u} \qquad 7.16\text{-}9$$

For a practical range of parameters of the grid, the shielding function at a distance *x* from the grid, *f(x)*, is independent of line characteristics and is a function only of the characteristics of the grid. The field E_G has the same phase as the field $\tilde{E}'_u$. Therefore, the grid-shielding function, *f(x)*, is a scalar. For example, assume that the unperturbed field at the grid is E'_u = 4 kV/m and, 20 m away, E_u = 2 kV/m (with the same phase angle of E'_u). The shielding efficiency *SE* is 50%, so that E_s = 1 kV/m (with the same phase angle of E'_u). The grid shielding function is $f = \frac{2-1}{4} = \frac{1}{4} = 0.25 \cdot$

When the unperturbed field has a phase angle that varies as a function of the distance from the grid, this angle should be included in the calculations. It has the effect of reducing the shielding efficiency. For instance, assume that the grid (with $f = 0.25$ as in the previous example) is used when $E'_u = 4$ kV/m and $E_u = 2$ kV/m (with a phase angle of 30° relative to $\tilde{E}'_u$). Equation 7.16-6 gives $E_s = 1.24$ kV/m, instead of 1 kV/m obtained when the unperturbed field at the calculation point ($\tilde{E}_u$) and the unperturbed field at the grid location ($\tilde{E}'_u$) have the same phase angle.

The grid-shielding function, *f(x)*, coincides with the shielding efficiency of a grid in a uniform electric field. It is given in Figures 7.16-4 and 7.16-5 as a function of the distance from the grid for different number of wires. Figure 7.16-4 is for a maximum grid height of 18 m. Figure 7.16-5 is for a maximum grid height of 12 m. The minimum grid height was kept constant at 6 m, a height that would not prevent the movement of most vehicles. Increasing the height of the bottom wire (while keeping the number of wires constant) reduces the shielding close to the grid, but has little effect on the shielding at distances from the grid greater than 2/3 H_{max}. The diameter of the wires has a small effect on shielding. The design curves presented are for a wire diameter of 0.95 cm (3/8 in.). The wires were considered uniformly spaced (spacing ratio $R = 1$). A spacing ratio $R = 3$ achieves a slightly better shielding. Placing the top wires of the grid closer to each other also reduces the electric field on the grid wire surface and the possibility of corona on the top wire.

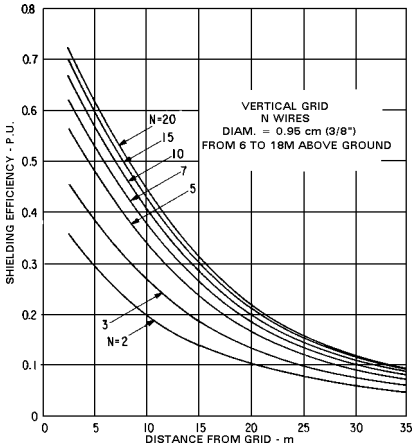

Figure 7.16-4 Shielding function (shielding efficiency in a uniform electric field) of a vertical grid. Wires uniformly spaced between 6 and 18 m above ground.

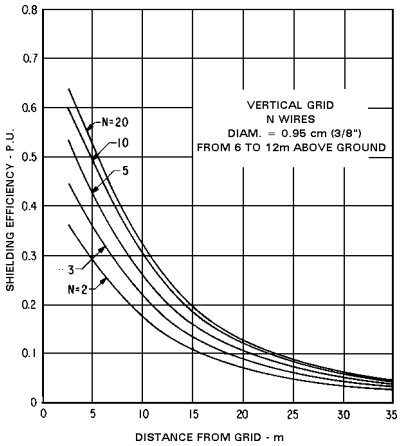

Figure 7.16-5 Shielding function (shielding efficiency in a uniform electric field) of a vertical grid. Wires uniformly spaced between 6 and 12 m above ground.

An accurate solution of transmission-line electric field shielding by a vertical grid of wires parallel to the transmission line can be obtained by accounting for all shield wires and transmission-line wires and using the calculation method illustrated in Section 7.3. The electric field in the presence of a grid of shield wires can be calculated using Applet EMF-5.

7.16.4 Shield Wire Mesh

It is expedient to use meshes of grounded wires rather than parallel wires to shield working areas or walkways. The shielding efficiency of meshes can be calculated using a 3-D electric field calculation program. An approximate solution can be obtained by translating the mesh into a set of parallel wires, for which electric field may be more easily calculated, using the methods of Section 7.16.2 for horizontal grids and Section 7.16.3 for vertical grids.

Assume that the mesh consists of two sets of wires: a set of wires with radius r_1 and spacing S_1 between wires and another set, perpendicular to the first, with wire radius r_2 and wire spacing S_2. An equivalent grid of parallel wires is obtained by removing one of the two wire sets—for instance, the second set—and increasing the radius of the wires of the first set from its value r_1 to a value r_{eq} given by Equation 7.16-10.

$$r_{eq} = \left(r_1 \cdot r_2 \cdot S_1^3 \Big/ \left(32 \cdot S_2\right)\right)^{1/4} \qquad 7.16\text{-}10$$

This equation is valid for $S_1/5 < S_2 < 5\ S_1$.

For example, if $r_1 = r_2$, $S_1 = 80\ r$, and $S_2 = 40\ r_1$, then $r_{eq} = 4.5\ r_1$. The effect of the mesh is equivalent to increasing the wire diameter of the first grid by a factor of 4.5.

7.16.5 Shielding by Objects

Calculations of electric field in the presence of conductive objects can be performed using 3-D electric field programs capable of simulating the geometry accurately. When the geometry is simple, accurate results may be obtained using

Applet EMF-4. The shielding factor of an object is a function not only of the shape of the object but also of the position of the object relative to the transmission line (Deno et al. 1987).

$$\tilde{SF} = 1 - f(x) \cdot \frac{\tilde{E}'_u}{\tilde{E}_u(x)} \qquad 7.16\text{-}11$$

Where:

$\tilde{SF}$ is the shielding factor—i.e., the ratio between the field with the object and the field without the object.

Note that $\tilde{SF}$ is a phasor—i.e., the field is not only modified in magnitude but also shifted in phase. Actually, $\tilde{SF}$ is a complicated operator that transforms an elliptically polarized vector in another elliptically polarized vector. However, for applications close to ground, where the electric field is practically a vertical vector, the shielding function, $f(x)$, may be considered a scalar, function only of the geometry of the object and of the location x relative to the object, and Equation 7.6-11 provides usefully accurate answers. $\tilde{E}'_u$ is the unperturbed field at the object location, and $\tilde{E}_u(x)$ is the unperturbed field, without the object, at the calculation location x.

Equation 7.16-11 is valid if the field does not vary significantly with height above ground. If the field is not uniform with height, Equation 7.16-11 is applied by substituting $\tilde{E}'_u$ with $\tilde{V}_{sp}/h$, where $\tilde{V}_{sp}$ is the unperturbed space potential at the top of the object (at a height, h, above ground).

The shielding function, $f(x)$, can be expressed in closed form for simple geometry (Deno et al. 1987).

Sphere above Ground

(radius r, height h)

$$f(x) = 2h^2 r \Big/ \left(h^2 + x^2\right)^{3/2} \qquad 7.16\text{-}12$$

Where:

x is the horizontal distance from the sphere.

Single Tree

A single tree may be equated to a sphere above ground with diameter W and height above ground h as indicated in Figure 7.16-6.

Cylinder above Ground

(radius r, height h)

$$f(x) = \frac{2h^2}{\ln\left(\frac{2h}{r}\right) \cdot \left(h^2 + x^2\right)} \qquad 7.16\text{-}13$$

Where:

x is the horizontal lateral distance from the cylinder.

Row of Trees

A row of trees can be equated to a cylinder above ground, as indicated in Figure 7.16-6

Vertical Cylinder

(height h, radius r)

$$f(x) = e^{-\frac{(x-r)/h}{(x_0-r)/h}} \qquad 7.16\text{-}14$$

$$\left(x_o - r\right)\Big/h = \left(1 - e^{-r/(1.4H)}\right)^{1/3} \qquad 7.16\text{-}15$$

Box

(W x L x H)

$$f(x) = e^{-\alpha\left(x - r_o\right)/h} \qquad 7.16\text{-}16$$

Where:

r_o is the distance from the box center to the box perimeter (see Figure 7.16-7).

$$\alpha = \left(1 - e^{-\sqrt{L^2 + W^2}/(2.8H)}\right)^{1/3} \qquad 7.16\text{-}17$$

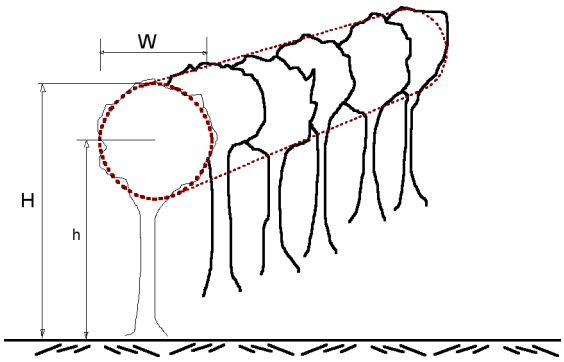

Figure 7.16-6 Representation of a row of trees with an equivalent cylinder.

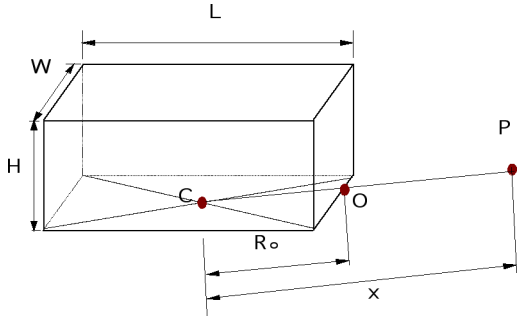

Figure 7.16-7 Parameters of a box for shielding evaluation.

Equation 7.16-16 applies when $H \leq 4W$ and $L \leq 4W$.

Complex Objects

For objects of complex shape, the shielding function may be determined by:

- Full-scale measurements near actual transmission lines
- Calculation using, for instance, the method presented in Appendix 7.6. Calculations should be performed using a uniform unperturbed field such as the field produced by a conductor located at a long distance from the object.

Multiple Shielding

The shielding calculations developed for individual objects assume that there is no other object affecting the field at the calculation point. When this is not the case, the mutual shielding among objects may have a significant effect.

The overall shielding may be calculated by using the approximate Equation 7.16-18.

$$\tilde{S}F = \tilde{E}_S / \tilde{E}_U = \prod_i (1 - f_i \tilde{E}_{oi} / \tilde{E}_U) \qquad 7.16\text{-}18$$

Where:

$\tilde{E}_s$ is the field at the measuring location in the presence of all shielding objects.

$\tilde{E}_u$ is the unperturbed field at the measuring location without the shielding objects.

f_i is the shielding function for object i calculated for the measuring location.

$\tilde{E}_{oi}$ is the unperturbed field (without object i present) at the location of object i.

7.16.6 Effect of Underbuilt Lines on Electric Field (Active Shielding)

While passive shielding of an electric field is provided by conductors at ground potential, active shielding is provided using energized conductors. However, it is not practical to energize conductors solely for the purpose of reducing electric field. Active shielding may be achieved by placing lower voltage lines at appropriate locations and phase arrangements.

Lower voltage lines built beneath EHV lines can provide a large reduction of the electric field at ground level. Position, bundle diameter, voltage, and phase angle of each phase conductor must be properly selected. Calculations of electric field and space potentials can be made using the methods illustrated in Section 7.3 or using Applet EMF-2. Calculation programs for three dimensions (see Appendix 7.6 or use Applet EMF-4) are needed if the underbuilt line has a different span and sag than the EHV line to be shielded.

An example of a 500-kV transmission line with two underbuilt 161-kV lines is shown in Figure 7.16-8. The line configuration is indicated in Figure 7.16-9. The calculated electric field at 1-m height above ground is shown in Figure 7.16-10. The calculations were performed for three conditions: no underbuilt lines, underbuilt line present and energized, and underbuilt lines present and grounded.

There are several practical considerations to take into account for the design, construction, and operation of

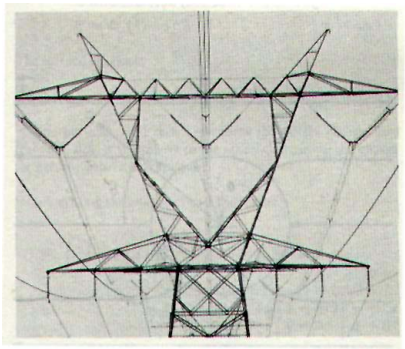

Figure 7.16-8 Tower with a 500-kV line and two underbuilt 161-kV lines (TVA).

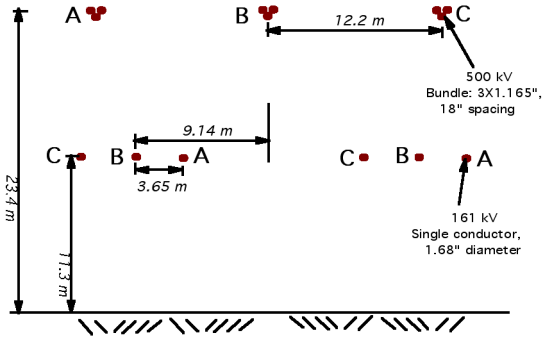

Figure 7.16-9 Geometry of a 500-kV line with two underbuilt 161 kV lines.

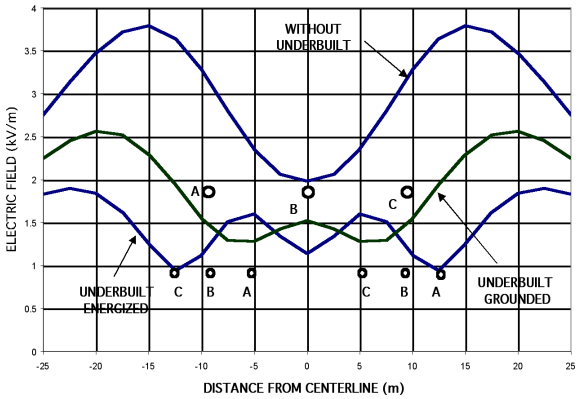

Figure 7.16-10 Electric field profiles for 500-kV line with underbuilt 161-kV line.

underbuilt lines. Underbuilt lines may be built in order to conserve right-of-way and not for the specific purpose of reducing electric field. In general, underbuilt line sections are relatively short, and coupling between EHV line and underbuilt is not significant. The EHV tower heights should be increased to obtain adequate clearances between conductors of different lines. Tower strength must be increased to support the underbuilt lines. Work on the underbuilt or on the EHV line, while the other line is energized, should be considered live work. Finally, currents induced by the higher voltage line during ground faults may affect the lower voltage underbuilt power system relaying. In order to keep underbuilt relaying sensitive, negative sequence relaying logic may be appropriate.

7.17 METHODS FOR REDUCING TRANSMISSION-LINE MAGNETIC FIELDS

7.17.1 Line Design for Low Magnetic Field

Magnetic field of transmission lines is a factor in line design. Several jurisdictions require that magnetic field levels outside the right-of-way do not exceed prescribed values (see Appendix 7.3). Public sensitivity to health issues may require designing for even lower magnetic field levels, particularly in areas with high population density or where particular activities take place.

The information in this chapter is useful for the design of new lines with fields lower than those of lines of traditional design and for reducing magnetic field levels of existing lines.

How much reduction of the magnetic field of overhead transmission lines can be achieved? The answer to this question depends on the level of effort that is justifiable to achieve the field reduction goal. While it is technically possible to reduce electric field to extremely low values using grounded grids of densely spaced wires (see Section 7.16), similar large reduction in magnetic field are often not practical. It is technically possible using traditional technology to significantly reduce the magnetic field for overhead 115-kV lines. With pipe-type cables, it is possible, although quite expensive, to practically eliminate the magnetic field of transmission lines with voltages from 69 kV up to 345 kV. Solid dielectric cables, which are being used for voltages up to 230 kV, offer an opportunity for significant field reductions except in the area above or very near the cables. Significant reductions are also possible for overhead lines, including those with voltage greater than 345 kV, using special techniques, such as the application of cancellation loops, which will be discussed in this section. The effort required to accomplish magnetic field reductions may or may not be justified. Several options may be available, and their field reduction effectiveness should be weighed against their cost and performance. This process is a part of what has been called "magnetic field management," which is defined as the prudent use of resources to effectively reduce exposure of people to power system magnetic field levels while maintaining power system reliability, safety, and effectiveness (EPRI 1999).

A particular technique that can be used to achieve significant magnetic field reductions is the use of a split-phase arrangement for either short sections or the entire length of a line. Split-phase arrangements are discussed in this section. However, split-phase arrangements are very expensive to construct for voltages of 345 kV or greater. For these voltages, the phases cannot be split without practically doubling the cross section of each phase. This is because the number of subconductors and the conductor diameter of each sub-phase are in large part governed by corona performance. The result is that split-phase sections of single-circuit transmission lines with voltages of 345 kV or greater approach the complexity and cost of double-circuit lines.

7.17.2 Optimization of Line Parameters

Modifying the parameters on which the field levels depend can reduce transmission-line magnetic fields. Changes in line parameters may affect electric field differently than magnetic field and may have another different effect on quantities such as radio noise, audible noise, resistive loss, corona loss, insulation performance, etc. Some changes in line design may affect the magnetic field under or close to the line, where the field is largest, differently than farther away from the conductors. Magnetic field, therefore, should be considered in the context of the overall line design.

The magnetic field depends on the following parameters: line currents, line configurations, height above ground, phase spacing, shield wires, and relative phasing of multiple circuits on the same right-of-way. Given these parameters, the magnetic field of a power line is calculated using the algorithms described in Section 7.4.

Line Currents

The magnetic field is proportional to the currents in the phase conductors, provided they vary in the same proportion and their phase angle remains constant. Unlike voltage, the current of a power line may vary significantly. Some transmission lines are steadily loaded; their magnetic field varies little with time. Some other lines have variable loads, showing pronounced seasonal, weekly, and daily variations. Even the most variable transmission-line loads, however, are not as variable as the loads of many other sources, such as electrical appliances, house wiring, and most distribution lines.

For assessing exposure to transmission-line magnetic field, the statistics of the line current over a long period of time is needed. A sample taken every hour during several days distributed over the period of time provides sufficient information to determine average current, load profiles, and 50%, 5%, and 1% exceedance levels. These parameters are affected by events such as outages and load capacity changes.

Line ratings are insufficient for the characterization of actual magnetic fields. In fact, average line currents and even the 1% exceedance levels are significantly lower than line ratings.

Phase Angles

For the purpose of calculating magnetic fields, the currents of most transmission lines may be considered symmetric (at 120º phase angle with each other). Transmission lines are also generally balanced, i.e., the phasor sum of the three phase currents is zero. However, certain system characteristics may give rise to an unbalance, which, however small, may have a measurable effect on the magnetic field outside the right-of-way. This may be of some significance should extreme magnetic field reductions be required at large distances from a transmission line. In fact, the unbalanced current constitutes a monopole (see Section 7.4), whose field decays in inverse proportion to the distance, while the balanced components of the line currents form a dipole, whose field decays in inverse proportion to the square of the distance. Thus, at some distances, the monopolar field generated by the unbalanced current becomes greater than the dipolar field, which exists with balanced currents.

Line Configuration

The line configuration affects both the magnitude and the polarization of the magnetic field. Simple expressions are presented in Section 7.4 for each line configuration. Expressions for flat, delta, and vertical configurations are shown in Table 7.4-3 and Figure 7.17-1. For instance, the magnetic field produced by a single-circuit line with flat configuration outside the right-of-way is linearly polarized, has an angle with the vertical equal to twice the line azimuth, and a magnitude, *B*, given to a good approximation by:

$$B = 2\sqrt{3}P\,I/R^2 \text{ (mG)} \qquad 7.17\text{-}1$$

Where:
